The β-TCP phase formation could also be visualized at FTIR. The infrared spectra are given in Figs. 4 and 5. All of them showed the typical bands originated mainly by phosphate molecule (PO_4^{3-}), with more intense phosphate stretching bands observed at around 1025 cm^{-1}, 600 cm^{-1} and 565 cm^{-1}. Figs. 6 and 7 display a higher magnification of the interest region of the spectra. Vibrational bands of 630 cm^{-1}, related to hydroxide anion (associated to hydroxyapatite) are well visualized at spectra of Fig. 6. The vibrational bands of 570 cm^{-1} 556 cm^{-1} evidenced at Fig. 7 suggest formation of β-TCP phase.

Discussion

Morphological and microstructural results demonstrated that the evaluated biomaterials exhibited extensively interconnected microporous microstructure, formed by fine grains with a few preferred sinterability regions. These features that may be favorable to wettability, capillarity and capillary and cell proliferation through surface of the biomaterial [3-5]. Furthermore, nanometer and submicron grain size presented at its structure may enhance the adsorption of proteins, the adhesion and cell proliferation, as well as the deposition of bone tissue [6-8].

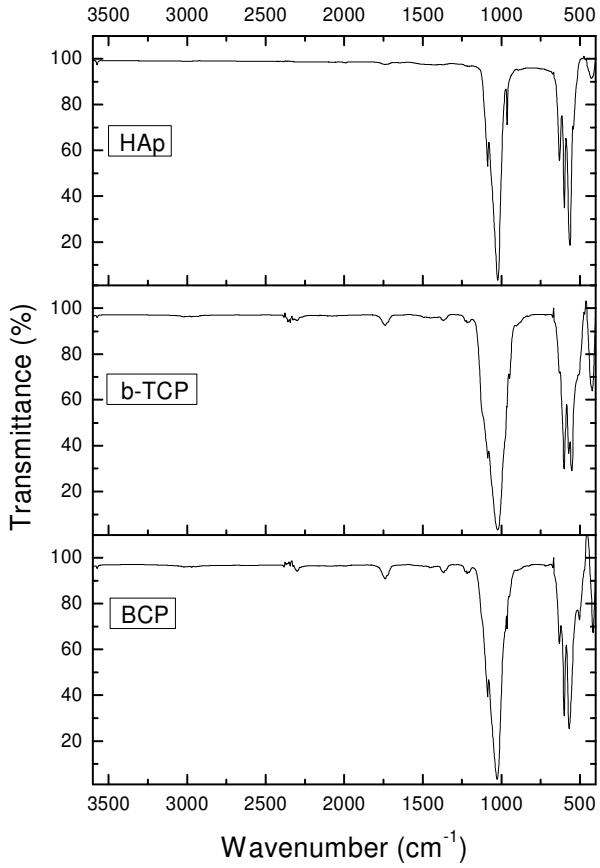

Fig. 4. FTIR spectra of HAp, β-TCP and BCP, essentially consisting of bands of phosphate molecules.

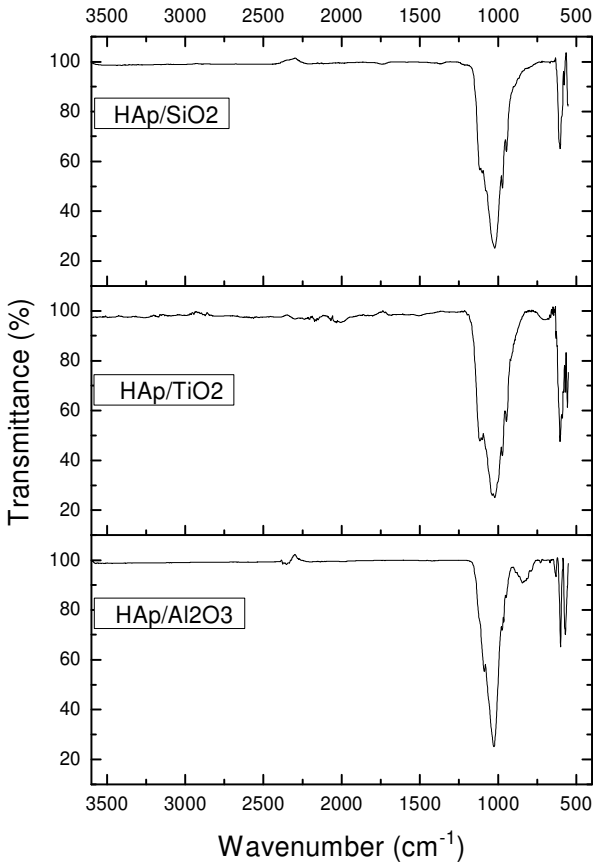

Fig. 5. FTIR spectra of HAp/Al_2O_3, HAp/TiO2 and HAp/SiO_2 nanocomposites, essentially consisting of bands of phosphate molecules.

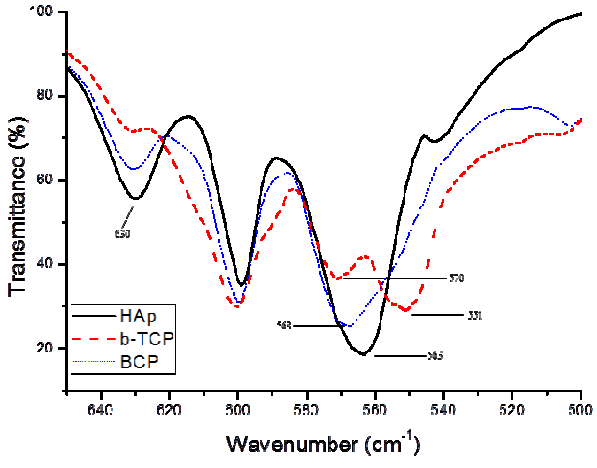

Fig. 6. Higher magnification of Fig. 4 spectra. In addition of phosphate typical vibrational bands, it can be seen (OH^-) vibrational band at $630cm^{-1}$.

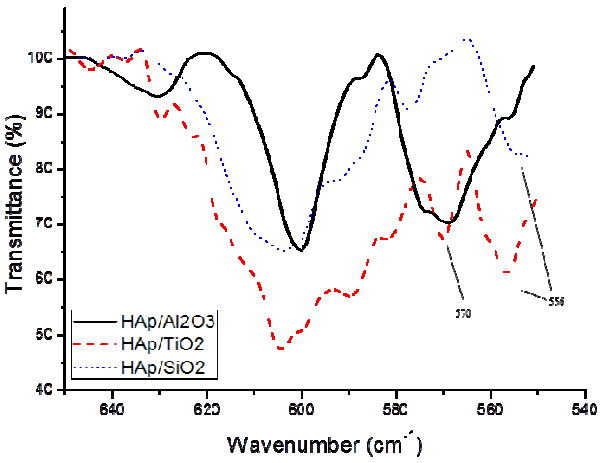

Fig. 7. Higher magnification of Fig. 5 spectra. It is possible to note lower intensity to (OH^-) vibrational band, and higher intensity to signals associated to (PO_4^{3-}) of β-TCP at $570cm^{-1}$ and $556cm^{-1}$.

The results obtained by XRD showed that the presence of a second phase of nanometer order, at a hydroxyapatite bioceramic matrix, may modify the surface diffusion of the grains and the kinetics of phase transformation of hydroxyapatite and beta tricalcium phosphate at a temperature of 1100°C. This temperature is below usual temperature expected for phase transformation of HAp/β-

TCP [9-10]. Beyond XRD, it can be realized at FTIR spectra that the intensity of 630 cm^{-1} band decrease according to β-TCP content, i.e., the presence of β-TCP phase within a composition of hydroxyapatite, can conduct to the attenuation of this band. It is related to the fact that beta tricalcium phosphate does not exhibit the hydroxyl group in its structure. Also, the presence of this β-TCP phase at hydroxyapatite composition may have modified the refraction indices, thereby altering the wavelength region at intensity of 551 cm^{-1} both for BCP as well as for nanocomposites. This wavelength (551 cm^{-1}) may be restricted to vibrational mode of PO_4^{3-} at β-TCP [11,12].

Conclusion

In the present work, six different nanostructured biomaterials were evaluated. Morphological and microstructural results demonstrated that the evaluated biomaterials exhibited extensively interconnected microporous microstructure, formed by fine grains with a few preferred sinterability regions. It was noticed an average diameter under 300 nm for all biomaterials, with the presence of nanostructured grains ($d < 100nm$). The results obtained by XRD and FTIR showed that the presence of a second phase of nanometer order, at a hydroxyapatite bioceramic matrix, may modify the surface diffusion of the grains and the kinetics of phase transformation of hydroxyapatite and beta tricalcium phosphate at a temperature up to 1100°C.

Keywords: Calcareous Shell, Biomaterial, Calcium Phosphate, Sintering and Characterization.

Abstract: Bioceramics of calcium phosphate, obtained from natural raw materials, are promising as bone substitutes because they exhibit crystallographic similarity with the bone tissue. This work deals with the sintering and characterization of calcium phosphate biomaterials from fossilized calcareous shells. Four compositions of biomaterials were prepared with Ca/P molar ratio ranging from 1.4 to 1.67. They were synthesized using a wet method and calcined at 900°C/2h providing calcium phosphate powder, then compressed into a metallic mould. The samples obtained from this compression were sintered at 1200ºC for 2h. The biomaterials recovered from sintering were subjected to a microstructural characterization by scanning electron microscopy [SEM] and by X-ray diffraction [XRD]. Mechanical properties were determined by compression tests. Finally, the Arthur method was used for determining the hydrostatic density and open porosity from these biomaterials. The value of fracture strength was between 54 and 84 MPa for compositions 1.5, 1.67 and 1.6 molar and for composition 1.4 molar about 328 Mpa. The results also showed was the amount of open porosity which ranged between 35 and 54% with increasing Ca/P molar ratio. These studies demonstrate that the production of biomaterials from fossilized calcareous shells may be a new alternative to the production of biomaterials for bone reconstruction.

Introduction

Hydroxyapatite (HAp) and beta tricalcium phosphate (β-TCP) are calcium phosphate bioceramics widely employed as bone substitutes. In addition to presenting chemical and crystallographic similarity to bone structure, they may also exhibit bioactivity and biocompatibility [1,2]. Natural raw materials, as marine coral, fossilized calcareous shells, sea urchins, oyster shells, egg shells and bovine cortical bone have been studied as bone substitute biomaterials [3,4]. Calcium phosphate powder has been previously developed with raw materials by wet method involving solid phase/liquid $CaCO_3$ and phosphoric acid [5].This method was able to provide hydrated calcium phosphate nanosized powders, which subsequently calcination at 900ºC/2h engendered biomaterials with new morphological characteristics and high surface area [5]. The microstructure of biomaterials obtained from fossilized calcareous shells present interconnected porosity, wettability, capillarity, and better cell matrix interactions [3,6]. The results presented here concern the sinterability and characterization of calcium phosphates biomaterials obtained of sintering at 1200°C/2h.

Materials and Methods

Initial powders were obtained from fossilized calcareous shells and were described elsewhere [5]. This synthesis method consists primarily of wet solid/liquid method with decarbonation of $CaCO_3$ from shells. Phosphoric acid addition formed precipitates of hydrated calcium phosphate which was subsequently calcined at 900ºC/2h providing the calcium phosphate powder. For the present characterization studies, four different compositions of calcium phosphate powder achieved from above mentioned method were packed in a metallic matrix with dimensions of 12mm in height and 5mm in diameter, with compression load applied to 30MPa. Uniaxial compaction process was

carried using a universal mechanical testing machine EMIC model DL30000 with displacement rate of the beam of 0.3 mm/min. The samples were sintered in a Linberg/Blue muffle furnace, with a heating rate of 5°C/min, level of sintering at 1200°C/2h, followed by cooling to room temperature.

Sintered samples of four different compositions were subjected to compression testing. All samples were dried 60ºC/24h before and the mechanical tests were performed in EMIC with load cell capacity of 1,000 kgf; beam displacement rate of 0.1mm/min. The tests were performed according to standard ASTM E9-89a.

The X-ray diffraction technique (XRD) was used in order to identify the phases present in the sintered biomaterials. The studies were performed using SHIMADZU X-ray diffractometer model XRD LAB X-6000, with anti-cathode cobalt tube [λ 1.78897Å]. The scanning angular range from 10° to 80° was used with a goniometer speed of 2º/min in function of 2θ, voltage 40kV and current of 30mA.

Microstructural characterization were carried out on fracture surface using the scanning electron microscopy technique (SEM) with ZEISS DSM 940A, through the secondary electrons (SE) method with working distance of 10 mm and voltage to 20kV.

The hydrostatic density and open porosity was determined used Arthur method [8]. This method consists of measuring the weight of the sample in air [Pair], and then the weight of the sample wet in xylene [Pxa]; xylene penetrates the open pores and then measured the weight of the sample with xylene after immersed in distilled water [Pxe]. After performing these measurements was determined hydrostatic density values through [Eq.1]; open porosity, with [Eq.2 and Eq.3] by the relation between the hydrostatic density and theoretical density in percent. The Fig.1 shows a schematic of how to perform the steps of the weight test samples dried, wet in xylene, and embedded in xylene in water.

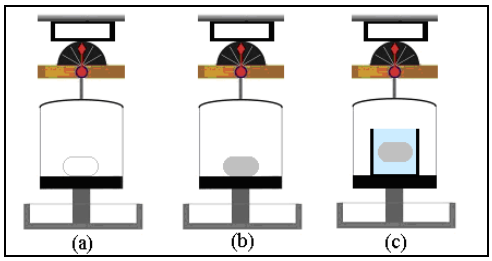

Fig. 1. Process measures: (a) P_{air} - air, (b) P_{xa} - air dipped in xylene, (c) P_{xe} - dipped in xylene in water [9].

Through these measures are determined the values of the hydrostatic density, open porosity and relationship between the hydrostatic density and the theoretical density (Eq.1, 2 and 3).

- Hydrostatic density:

$$dh = \frac{Par.de}{Pxa - Pxe} \quad (1)$$

- Open porosity:

$$P.A. = \frac{(Pxa - Par).de}{(Pxa - Pxe).dx}.100 \quad (2)$$

- Theoretical density in Percent:

$$\frac{dh}{dth} = \frac{Par.de}{(Pxa - Pxe).dx}.100 \quad (3)$$

With:
P_{air} – air-dried weight (g);
P_{xa} - soaked in xylene in air weight (g);
P_{xe} – soaked in xylene immersed in distilled water weight (g);
dh - hydrostatic density (g/cm^3);
dth - theoretical density of the material (g/cm^3);
dx - xylene density (0.8802 g/cm^3);
de - water density (g/cm^3);
P.A. - open porosity in %.

The hydrostatic density and open porosity measurements were performed using three samples of each composition initially dried in an oven to 100°C/24h to remove humidity present in the grain surfaces and micropores. After weighing on a precision balance, the samples were embedded in

xylene [dx=0.8802 g/cm^3] with a desiccator connected to a vacuum pump for 30 minutes. Once removed from the desiccator, the samples were weighed quickly in air [Pxa] and immersed in distilled water [Pxe].

Results

The results showed coarsening calcium phosphate grains to Ca/P molar ratio 1.4 and 1.5 [Fig.2 and 3]. The Ca/P molar ratio biomaterials 1.6 and 1.67 presented microporous microstructure formed by fine grains with micropores volume of 44.42% to ratio 1.6 and 54% to 1.67, as shown on the micrographs represented in Figs. 4, 5 and Table 1.

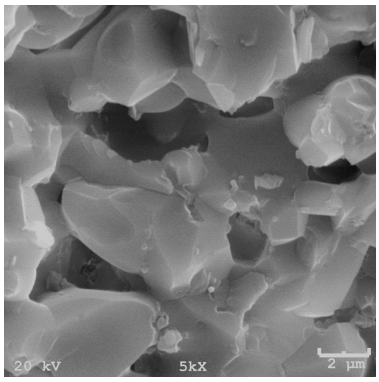

Fig.2. Ca/P molar ratio 1.4 biomaterial morphology

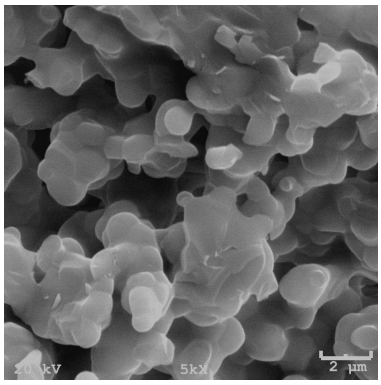

Fig.3. Ca/P molar ratio 1.5 biomaterial morphology

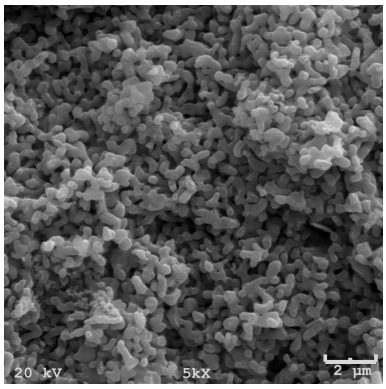

Fig.4. Ca/P molar ratio 1.6 biomaterial morphology

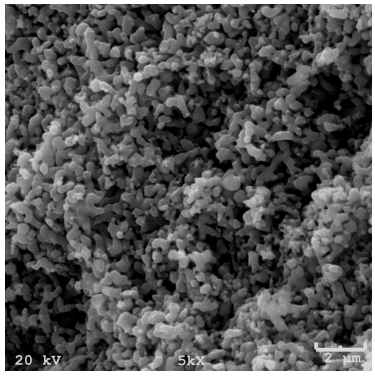

Fig.5. Ca/P molar ratio 1.67 biomaterial morphology

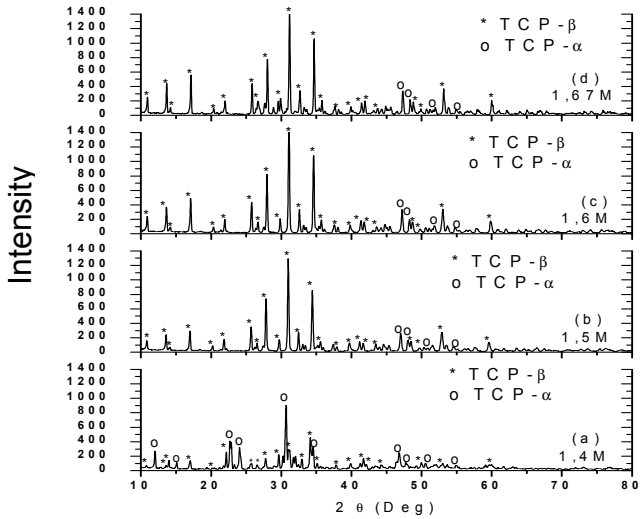

Fig.6. X-ray diffraction patterns of sintered biomaterials at 1200°C/2h

The X-ray diffraction results from the different biomaterials showed the presence of β-calcium phosphate [β-TCP] and α-calcium phosphate [α-TCP] phases, according to the Fig. 6.

The open porosity and hydrostatic density results showed an increase on porosity and reduction of density with variation Ca/P molar ratio. The values are shown in Table 1.

TABLE1. DATA OPEN POROSITY [P.A], HYDROSTATIC DENSITY [DH] AND THEORETICAL DENSITY [DH/DTH]

Compositions	P.A. (%)	dth(g/cm^3)	dh(g/cm^3)	dh/dth (%)
Ca/P 1.4 M	37.71± 2.00	3.07	2.25± 0.06	73.38± 2.00
Ca/P 1.5 M	41.80± 0.13	3.07	1.8± 0	58.76± 0.13
Ca/P 1.6 M	44.42± 0.49	3.07	1.55± 0.06	50.78± 0.49
Ca/P 1.67M	54.40± 0.95	3.10	1.45± 0.02	46.94± 0.95

The compression test results showed that Ca/P molar ratio can certainly influence the biomaterial sinterability, as shown in Table 2.

TABLE 2. BIOMATERIALS FRACTURE STRENGTH

Compositions	Fracture strength (MPa)
1.4 M	328.00 ± 68.90
1.5 M	84.68 ± 8.26
1.6 M	8.15 ± 9.02
1.7 M	54.24 ± 9.12

Discussion

The Ca/P molar ratio biomaterials 1.4 and 1.5 presented calcium phosphate grain coalescence during the sintering process. This coalescence led to the achievement of grain interface quality, which contributed to biomaterial sinterability, with grain boundaries and interfaces with well-defined open microporosity volume about 37.71% for the biomaterial with Ca/P molar ratio 1.4 and 41.42% for Ca/P molar ratio 1.5 [Figs. 2 and 3] and table 1.There was a microporous microstructure composed of fine grains to Ca/P molar ratio1.67 and 1.6 biomaterials [Figs. 4 and 5]. It is known that for the calcium phosphate biomaterials, interconnected microporosity, grain surface and micropores are favorable to wettability, solubility, cell adhesion of osteoblasts on the surface of grains and micropores, which is associated with the volume of micropores already existing and known by the bioactivity of calcium phosphate biomaterials [7]. These properties can contribute to the osteointegration and bone formation process.

The X-ray diffraction results [Figure 6] revealed to 1.4 ratio molar the presence of the higher concentrations of α-calcium phosphate, may explain the better biomaterial sinterability, which also contributed significantly to superior mechanical properties for this composition.

The open porosity and hydrostatic density results observed the highest density value for the biomaterial in the Ca/P molar ratio 1.4 and a lower value for the biomaterial Ca/P molar ratio 1.67. The same way, there was a higher value of open porosity for biomaterial in the Ca/P molar ratio 1.67 with 54 %, observed in Table 1. A comparative study relating the hydrostatic density with the theoretical density [d_h/d_{th}] in percentage between the biomaterials was performed to evaluate the approach of theoretical density with hydrostatic. Relating (the open porosity results) with those obtained by the scanning electron microscopy technique, one can say that, while varying the Ca/P molar ratio from 1.4 to 1.67, there was a change in the sinterability of these biomaterials, which can be explained by the presence of α-calcium phosphate phase in the compositions. For the biomaterial composition Ca/P molar 1.67, there was a higher value for the porosity and smaller grain size [Table 1] and [Fig. 5]. This result demonstrated that the Ca/P molar ratio and the synthesis process influence directly on the powder sinterability.

The biomaterial interconnected microporous microstructure is a promising property in biomedical applications, as already observed by [10]. It is known that calcium phosphate microporous biomaterials have a better response as biomaterials for repairing defects or as guide plates for bone tissue reconstruction [11], as confirmed by other authors who produced microporous calcium phosphates from natural raw materials, using other synthesis methods [1,2,10,11].

The presence of α-calcium phosphate phase in the compression tests can influenced the biomaterial sinterability and mechanical properties, observing a higher value of fracture strength to Ca/P molar ratio 1.4, which had a 328.00 ± 68.90 value. This type of biomaterial can be improved and used in the near future as a bone implant. Another observation was the smallest open porosity value, better grain interface quality, which confer biomaterial sinterability and mechanical properties [Table 2] [Fig. 2]. In what concern the compositions on the Ca/P molar ratio 1.5 and 1.6 and 1.67 these values showed similar fracture strength, these values are presented close to those found in the literature, for human cortical bone results in compression and bending [80-200MPa] [13]. This result can be explained by the presence of open porosity, fine grain morphology and grain boundaries connection interface, which inhibit the biomaterial mechanical properties.

Conclusion

Fossilized natural materials may be an alternative for the development biomaterials in biomedical applications, due to these natural raw materials have differentiated morphological characteristics according with variable Ca/P molar ratio within the range 1.4-1.67. These materials are also promising in orthopedic applications, tooth structure repairing and traumatology, as well as biomaterials capable of exercising drug delivery in cancer treatment. It is known that the grain morphology, interconnected microporosity, surface area of grain and micropores are prerequisites for a favorable biomaterial provides a means to oxygenation, wettability, capillarity, osteoinduction, osteointegration and bone formation.

Keywords: Gamma-irradiation, Edible mushroom, Medicinal mushroom, Physiologically active component

Abstract: Dry samples of fruit bodies of *Cordyceps militaris* and *Agariucs blazei,* mycelia of *Antrodia camphorata*, and hot water extracts of *Ganoderma tsugae* were ground and irradiated with γ-rays at doses of 0, 2.5, 5, and 10 kGy. After γ-irradiation, the content of γ-aminobutyric acid, adenosine, cordycepin, and triterpenoids in medicinal mushrooms did not significantly change. Gamma-irradiation only affects *A. camphorata* mycelia polysaccharide content, and an increase in irradiation dose (0-10 kGy) significantly reduces its content (111.85-101.88 mg/g). The content of high molecular weight (2.7×10^5 Da) polysaccharide in *G. tsugae* by γ-irradiation with increasing doses gradually increased. Gamma-irradiation could significantly affect the content of vitamin D_2 and ergosterol. However, ergosterol content in non-irradiated *C. militaris*, *A. blazei*, *A. camphorata*, and *G. tsugae* was 2.34, 1.31, 2.33, and 1.15 mg/g, and of that in 10 kGy γ-irradiated mushrooms was 2.75, 1.88, 2.19, and 0.94 mg/g, respectively. Summarily, γ-irradiation does change some medicinal mushrooms by the content of physiologically active substances. When using γ-irradiation sterilization to maintain the physiological activity of mushroom products, one should consider its impact on the physiologically active substances.

Introduction

Mushrooms have recently become attractive as functional food, considered a source for biological and useful substances material. Edible and medicinal mushrooms contain many physiologically active substances, including γ-aminobutyric acid, adenosine, cordycepin, triterpenoids, polysaccharide, vitamin D and ergosterol [1]. Several methods for the prevention the contamination have been developed, such as the exposure to ionizing radiation: γ-rays [2]. Irradiation with an average dose of 10 kGy has shown no toxicological hazards and introduced no specific microbial and nutritional problems [3]. Several studies on γ-irradiation of spices at the doses up to 10-15 kGy have shown that no substantial changes occurred in volatile oils, flavor profiles, spicing power [3] and antioxidant properties [4]. However, the effect of γ-irradiation on medicinal mushrooms has not been investigated.

Medicinal mushrooms are important for developing health foods in Taiwan, and γ-irradiation is a technique for elongation of their shelf life. However, the content of physiologically activity substances (γ-aminobutyric acid, adenosine, cordycepin triterpenoids, polysaccharide, vitamin D_2, and ergosterol) in medicinal mushrooms with γ-irradiation is unknown. Our objective was to study the content of physiologically activity substances in medicinal mushrooms (*C. militaris*, *A. blazei*, *A. camphorata* and *G. tsugae*) with various doses (0, 2.5, 5, and 10 kGy) of γ-irradiation.

Experimental and method

Mushrooms and γ-irradiated

Fresh fruit bodies of *A. blazei* were originally obtained from the Rich-Year Farm, Puli, Nantou County, Taiwan. Fresh fruit bodies of *C. militaris* were originally obtained from the Star-Ocean International Co., Taichung City, Taiwan. Extracts of *G. tsugae* were obtained from the Yen-Ten Farm, Zhongpu, Chiayi County, Taiwan. Mycelia of *A. camphorata* were obtained from the Biotechnology Center, Grape King Inc., Chungli, Taiwan. Images of the four samples are displayed in Fig. 1. Sample (20 g) was packaged in polyethylene packaging. After packaging, mushrooms were transported to the China Biotech Corp., Taichung City, Taiwan. Mushrooms were either unirradiated (control) or γ-irradiated with doses of 2.5, 5 and 10 (± 10%) kGy 60Co (600000 Ci, 6.78×10^2 kGy/h) at ambient temperature.

Color Measurement

The reflective surface color of steamed buns was measured on crumbs using an S80 color measuring system (Nippon Denshoku Inc., Tokyo, Japan) and L, a and b values were recorded. A standard white plate (X = 91.98, Y = 93.97 and Z = 110.41) was used to standardize the instrument. Whiteness index (WI) was calculated based on the following equation [5]:

$$WI = 100 - \sqrt{(100 - L)^2 + a^2 + b^2}$$

Gamma-aminobutyric acid, adenosine, cordycepin, triterpenoids, vitamin D_2 and ergosterol assays

Each γ-aminobutyric acid [6], adenosine [7], cordycepin [7], triterpenoids [8], vitamin D_2 [9] and ergosterol [9] were identified using the authentic compound (Sigma) and quantified by its respective calibration curve.

Polysaccharides content and molecular weight assays

Mushroom powder (1 g) was refluxed with 50 mL of deionized water for 30 min. The filtrate was dialyzed using a Cellu Sep T2 tubular membrane (MWCO: 6,000-8,000, Membrane Filtration Products, Seguin, TX, USA) for 24 h. The polysaccharide content was then determined by the phenol–sulfuric acid assay according to Dubois et al [10]. The polysaccharide molecular weights were analyzed according to the method of Hsieh et al. [11].

Statistical analysis

All the measurements were determined in triplicate. The experimental data were subjected to an analysis of variance for a completely random design to determine the Fisher's least significant difference among means at $P < 0.05$.

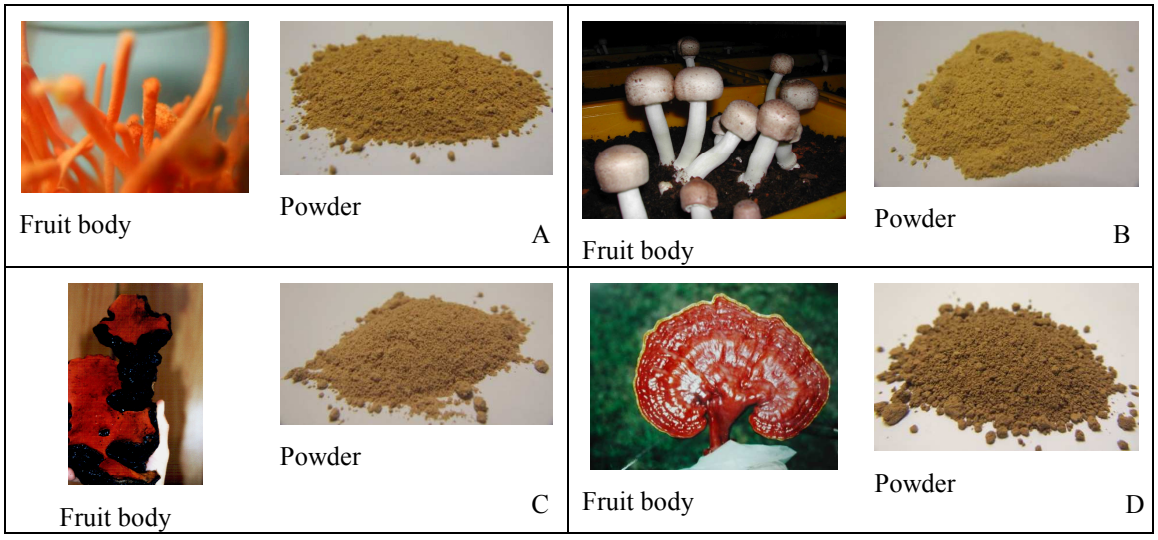

Fig. 1 Photographs of (A) *C. militaris*, (B) *A. blazei*, (C) *A. camphorata* and (D) *G. tsugae*, respectively.

Results and discussion

Color properties

G. tsuge showed lower lightness and WI values than *C. militaris*, *A. blazei*, and *A. camphorata* (Table 1). With regard to a and b values, *A. blazei* showed low redness and more yellowness. After γ-irradiation, the color properties in *C. militaris*, *A. blazei*, *A. camphorata* and *G. tsugae* did not significantly change.

TABLE 1 THE COLOR PROPERTIES OF MEDICINAL MUSHROOMS WITH VARIOUS DOSES OF Γ-IRRADIATION.

a	12.25-12.29	7.92-8.04	12.35-12.39	13.16-13.22
b	34.94-36.56	38.73-38.80	24.40-24.41	25.02-25.14
WI	50.32-50.72	51.44-51.49	56.71-57.06	41.99-42.61

Physiologically active substances contents

The γ-aminobutyric acid and adenosine content of *A. blazei* was significantly higher than that in *C. militaris*, *A. camphorata* and *G. tsugae* (Table 2). Surprisingly, γ-aminobutyric acid (GABA), a hypotensive agent [12], was found in these four mushrooms. Cordycepin was detected in *C. militaris* (2.35-2.39 mg/g) but not detected in *A. blazei*, *A. camphorata* and *G. tsugae*. The content of triterpenoids in *C. militaris*, *A. blazei*, *A. camphorata* and *G. tsugae* was 21.12-23.27, 18.88-21.46, 22.81-23.57 and 18.36-20.14 mg/g, respectively. After γ-irradiation, the content of γ-aminobutyric acid, adenosine, cordycepin, and triterpenoids in medicinal mushrooms did not significantly change.

TABLE 2 CONTENT OF PHYSIOLOGICALLY ACTIVE SUBSTANCES IN MEDICINAL MUSHROOMS WITH VARIOUS DOSES OF Γ-IRRADIATION.

	Contents（mg/g dry weight）			
Physiologically active substances	*C. militaris*	*A. blazei*	*A. camphorata*	*G. tsugae*
γ-Aminobutyric acid	1.27-1.35	13.02-13.43	2.12-2.23	0.14-0.15
Adenosine	1.56-1.60	4.61-4.65	2.17-2.20	0.12
Cordycepin	2.35-2.39	nd	nd	nd
Triterpenoids	21.12-23.27	18.88-21.46	22.81-23.57	18.36-20.14

Vitamin D_2 and ergosterol content

The content of vitamin D_2 in *C. militaris, A. blazei, A. camphorata* and *G. tsugae* was 2.31-2.75, 1.33-1.88, 2.19-2.53 and 0.94-1.18 μg/g, respectively (Fig. 2A). The content of ergosterol in *C. militaris, A. blazei, A. camphorata and G. tsugae* was 18.41-22.87, 4.80-7.45, 0.28-13.98 and 14.29-17.78 mg/g, respectively (Fig. 2B). It seems that the increase of vitamin D_2 and ergosterol content is not dose-dependent. About the fresh common mushrooms, Simon et al. [13] found that no significant difference in ergosterol concentration was detected between the UVB light treated and control mushrooms, which contained 5.80 mg/g and 5.78 mg/g, respectively, but sunlight exposure could significantly increase ergosterol concentration (6.33 mg/g). Fortunately, mushrooms process a large amount of ergosterol that can be converted to vitamin D under ultraviolet light irradiation or pulsed ultraviolet light [14-15]. Our results showed that γ-irradiation is a new method to produce vitamin D_2 in medicinal mushrooms.

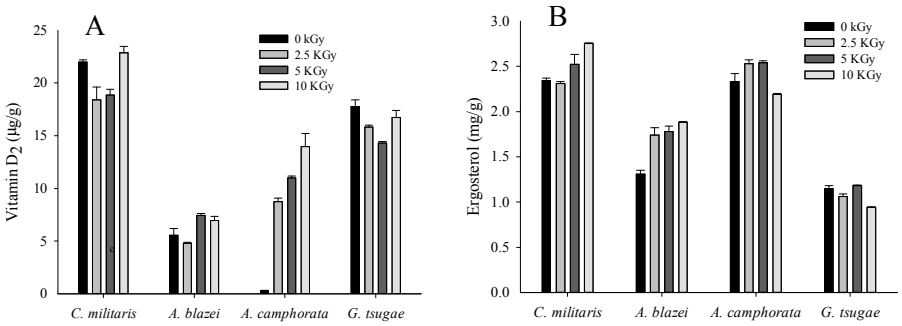

Fig. 2 Effect of γ-irradiation on vitamin D_2 (A) and ergosterol (B) content of medicinal mushrooms.

Polysaccharide content and molecular weight

The content of polysaccharide in *C. militaris*, *A. blazei*, *A. camphorata* and *G. tsugae* was 30.99-31.41, 71.29-71.67, 101.88-111.85 and 176.08-181.58 mg/g, respectively (Table 3). However, polysaccharide content in *A. camphorata* decreased after γ-irradiation. The γ-irradiation might cause the decomposition of polysaccharides in *A. camphorata* mycelia. The content of high molecular

TABLE 3. CONTENT OF POLYSACCHARIDES IN EDIBLE MUSHROOMS WITH VARIOUS DOSES OF Γ-IRRADIATION.

	Polysaccharides Content [1] （mg/g dry weight）			
edible mushrooms	0 kGy	2.5 kGy	5 kGy	10 kGy
Fruit bodies of *C. militaris*	31.25 ± 0.85 ^{A}	31.41 ± 0.60 ^{A}	31.13 ± 0.28 ^{A}	30.99 ± 0.59 ^{A}
Fruit bodies of *A. blazei*	71.25 ± 0.71 ^{A}	71.39 ± 0.60 ^{A}	71.67 ± 0.75 ^{A}	71.29 ± 1.27 ^{A}
Mycelia of *A. camphorata*	111.85 ± 1.96 ^{A}	106.75 ± 1.06 ^{B}	105.24 ± 2.32 ^{BC}	101.88 ± 1.87 ^{C}
Extracts of *G. tsugae* fruit bodies	179.32 ± 3.83 ^{A}	176.08 ± 3.85 ^{A}	181.58 ± 3.58 ^{A}	176.53 ± 2.56 ^{A}

[1] Each value is expressed as mean ± SD (n=3). Means with different letters within a row are significantly different ($p < 0.05$).

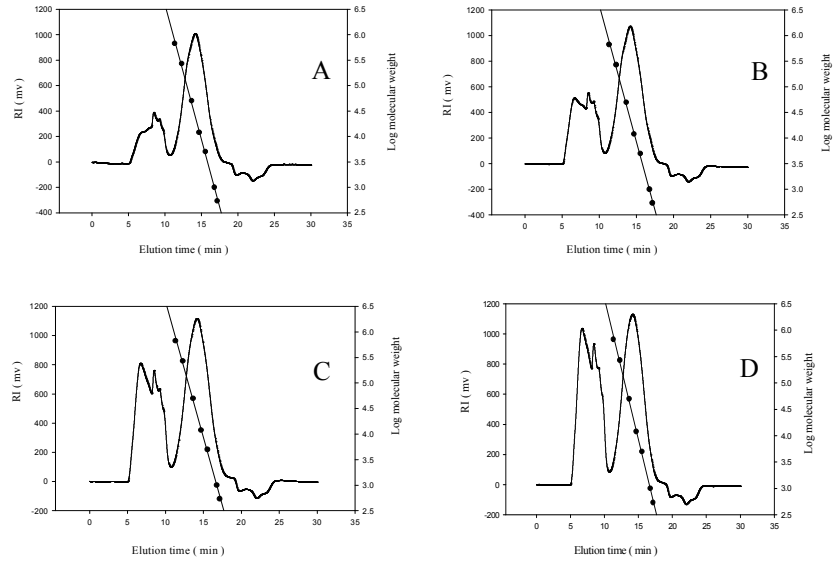

Fig. 3 The chromatography of polysaccharides from extract of *G. tsugae* fruit bodies with (A) 0 kGy, (B) 2.5 KGy (C)5 KGy and (D)10 kGy of γ-irradiation.

weight (2.7×10^5 Da) polysaccharide in *G. tsugae* by γ-irradiation with increasing doses gradually increased (Fig. 3). After γ-irradiation, the molecular of polysaccharide in *C. militaris*, *A. blazei* and *A. camphorata* did not have significant effects (data no shown).

Conclusions

Based on the results obtained, γ-irradiation did not markedly change the content of physiologically active substances. When using γ-irradiation sterilization to maintain the physiological activity of mushroom products, one should consider its impact on the physiologically active substances.

Acknowledgments

Keywords: biocements, synthesis, characterization.

Abstract. Calcium phosphates biocements are biomaterials that present crystallographic and mineralogical characteristics similar to human skeletal structure. This has led to the development of new calcium phosphates biomaterials for biomedical applications, especially biomaterials for repairing defects and bone reconstruction. Calcium phosphates biocements are a promising alternative in biomedical applications, for they are easy to mold, they have good wettability, hydration and hardening capacity during its application in biological environment. This work aimed at the synthesis of hydrated calcium phosphates powder, precursor to late biocements development. Three calcium phosphates compositions were produced via $CaCO_3$/phosphoric acid reactive method in the ratios Ca/P = 1,5; 1,6 e 1,67 molar. The presented results are associated to hydrated powder morphology and synthesis process control. Field Electronic Microscope helped with the morphological characterization of the powders, Fourier Transformed Infrared Spectroscopy (FTIR) gave support to the identification of H_2O e PO_4^{3-} grouping vibrational bands and x-ray diffractometry (XRD) served on crystallographic characterization of hydrated calcium phosphates. The work showed that for the different powder compositions the hydrated calcium phosphate phase is formed by clustered fine particles. This demonstrated that the chosen synthesis method permits the obtaining nanoparticles of hydrated calcium phosphates, precursors for later biocement production.

Introduction

Materials and tissue engineering contribute to the development of new biomaterials and to the assessment of their behavior in *in vivo* studies. The results obtained from different studies show that calcium phosphate biomaterials are promising as post traumatic bone restoration, surgical or pathological injuries materials, such as bone tumors or osteoporosis. Calcium phosphate biocements can be used not only as bone replacement, but also as vehicles for controlled drug supply, being also widely used as medication carrier systems [1, 2, 3].

Calcium phosphate cements are produced from cement paste composed of calcium phosphate and a aqueous liquid [4] and present high osteoconductivity and easy manipulation, giving it high potential for application in orthopedics, for the correction of bone malformations that don't receive heavy loads [5, 6], having as main advantage it's capacity to easily adapt to the bone defect. Due to its molding capacity, these biocements can fit perfectly into the filling or restoration place, optimizing bone-biomaterial contact, even in geometrically complex bone defects, being considered the most promising biomaterials for minimally invasive surgeries [7].

This work aimed at the synthesis and characterization of hydrated calcium phosphate powders, precursors for later elaboration of biocements. The presented results are associated to the synthesis process and morphology control of hydrated powders. Scanning Electron Microscopy (SEM) helped with the powder's morphological characterization, laser analysis method was used to determine particle size and Fourier Transform Infra-Red (FTIR) gave support to the identification of vibrational bands of H_2O and PO_4^{3-} groupings.

Materials and Methods

The process of obtaining hydrated calcium phosphate powder, precursor of biocement, was performed using the reactive calcium carbonate / phosphoric acid method in the quantities required for forming the desired molar ratio of Ca/P. Three compositions of hydrated calcium phosphates were prepared on the molar ratios Ca/P = 1,5; 1,6 e 1,67.

Synthesis of Hydrated Calcium Phosphate Powders

The synthesis of hydrated calcium phosphate powders was performed by sequence shown in figure 1:

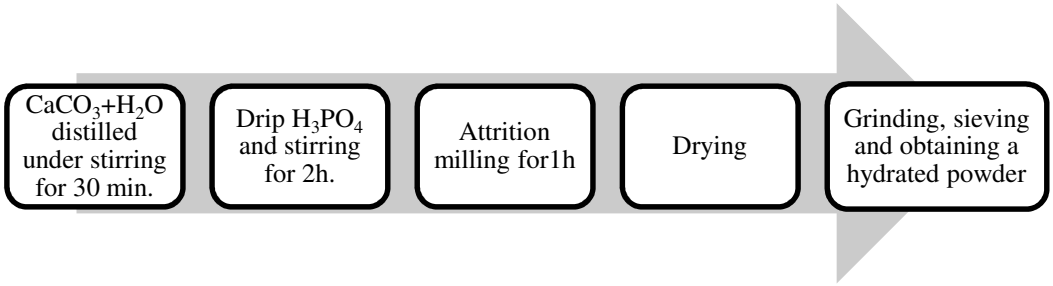

Figure 1: Synthesis flowchart of powders from hydrated calcium phosphate.

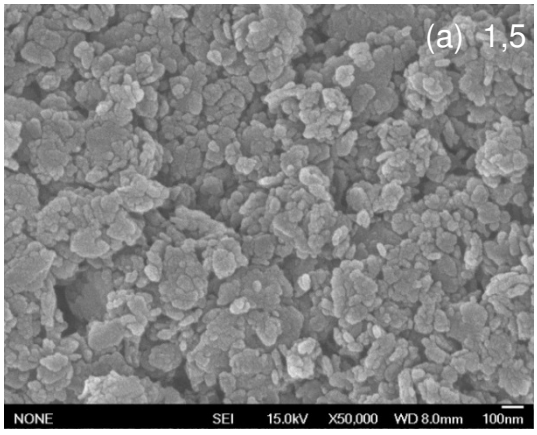
Morphological Characterization

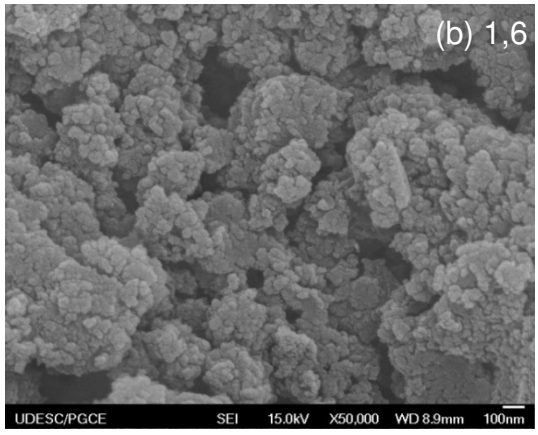
Morphological characterization studies were performed with the help of a JEOL Field Electronic Microscope (Field Emission Gun–FEG). Observation studies were performed with hydrated calcium phosphate powders recovered by sieving at 100μm through secondary electrons system.

Chemical Characterization by Fourier Transform Infrared Spectroscopy (FTIR)

Fourier Transform Infra Red Spectroscopy technique (FTIR) was used for chemical analysis, which allowed the identification of OH^-, HPO_4^{2-} and PO_4^{3-} groupings vibrational bands present on hydrated calcium phosphates. Studies were performed using a Perkin Elmer Spectrum equipment, with attenuated reflectance, with resolution of 4,00 cm^{-1}.



Physical Characterization by XRD



X-ray diffractometry served on crystallographic characterization of hydrated calcium phosphates. In this study a SHIMADZU x-ray diffractometer model XRD LAB X-6000, with anti-cathode copper tube, was used. To obtain the x-ray diffraction, a 40 kV voltage and current of 30mA were used, being the scanning angular range from 5° to 80°, with a goniometer speed of 2º/min in function of 2θ.

Results and Discussion

Morphological Characterization

Morphological characterization studies obtained from the hydrated calcium phosphate powders showed for ratios Ca/P = 1,5; 1,6 e 1,67 molar a morphology of fine clustered particles, as seen on figure 2(a), 2(b) and 2(c).

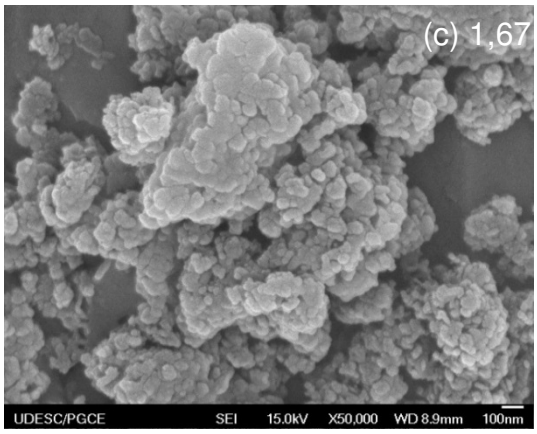


Figure 2. Micrographs obtained for the different compositions of hydrated calcium phosphate (a) Ca/P 1,5 molar; (b) Ca/P 1,6 molar e (c) Ca/P 1,67 molar.

Chemical Characterization by Fourier Transform Infrared Spectroscopy (FTIR)

Figure 3 presents the FTIR spectogram obtained from the Ca/P = 1,5 molar ratio powder, noticing the presence of the vibrational band at 1650 and 633cm^{-1}, indicating the presence of water molecules on the surface of the particles. OH^- grouping is represented by vibrational bands between 2900 and 3600cm^{-1}, typical for hydrated calcium phosphates, as already observed by other authors [8]. Vibrational frequencie at 1450cm^{-1} correspond to the CO_3^{2-} grouping bond. Vibrational bands at 562, 600, 960, 1027 and 1094cm^{-1} were also noticed, which are associated to PO_4^{3-} groupings. Also oberved was the 875 cm^{-1} band, associated to HPO_4^{2-}, as observed by other authors [9].

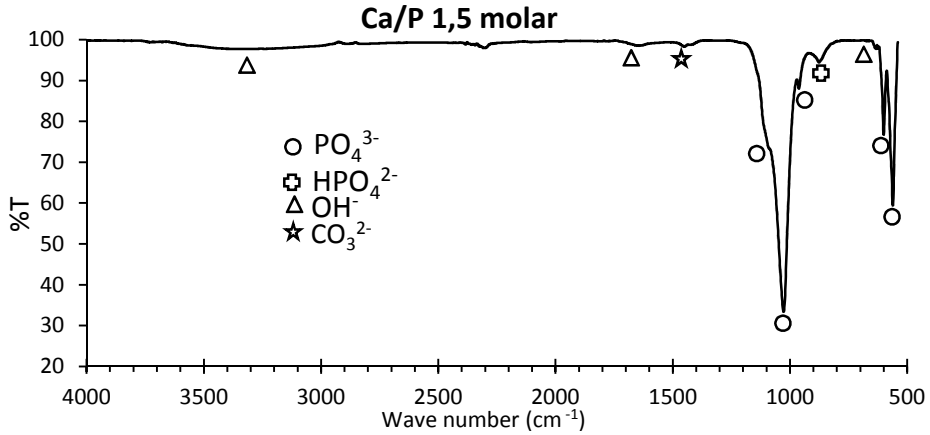

Figure 3: FTIR spectrum of hydrated calcium phosphate of molar ratio Ca/P = 1,5.

At ratio Ca/P = 1,6 molar, figure 4 shows that the PO_4^{3-} grouping appeared at 561, 600, 960 and 1025 cm^{-1}. Just like for Ca/P = 1,5 molar ratio, the vibrational band of the grouping HPO_4^{2-} was also observed at 875 cm^{-1}. Grouping CO_3^{2-} shows at 1450 cm^{-1}, indicating residual carbonate, and OH^- is shown at 1650 cm^{-1}. Adsorved water is between 3000 and 3600 cm^{-1} (which will became narrower under the influence of thermal treatment).

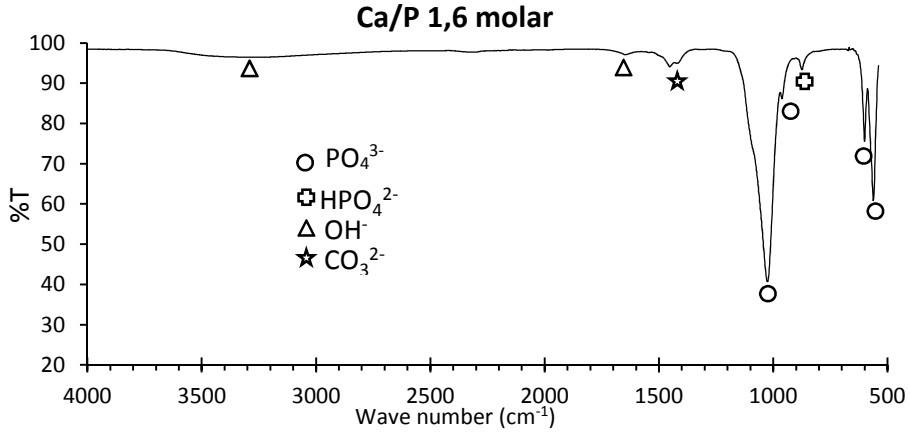

Figure 4: FTIR spectrum of hydrated calcium phosphate of molar ratio Ca/P = 1,6.

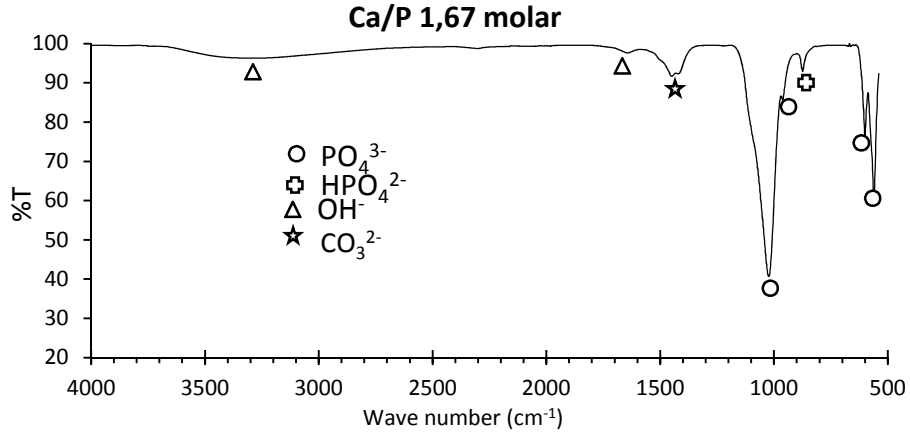
The spectrogram of molar ratio Ca/P = 1,67 appeared similar to the ratio Ca/P = 1,5 and 1,6, however with more accentuated CO_3^{2-} e HPO_4^{2-} grouping bands, as shown on figure 5, due to increase of molar ratio.



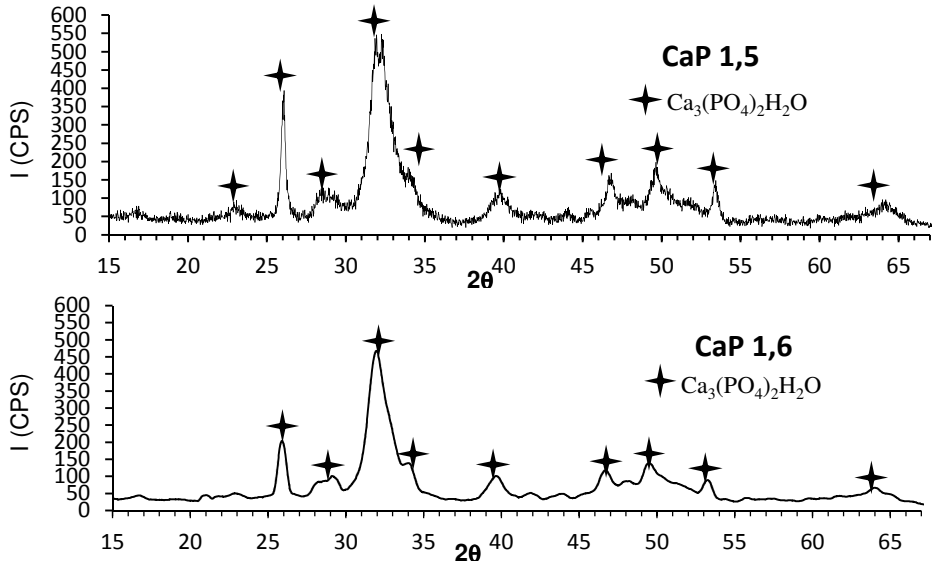


Figure 5: FTIR spectrum of hydrated calcium phosphate of molar ratio Ca/P = 1,67.

Physical Characterization by XRD

The results obtained by x-ray diffractometry of the powders recovered from rotatory evaporator revealed in their x-ray diffractograms the presence of hydrated calcium phosphates, as shown in the x-ray diffractograms in figure 6, in the composition $Ca_3(PO_4)_2H_2O$ for three molar ratios studied.

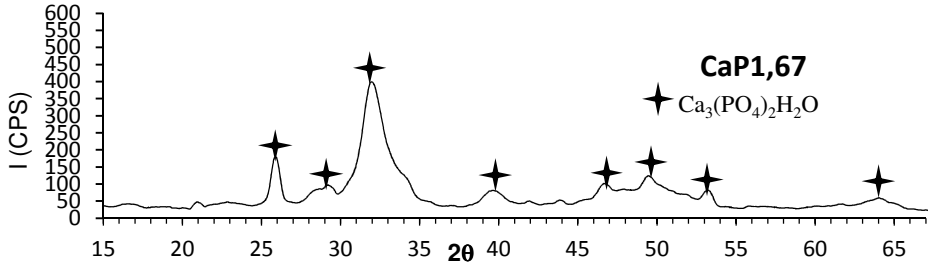

Figure 6. X-ray diffractograms obtained from molar ratios Ca/P = 1,5, Ca/P = 1,6 and Ca/P = 1,67.

Conclusions

The reactive calcium carbonate / phosphoric acid method allowed to obtain hydrated calcium phosphates. It was found in the results obtained for different compositions of calcium phosphate hydrated powders, a morphology composed of fine agglomerated particles. The FTIR spectra clearly showed the presence of PO_4^{3-} vibrational bands, indicating the presence of hydrated calcium phosphate phase in the compositions, which was proved by x-ray diffractrograms.

It is concluded that the synthesis method used allows obtaining precursors of hydrated calcium phosphate for subsequent preparation of biocements.

Keyword: oleoylchitosan; Poly (lactic-co-glycolic acid); nanoparticles; drug delivery system

Abstract: A solid oleoylchitosan (OCS) coated Poly (lactic-co-glycolic acid) (PLGA) nanoparticles (OCS-coated PLGA NPs) were prepared using the emulsification–evaporation method. The nanoparticles in suspension (TEM) and solid state (SEM) were spherical and very regular and compact. The effects of OCS concentration, PLGA concentration, drug concentration, and release media on drug entrapment efficiency and in vitro drug release behavior were investigated for the release properties using rifampicin (RFP) as a model drug. Both the increase of PLGA concentration and the increase of OCS concentration could decrease the drug release rates. The RFP release rates decreased as the RFP concentration increased. The RFP release rate was sensitive to the pH of the release media.

Introduction

Recently, much attention has been drawn to various amphiphilic block polymers, because they can form self-assembled nanoparticles and because they exhibit unique physicochemical characteristics such as a nanoparticle structure, biodegradability, and thermodynamic stability. [1, 2] The drug can be loaded into a polymeric micelle in three ways: simple physical embedding, electrostatic interactions or chemical bonding method. [3,4] The drug release rate is largely determined by the stability of the micelles, physical state of micelle core, drug molecular size, the position of drug in micelles, and the dissociation rate. Sometimes in order to delay drug release rate, further crosslink can be used including nuclear crosslinked micelles and micelles crosslinked hydrophilic shell. [5]

Chitosan, its unique characteristics such as positive charge, biodegradability, biocompatibility, and nontoxicity make this macromolecule ideal as a drug carrier and delivery material.[6,7] PLGA is by far the most common biodegradable polymer used for the controlled delivery of drugs due to its early use and approval as compatible biomaterial in humans. [8]

The author has prepared oleoylchitosan nanoparticles (OCS) and illustrated the OCS had good biocompatibility from the cytotoxicity testing and erythrocyte toxicity assay. [9] The hydrophobic drugs can be directly wrapped into OCS micelle core and drug release by passive diffusion out from the micelles. Thus, it was expected that the introduction of PLGA to the core of OCS micelles would delay the release of drug. Herein, we prepare the OCS coated PLGA nanoparticles (OCS-coated PLGA NPs) and study the characteristic and in vitro release profiles of the nanoparticles.

Experiment

Materials

Chitosan, degree of deacetylation 82%, molecular weight 38 KDa, was purchased from Biotech Co. (Mokpo, Korea). PLGA (MW 60KDa, 50/150) were purchased from Sigma Chemicals. Rifampicin was kindly donated by the Jiangbei Pharmaceutical Factory (Zhejiang, China).

Preparation of OCS-coated PLGA NPs

The OCS-coated PLGA NPs were prepared using the emulsification–evaporation method.[10]

Fourier Transform Infrared Spectroscopy (FT-IR)

The FT-IR spectra of OCS NPs and OCS-coated were recorded using a an Avater-360 Fourier transform infrared spectrometer. [11]

Morphology of the OCS-coated PLGA NPs

The morphology of the OCS-coated PLGA NPs suspension was observed by transmission electron microscope (TEM, JEM-2010). The morphology of the OCS-coated PLGA NPs powder was observed by a scanning electron microscope (SEM, JSM-T330A, Nihon Denshi, Japan).

Evaluation of in vitro drug release

The rifampicin (RFP) loaded nanoparticles were prepared by dissolving RFP in methylene chloride and subsequently as above described to prepare blank nanoparticles.

A cellulose membrane (8,000-10,000) tube containing 3 ml of the RFP loaded nanoparticles solution was placed in 97 ml of buffer at 37℃ under protection from light. The amount of released RFP was assayed by spectrophotometry at 475 nm in comparison to the standard curve. [12]

Results and Discussion

FT-IR of OCS Coated PLGA Nanoparticles

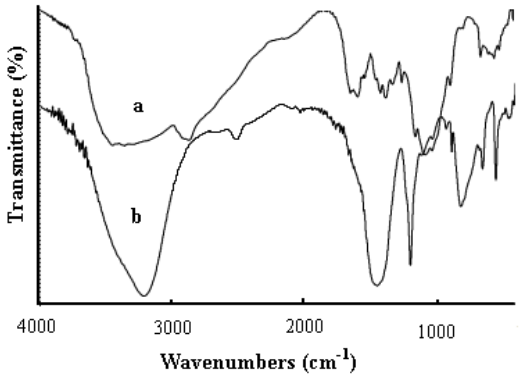

Figure 1 FT-IR of OCS NPs (a) and OCS-coated PLGA NPs (b)

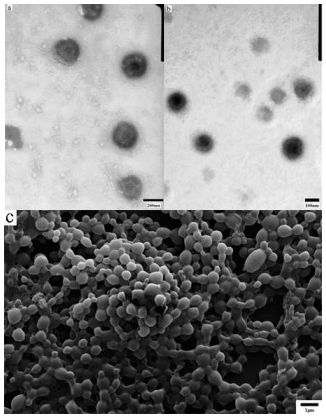

Figure 2 TEM and SEM photographs of OCS-coated PLGA NPs (a)TEM: 40000×; (b) TEM: 50000×; (c)SEM

The FT-IR spectra of OCS NPs and OCS-coated PLGA NPs are shown in Figure 1. The OCS had the basic characteristics (Figure 1 a) at: 3455 cm^{-1} (O–H stretch), 2900 cm^{-1} (C–H stretch), 1596 cm^{-1} (N–H bend), 1154 cm^{-1} (bridge-O- stretch), and 1094 cm^{-1} (C–O stretch). The spectra of OCS-coated PLGA NPs (Figure 1 b) exhibited alterations compare to OCS NPs. It had characteristic peaks of PLGA at 3326 cm^{-1}(C-H), 2400 cm^{-1}, 1750 cm^{-1}(C=O), 1100 cm^{-1}(C-O). These results indicated the success of the preparation of OCS-coated PLGA NPs.

Morphology of OCS-coated PLGA NPs

The TEM image of OCS-coated PLGA NPs is shown in Figure 2 (a, b). It could be confirmed that polymeric micelles are spherical in shape and a light circle could be seen around the nanoparticles. The hydrophilic groups could form hydrated layer in aqueous media to avoid the aggregation of the micelles. The results also suggested that the OCS-coated PLGA NPs were fairly dispersed in aqueous media and formed homogeneous small-sized micellar structures. The majority number of the particles was around 200 nm in size.

TABLE 1 EFFECTS OF OCS, PLGA, AND RFP ON DRUG LOADING AND ENCAPSULATION EFFICIENCY

	(g/L)	Encapsulation efficiency (%)	Drug loading (%)
OCS	1.00	76.75±2.90	65.12±1.02
	2.00	81.03±3.01	54.71±3.50
	3.00	83.75±4.01	47.63±2.56
PLGA	0	80.10±2.18	61.53±1.56
	0.65	81.03±3.01	54.71±3.50
	2.00	81.30±1.97	44.50±4.20
RFP	2.00	83.05±2.36	38.52±3.01
	4.00	81.03±3.01	54.71±3.50
	6.00	74.75±1.02	62.62±1.29

AS for the solid state of OCS-coated PLGA NPs, SEM was used to observe the morphology Figure 2 (c). The images revealed that formulated OCS-coated PLGA NPs have regular spherical shape with narrow size distribution and smooth surface without any noticeable pinholes, tiny pores or cracks at the resolution level within the equipment resolution.

In Vitro Release Of Rifampicin From Nanoparticles

The encapsulation efficiency (EE) and drug loading (DL) of RFP loaded nanoparticles with different PLGA concentrations was listed in Table 1. It can be found that all formulations gave high EE, which higher than 80%. There was no significant difference in EE in the samples with different concentration of PLGA. Figure 3 (a) shows the release profile of RFP from OCS-coated PLGA NPs prepared with different PLGA concentrations. It could be found that the release rate of RFP from nanoparticles decrease with an increase of PLGA concentrations. The nanoparticles prepared with PLGA concentration 2.00g/L, 0.65g/L, 0 released 35.46%, 46.08%, 59.12% after 36 h, respectively. This result could be explained by polymeric micelles formed by OCS solubilize hydrophobic drugs RFP suffering from poor water solubility. RFP was physically entrapped in the hydrophobic core of the micelle. Accordingly, the in vitro release behaviors of a drug from these polymeric micellar systems are largely affected by its inner core with hydrophobic properties. The nanoparticles might act as a barrier against the release of drug. Therefore, as the PLGA concentration inceresed, resulting in the decrease of drug release rates. [13, 14]

The EE and DL of RFP-loaded nanoparticles with different OCS concentrations was listed in Table 1. The EE increased as the increase of OCS concentration. And the DL decreased as the increase of OCS concentration. The increase of OCS concentration can increase the number of nanoaprticles. Accordingly, the EE increase as the increase of OCS concentration. Figure 3 (b) shows release profiles of RFP from samples with different concentration of OCS. It could be found that the release rate of RFP from nanoparticles decrease with an increase of OCS concentrations. The nanoparticles prepared with OCS concentration 1.00g/L,2.00g/L, 3.00g/L released 52.87%, 46.08%, 39.13% after 36 h, respectively. OCS is an amphiphilic polymer which can increase the wetting behaviors between oil phase and water phase and reduce the surface free energy of droplet.[15] The surfactants may be formed on the surface of droplet of a protective film to prevent the formation of agglomeration. Thus, the addition of OCS contributed to the formation of stable and homogeneous nanoparticles. Therefore, as the OCS concentration inceresed, the physically bound and binding affinity to drug increased, resulting in the decrease of drug release rates.

The EE and DL of RFP-loaded nanoparticles with different RFP concentrations was listed in Table 1. The DL increased as the increase of RFP concentration while the EE decreased as the increase of RFP concentration. Figure 3 (c) shows release profiles of RFP from samples with different concentration of RFP. The nanoparticles prepared with RFP concentration 6.00g/L, 4.00g/L, 2.00g/L released 28.84%, 46.08%, 52.84% after 36 h, respectively.

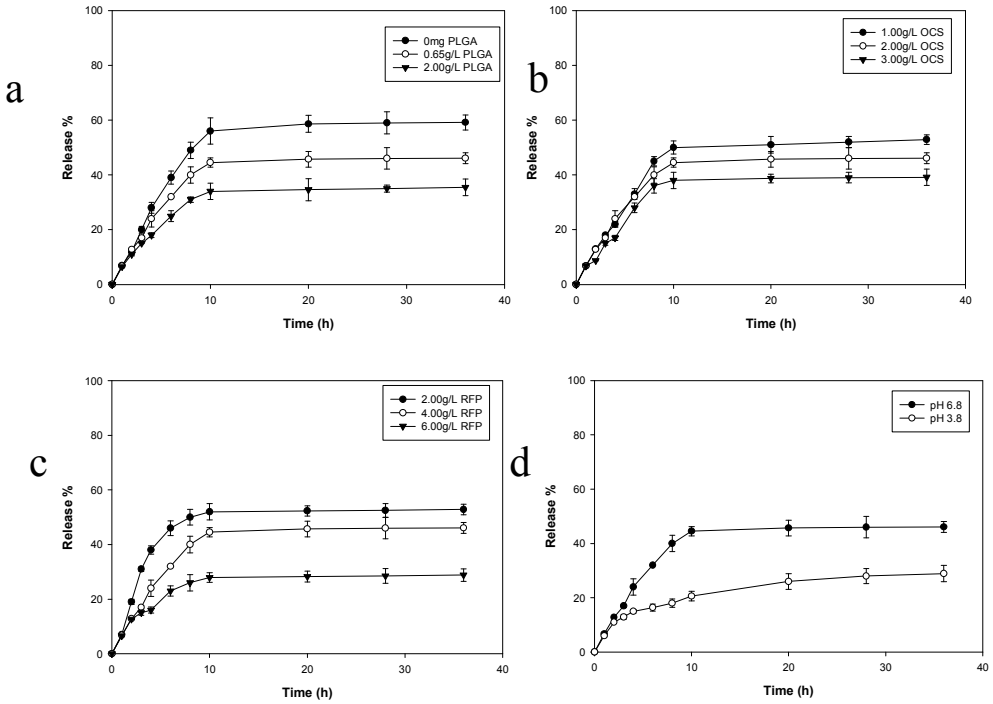

Figure 3 The effects of PLGA concentration (a), OCS concentration (b), drug concentration (c), and release media (d) on drug release behavior

The release profile of RFP from the nanoparticles in intro in different buffer solution was shown in Figure 3 (d). From the release profile, we can see that the release of rifampicin from solution with pH 6.8 was rapid. The release from solution with pH 3.8 had the slower rate. That was related to the stability of the nanoparticles in the solution. OCS was soluble in an aqueous acidic solution below pH 6.5. However, it was not soluble at neutral or alkali pH. That made the nanoprticles was less stable in the system above pH 6.5 than in the system below pH 6.5. And that also made the release of drug from solution below pH 6.5 slower than from solution above pH 6.5.

Conclusion

In this study, OCS-coated PLGA NPs were prepared using an emulsification–evaporation method. The nanoparticles in suspension were spherical and very regular and compact. AS for the solid state, the OCS-coated PLGA NPs had regular spherical shape with narrow size distribution and smooth surface without noticeable pinholes, tiny pores or cracks. The effects of OCS concentration, PLGA concentration, RFP concentration and release media on drug entrapment efficiency and in vitro drug release behavior were investigated for the release properties. There was no significant difference in DL and EE in the samples with different concentration of PLGA. The RFP release rates decreased as the PLGA concentration increased. As the PLGA concentration inceresed, the physically bound and binding affinity to drug increased, resulting in the decrease of drug release rates. The EE increase as the increase of OCS concentration. While the DL decrease as the increase of OCS concentration. As the OCS concentration increased, the physically bound and binding affinity to RFP increased, resulting in the decrease of drug release rates. The RFP release rates decreased as the RFP concentration increased. The RFP release rate was sensitive to the pH of the release media.

Keywords: pH-sensitive;Magnetic nanoparticles;Drug delivery;Doxorubicin

Abstract: Efficient delivery of drug to tumor cells is one of the crucial issues in cancer therapy. This letter addresses for the first time that poly(acrylic acid) (PAA), a pH-sensitive polymer, is tethered to the surface of the nanoparticles by chemical grafting. The release rates of doxorubicin (DOX) are subsequently studied in vitro. The results reveal that DOX can be released preferentially at the desired lysosomal pH, and show that the anti-cancer drug carrier can be applied to the biomedical applications.

Introduction

In recent years, magnetic nanoparticle-based drug delivery systems have shown high degree of efficiency in cancer treatments because they can improve pharmacokinetics and bio-distribution profiles via the enhanced permeability and retention (EPR) effect.[1-3] However, the poor cellular internalization and insufficient drug release limits the dosages of anticancer drugs to level below the optimum therapeutic value.[1] Therefore, the effective absorption and release of anticancer drugs is of vital importance in ensuring the tumor targeting and choosing the suitable targeting ligand. Recently, some stimuli-sensitive materials have been reported to improve the absorption of anticancer drugs because they can make sharp respond according to the changs in microenvironment of some pathological sites, such as heat, light, or acidic conditions.[4-6] Among the various stimuli, pH is the most widely used chemical stimuli because pH values vary significantly in different tissues and cellular compartments. Futhermore, introduction of specific ligands such as folic acid (FA) can also help the magnetic nanoparticles (MNPs) deliver the dugs to the targeted cells via the receptor mediated endocytosis.[7]

In this work, a biocompatible and very sensitive to pH and ionic strength material, i.e., PAA, is chosen for improving the absorption of the magnetic nanoparticles-based drug. In addition, it provokes little antigenic reaction in vivo.[8] In fact, PAA has already been used for the synthesis of PAA coated magnetic nanoparticles with the potential application as solvent absorbers and drug delivery devices.[8,9] However, in these studies, PAA is attached to the magnetic nanoparticles through electrostatic interaction, which is not stable enough in the acid and alkaline environment. In this paper, we present an efficient method to prepare magnetic nanoparticles containing PAA and FA via the method of chemical grafting, which are stable in acid and alkaline environment and exhibite high encapsulation efficiency and loading capacity, as well as good pH-responsive release profile. In addition, the magnetic nanoparticles can also realize passive targeting and active targeting at the same time.

Experiment

The initial chemical agents were ferric chloride, ferrous sulfate, ammonia (25 wt%), 3-aminopropyl triethoxysilane (APTES), N-hydroxysuccinamide (NHS), 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC), poly(acrylic acid) (PAA), folic acid (FA), Doxorubicin hydrochloride (DOX·HCl). In an experimental procedure, PAA was dissolved into distilled water, and then EDC and NHS was also dissolved into distilled water with stirring. The pH value of the system was maintained at 7.0-7.5 with dilute NaOH solution. The molar ratio of PAA:EDC:NHS was 1:2:2. The obtained transparent solution was carried out at RT for 4h. Then amine functionalized magnetic nanoparticles (NH_2-MNPs) which were prepared by grafting APTES described in previous reports[2] were dispersed into water by sonication and added into the above solution and carried out at RT for 24 h. The mass ratio of NH_2-MNPs:PAA was 150:1. Thereafter, the PAA modified magnetic nanoparticles (PAA-MNPs) were magnetically precipitated and washed several times with distilled water. Finally FA was connected to the as-prepared PAA-NMPs (FA-PAA-MNPs) according to the reported procedure with little modification.3 DOX, an anticancer drug, was loaded into the pH-sensitive Magnetic nanoparticles (DOX-MNPs). In brief, 5 mg FA-PAA-MNPs were added to 5 mL 0.3 mg mL^{-1} DOX solution and the mixture was kept in a shaker for 24 h. The release rates of DOX were subsequently studied in vitro at 37℃ in simulate environments with different pH values, corresponding to the physiological condition of the blood (pH 7.4) and acidic environment in intracellular lysosomes (pH 5.0).

The sizes and shapes of these samples were observed by transmission electron microscopy (TEM, Model Tecnai 12, Philips Co. Ltd., Holland). Magnetic properties of the particles were measured at room temperature using a vibrating sample magnetometer (VSM, Model 7410, Lake Shore Co. Ltd., USA). The thermal stability was detected by thermogravimetricanalysis (TGA, Model TA 2100, TA Instruments, USA) under an inert atmosphere (N_2). DOX content was determined by measuring ultraviolet and visible spectrum (UV759S, Shanghai Precision & Scientific Instrument Co. Ltd., China).

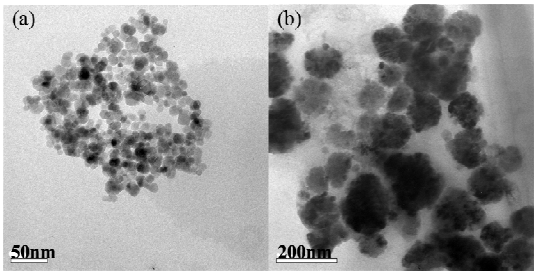

Figure 1 (a) TEM image of NH_2-MNPs and (b) TEM image of FA-PAA-MNPs

Figure 1 (a), 1 (b) show the TEM image of the NH2-MNPs (a) and the FA-PAA-MNPs (b). In Fig. 1 (a), the nanoparticles are well dispersed, spherical in nature with average particle size 10-15 nm. In Fig.1 (b), almost spherical nanocomposites can be observed and the dispersion of the nanoparticles is also well. The majority of the nanoparticles have a diameter size of about 100-160 nm. Shivang has summarized that NPs should typically be between 100 and 200 nm to avoid sequestration and extravasation to the tissues in order to maximize confinement to the vasculature.1 This means the size of nanoparticles is well within the preferred range of the nanoparticles useful for effective drug-delivery.

Figure 2 (a) displays the magnetic properties of various nanoparticles where typical ferromagnetic behavior can be observed. The saturated magnetization values (Ms) for NH2-MNPs, PAA-MNPs and FA-PAA-MNPs are calculated to be 62, 51, and 46 emu/g, respectively. Gradual decrease in the Ms values with surface modification is due to decrease in magnetic dipolar

interaction with diamagnetic coating. In each stage of nanoparticles preparation and subsequent surface modification, the nanoparticles are isolated from the aqueous dispersion by simple magnetic precipitation. From magnetic studies, it may be concluded that these magnetic particles show a high enough Ms value which have the potential ability to be used in magnet-guided drug delivery applications.

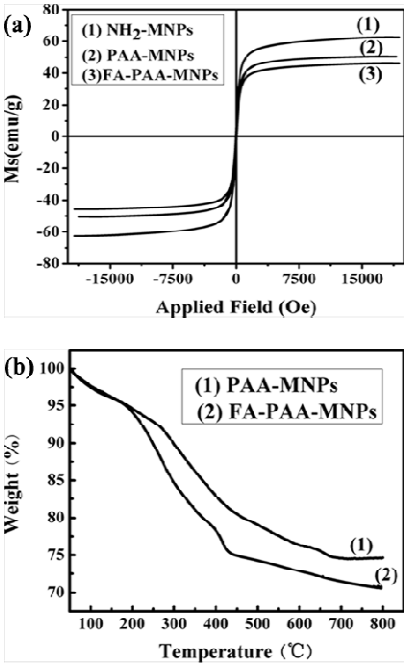

Figure 2 The VSM and the TG measurement results

Fig. 2 (b) displays the TG measurement result of the PAA-MNPs and FA-PAA-MNPs, respectively. In Fig. 2 (b) (2), the first stage is a weight loss of up to less than 3% in the range of 50–100 ℃, mainly relates to the evaporation of the physically adsorbed water of the sample. The second stage appears in the temperature range of 200 – 420 ℃, which has a weight loss of up to 19%. It is due to dehydration and decarboxylation of the carboxylic acid groups of PAA polymers and the degradation of APTES and FA. The third stage appears in the temperature range of 420 – 800 ℃ which has a weight loss of up to 5%, and it is mainly associated with the degradation of PAA polymer backbone and the remaining part of FA. Combined with TEM, VSM and TG results, it is suggested that Fe3O4 nanoparticles have been coated by PAA and FA in the chemical grafting process.

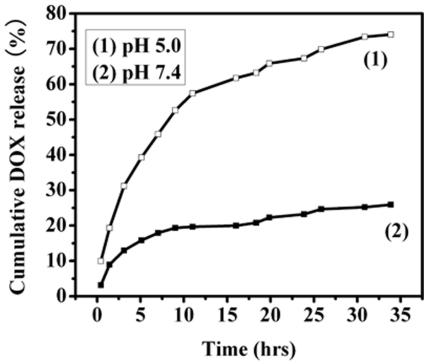

Fig 3 Release curves of DOX-MNPs with time (1) pH 5.0 and (2) pH 7.4

DOX possesses an ionizable amino group on the sugar ring when DOX is in the form of hydrochloride. DOX can be binded to nanoparticles through ionic interaction as sodium ions on the PAA form a salt bridge and produce sodium chloride as a byproduct. The loading content = weight of drug in nanoparticle/weight of nanoparticles taken, The entrapment efficiency = weight of drug

in nanoparticle/weight of drug injected. According to these equations, the loading content and entrapment efficiency of DOX in FA-PAA-MNPs are found to be 23.2% and 79.5%, respectively. The DOX loading amount in the polymeric shell observed here are found to be much higher than those in other polymer shells as suggested in earlier reports.4,10,11 In vitro, the release of DOX from DOX-MNPs at different conditions is shown in Fig.3. The release performance is studied at both physiological and lysosomal pH conditions at 37 ℃. The drug release profile reveals that the release rate is pH-dependent. About 74% of the loaded DOX is released in the stage of 0–35 h at pH 5.0 at 37 ℃, whereas only about 26% drug is released at pH 7.4 at the same time interval and temperature. Compared with pH 7.4, there is a drastic increase in drug release amount and rate at pH 5.0, indicating that the release amount and rate are dependent on pH. The result owing to the protonation of carboxylic groups of PAA at pH 5.0, the DOX-MNPs interaction becomes weak and DOX is released at a much faster rate and in larger amount. The drug release pattern indicates that the pH responsive polymer plays a key role on release of loaded drug in a desired fashion.

Summary

In summary, we have shown that the pH-sensitive nanoparticles prepared by chemical grafting is in desired size-range for drug delivery application. They possess high saturation magnetizations and good stability in physiology medium. Moreover, the loading content and entrapment efficiency can reach as high as 23.2% and 79.5%, respectively. It means the outer PAA and FA shell encapsulate large amount of DOX. Further, the drug release study reveals that DOX-MNPs release DOX preferably at pH 5.0, meaning that the as-prepared nanoparticles achieve excellent efficiency for simultaneous targeting. It is expected that the magnetic nanoparticles have applications in the biomedical field.

Keywords: Phellinus pini, polysaccharide, preparation, anti-tumor activity

Abstract: Polysaccharides PS Ⅰ and PS Ⅱ were isolated from liquid-cultured mycelia of *Phellinus pini*. The average molecular weight: PS Ⅰ 36 kDa, PS Ⅱ 49 kDa; sulfate content: PS Ⅰ 5.25%, PS Ⅱ 0.65%; monosaccharide composition: PS Ⅰ glucose, galactose and mannitose; PS Ⅱ glucose, mannitose and xylose. Anti-tumor activities of PS Ⅰ and PS Ⅱ (400 mg/kg·d, i.g.) were investigated in S180-bearing mice. Results indicated that PS Ⅰ and PS Ⅱ significantly inhibited the growth of S180-solid tumors. PS Ⅰ and PS Ⅱ effectively protected immune organs (thymus and spleen) and increased activities of immune cells (NK cells, macrophages, T and B lymphocytes). Results suggest that polysaccharides PS Ⅰ and PS Ⅱ from *Phellinus pini* have potential anti-tumor activities, which might attributed partly to their immunomodulatory properties.

Introduction

Mushroom polysaccharides have attracted considerable attention due to their various and potentially significant pharmacological activities and low toxicity[1-3]. The genus *Phellinus* includes many species, of which *Phellinus linteus*, *Phellinus baumii Pilát* and *Phellinus igniarius* are well-known traditional medicinal mushrooms in Eastern countries such as China, Korea and Japan[4-6]. Many researchers have investigated the biological activities of polysaccharides isolated from these *Phellinus* species in recent years. Results indicated that polysaccharides isolated from *Phellinus linteus*, *Phellinus igniarius*, etc. exerted anti-tumor effects by activating immune cells (e.g., T cells, B cells, dendritic cells (DC) and macrophages) and directly acting on the tumor cells[5-7].

Due to the limited resource of the genus *Phellinus* in nature and some disadvantages associated with traditional solid culture, the submerged fermentation technology has been applied to obtain mycelia for the production of polysaccharides[8-11]. A higher mycelia production in a more-compact space over a shorter time could be achieved using submerged culture technology. *Phellinus pini* is a species belonging to the genus *Phellinus* that fructifies over the stem of *Pinus pinaster*. Being exploited lately, there are few reports focusing on the bioactivities of polysaccharides from *Phellinus pini*. In the present study, the immunologically active polysaccharides PS Ⅰ and PS Ⅱ were prepared from *Phellinus pini* mycelia, which was obtained using submerged culture technology. The anti-tumor activities of PS Ⅰ and PS Ⅱ *in vivo* were investigated in S180-bearing mice. Results of this study suggest that polysaccharides PS Ⅰ and PS Ⅱ from *Phellinus pini* have potential anti-tumor activities, which might attributed partly to their immunomodulatory properties.

Materials and methods

Fermentation and preparation of crude polysaccharides.

The submerged-fermentation of *Phellinus pini* were performed under the following conditions: 26℃, pH 7.0, 160 r/min, seed age 3 d, inoculum size 15%, bottling capacity 70 mL/250 mL, 7 d; carbon resource: glucose 2.66%, soluble starch 2.11%, nitrogen resource: yeast extract 0.76%, peptone 0.82%. The crude polysaccharides were applied to a DEAE-cellulose column and further purified by gel filtration chromatography on Sepharose CL-4B and Sepharose CL-6B column. Two fractions were concentrated, dialyzed, lyophilized and named as PS Ⅰ and PS Ⅱ, respectively.

Composition analysis of PS Ⅰ and PS Ⅱ.

The total polysaccharide content was determined using the phenol-sulfuric acid method and the protein content was measured by Lowry method using D-glucose and bovine serum albumin as standard, respectively. The sulfur content was determined by sodium rhodizonate method. Gas chromatography analysis of monosaccharide composition was performed on a Shimadzu GC-9A instrument: hydrogen flame ionization detector (FID), the flow rate of N_2, H_2 and air were 40 mL/min, 50 mL/min and 500 mL/min, respectively; the column temperature: 180℃; the inlet temperature: 210℃. Standard monosaccharides (xylose, ribose, mannose, galactose and glucose) were used as standards. The average molecular weight of PS Ⅰ and PS Ⅱ was determined by high-performance size-exclusion chromatography (HPSEC) on an Ultrahydrogel^{TM}1000 column. The calibration curve was made with the T-series Dextran standards (Dextran T-10, T-40, T-70, T-110, T-500 and T-2000).

Animals and experimental design.

Animals (*Kunming* mice, male/female, 6-8 weeks old, 20-22 g) were randomly divided into four groups (n=10 in each group). PS Ⅰ group and PS Ⅱ group were treated once daily with an oral administration of PS Ⅰ (400 mg/kg·bw) or PS Ⅱ (400 mg/kg·bw) for 28 days, respectively. Control group and Model group were administered with an equal volume of distilled water. On day 14, Sarcoma 180 tumor cells (1×10^7 cells/ml, 0.2 ml) were inoculated subcutaneously into the left armpit of the mice in Model, PS Ⅰ and PS Ⅱ groups. All animal experiments were performed in strict accordance with the National Institutes of Health Guidelines for the Care and Use of Laboratory animals. Animals were weighed every two days. The length (L) and width (W) of solid tumors were measured using a caliper. After 28 days of oral administration, mice were sacrificed by cervical dislocation. Thymus index and spleen index were defined as the ratio of the corresponding organ's weight (mg) to the body weight (g).

Assay of natural killer (NK) cells activity.

The activity of NK cells were assayed by MTT method. Spleen cells (2×10^6 cells/ml) together with S-180 cells (1×10^5 cells/ml) were incubated overnight at 37℃ in a 96-well culture plate. 10 μl MTT (5 mg/ml) was added to each well. After another 4 h of incubation, 150 μl DMSO was added to each well and shaken until all crystals dissolved. The wells of target cells control, blank control and effector cells control were treated simultaneously. The absorbance of each well was recorded at 570 nm.

Macrophage phagocytosis assay.

Mice were injected intraperitoneally with 1 mL sterile soluble starch (5%) daily for 3 days. Peritoneal exudates were harvested by a lavage of the peritoneal cavity with 5 ml of PBS on day 4. Cells were added (100 μl/well) into a 96-well plate, and incubated for 3 h at 37℃. After washed twice with PBS, 0.073% neutral red was added (200 μL/well) and incubated for another 3 h. Each well was added 100 μl cell lysis solution (acetic acid: anhydrous ethanol= 1:1) and incubated overnight. The absorbance was read at 540 nm.

Lymphocyte proliferation assay.

A single spleen cell suspension was prepared. Cells were pipetted into a 96-well flat-bottom plate (100 μl/well) in the presence or absence of Con A (5 μg/ml) or LPS (10 μg/ml). After incubation at 37℃ for 44 h in a 5% CO_2 incubator, 20 μl MTT solution (5 mg/ml) was added to each well and the plate was further incubated for 4 h. 150 μl DMSO was added to each well and shaken until all crystals dissolved. The absorbance was detected at 570 nm.

Statistical analysis.

Results were expressed as the means±SD. Statistical analysis was performed by the Student's *t*-test. $p<0.05$ was considered statistically significant.

Results and discussion

Preparation and composition analysis of PS Ⅰ and PS Ⅱ.

In the present study, an artificial cultivation of *Phellinus pini* mycelia was performed using submerged fermentation technology. The yield of crude polysaccharide from *Phellinus pini* mycelia was 6.70%. Two purified fractions PS Ⅰ and PS Ⅱ were obtained. Composition analysis of PS Ⅰ and PS Ⅱ indicated: the total sugar content of PS Ⅰ 75.31%, PS Ⅱ 86.28%; protein content: PS Ⅰ 4.52%, PS Ⅱ 6.87%; sulfate content: PS Ⅰ 5.25%, PS Ⅱ 0.65%; the average molecular weight: PS Ⅰ 36 kDa, PS Ⅱ 49 kDa. And the results of monosaccharide composition analysis indicated that PS Ⅰ was mainly composed of hexose (92%) and the molar ratio of glucose, galactose and mannitose was 68:15:7; PS Ⅱ was composed of hexose (95%, glucose: mannitose 86:8) and pentose (5%, mainly xylose).

Anti-tumor activity of PS Ⅰ and PS Ⅱ.

Anti-tumor activity of PS Ⅰ and PS Ⅱ *in vivo* were investigated in S180-bearing mice in the present study. Results indicated that both polysaccharides PS Ⅰ and PS Ⅱ (400 mg/kg·d, i.g.) significantly inhibited the growth of S180-solid tumors. The tumor inhibition ratio of PS Ⅰ and PS Ⅱ was 94.58% and 84.65%, respectively.

Effects of PS Ⅰ and PS Ⅱ on immune organ index.

Thymus and spleen are important immune organs. In the present study, the effects of PS Ⅰ and PS Ⅱ on the immune organs (thymus and spleen) were investigated. As shown in Fig.1, the thymus index and spleen index in PS Ⅰ and PS Ⅱ treatment groups were significantly increased (PS Ⅰ: $p<0.05$, $p<0.05$; PS Ⅱ: $p<0.05$, $p<0.05$ vs. S-180 model group), indicating the protective effects of PS Ⅰ and PS Ⅱ on the immune organs.

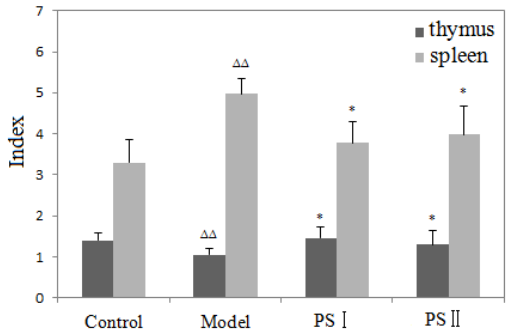

Fig.1 Comparison of thymus and spleen index of mice from different groups

ΔΔp<0.01 vs. Control group; *p<0.05 vs. Model group

Effects of PS Ⅰ and PS Ⅱ on NK cell activity.

Natural killer (NK) cells are important lymphocytes of the innate immune system. There is accumulating evidence of the crucial contribution of NK cells to the immunosurveillance of tumor. The effects of PS Ⅰ and PS Ⅱ on NK cell activity in S180-bearing mice were investigated in the present study. As shown in Fig.2, the NK cell activities were significantly increased in the PS Ⅰ- and PS Ⅱ-treated animals (PS Ⅰ: $p<0.05$; PS Ⅱ: $p<0.05$) .

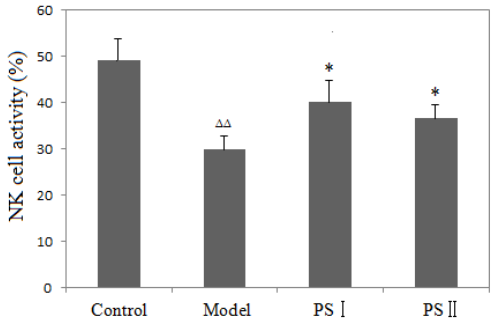

Fig.2 Effect of PS Ⅰ, PS Ⅱ on splenic NK cell activity in S180-bearing mice

ΔΔp<0.01 vs. Control group; *p<0.05 vs. Model group

Effects of PS Ⅰ and PS Ⅱ on phagocytic activity of macrophages.

The effects of PS Ⅰ and PS Ⅱ on the phagocytic activity of macrophages were investigated in the present study. Macrophages are considered as the important immunocytes in the host defense system. The phagocytic activities of peritoneal macrophages in PS Ⅰ- and PS Ⅱ-treated animals were significantly increased ($p<0.01$, $p<0.01$ vs. Model group, Fig.3), and a greater increment was observed in PS Ⅰ group ($p<0.05$ vs. PS Ⅱ group), which might be related to their different chemical structures, e.g. molecular weight, monosaccharide composition.

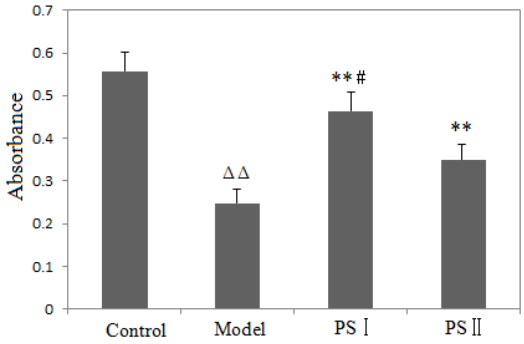

Fig.3 Effect of PS Ⅰ, PS Ⅱ on phagocytic activity of peritoneal macrophages in S180-bearing mice

ΔΔp<0.01 vs. Control group; **p<0.01 vs. Model group; #p<0.05 vs. PS Ⅱ group

Effects of PS Ⅰ and PS Ⅱ on lymphocyte proliferation.

As shown in Fig.4, both PS Ⅰ and PS Ⅱ significantly increased (PS Ⅰ: $p<0.05$; PS Ⅱ: $p<0.05$) splenic lymphocytes proliferation in the presence of Con A (stimulates T lymphocytes). The effects of PS Ⅰ and PS Ⅱ were more obvious (PS Ⅰ: $p<0.01$; PS Ⅱ: $p<0.01$) in the presence of LPS (stimulates B lymphocytes) and significant difference ($p<0.05$) was observed between PS Ⅰ and PS Ⅱ. Lymphocytes play significant roles in the host defense against tumor cells. Results of this study indicated that the stimulating effects of PS Ⅰ and PS Ⅱ on proliferative activity of lymphocytes especially B lymphocytes might contribute greatly to the anti-tumor activities of PS Ⅰ and PS Ⅱ.

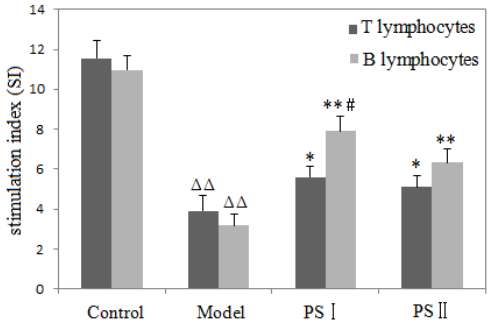

Fig.4 Effect of PS Ⅰ, PS Ⅱ on splenic lymphocyte proliferation of S180-bearing mice (n=8)

ΔΔp<0.01 vs. Control group; *p<0.05, **p<0.01 vs. Model group; #p<0.05 vs. PS Ⅱ Group

Conclusions

In the present study, polysaccharides PS Ⅰ and PS Ⅱ were prepared from *Phellinus pini* mycelia, which was obtained using submerged fermentation technology. Composition analysis of PS Ⅰ and PS Ⅱ was performed. The anti-tumor activities of PS Ⅰ and PS Ⅱ were investigated in S180-bearing mice. Results indicated PS Ⅰ and PS Ⅱ significantly inhibited the growth of S180-solid tumors and effectively protected immune organs and activated immune cells. Although further studies are needed, the results of this study suggest that polysaccharides PS Ⅰ and PS Ⅱ from *Phellinus pini* have potential anti-tumor activities and the difference observed between PS Ⅰ and PS Ⅱ might be related to their different chemical structures.

Keywords: magnetic nanoparticles; composite particles; emulsion polymerization; high saturation magnetization; biomedical application

Abstract: Magnetite nanoparticles (MNPs) coated with poly(divinylbenzene-co-glycidyl methacrylate) particles (mPDGs) are prepared by co-polymerization of 1,4-divinylbenzene and glycidyl methacrylate monomers via batch emulsion polymerization. The Fe_3O_4 nanoparticles modified by oleic acid are obtained by chemical precipitation. The chemical composition, morphology, magnetic content, magnetic properties and particle size of the composite particles are investigated using transmission electron microscopy, thermogravimetric analysis, vibrating sample magnetometer, and dynamic light scattering, respectively. The results show that the magnetic nanoparticles have been coated by 1,4-divinylbenzene and glycidyl methacrylate, with the high saturation magnetization being 33.66 emu/g. The mean size of the mPDGs with good dispersion is about 200 nm. Subsequently, the polymer shell with reactive epoxy group is expected to be useful for chemical grafting of any biomolecule containing reactive functional groups (-NH_2, -OH, -COOH, etc) or can be chemically modified to desired functional groups. These magnetic nanospheres with multifunctional groups have potential application in biomedical applications.

Introduction

Recently, MNPs have generated considerable interests in various areas, especially in the biomedicine field,[1] which is attributed to their small size, large surface-to-volume ratio and size dependent magnetic properties.[2] Magnetite nanoparticles possess magnetism in the magnetic field. Owing to this character, MNPs may be used as drug carriers because it can transfer the carried particle to the chosen site with the help of localized magnetic field. Moreover, the MNPs can be held by the magnetic field until finish of the therapy and finally can be removed by the magnetic field.[3] Unfortunately, only small amount of drugs can be carried by MNPs, and the biocompatibility and stability of the MNPs should be improved.

It has been reported that coating the surfaces of MNPs with polymers to form functional magnetic polymer nanoparticles or microspheres (FMPLs) is a good way to solve these problems. By coating the polymer shell, appreciable amount of drugs can be loaded onto the surfaces of the polymer shell, and aggregation of Fe_3O_4 nanoparticles is prevented both in biological medium and magnetic field, meaning that the stability of the Fe_3O_4 nanoparticles is improved.[4-7] Moreover, the surfaces of magnetic nanoparticles modified by polymers are suitable for further functionalization by the attachment of various bioactive molecules.[8]

In general, all biomedical applications of magnetic nanoparticles require that nanospheres should fulfill certain criteria, for example, no sedimentation, uniform size, high saturation magnetization, and abundant functional groups. In the last decade, several interesting approaches have been developed to prepare these hybrid particles, including classical heterogeneous polymerization processes using mini-emulsions, inverse emulsions or inverse micro-emulsions, as well as some multi-step synthesis procedures.[9,10]

Mini-emulsion polymerization has been used for the preparation of carboxylated magnetic polymer nanoparticles by Zheng et al.[11] and epoxy-functionalized magnetic polymer microspheres by Lee et al.[12] However, these obtained magnetic spheres cannot match the above-mentioned biomedical requirements simultaneously. Batch polymerization process is reported to be the most

widely used method to synthesize microgel materials.[13] Montagne et al.[14] have firstly reported the use of o/w magnetic emulsion droplets as the seed in emulsion polymerization. This new approach is based on the transformation of magnetic emulsion droplets into magnetic latex particles by emulsion polymerization using hydrophobic monomers such as styrene.[15] Homogeneous encapsulation of Fe_3O_4 nanoparticles can also be efficiently achieved using a styrene/1,4-divinylbenzene (DVB) monomer mixture in the presence of potassium persulfate (KPS) as initiator. The magnetic seeds used are submicron droplets of a highly stable magnetic emulsion and the particle size distribution of the magnetic polymer emulsion is controlled by the size distribution of the initial magnetic emulsion. In this article, poly(divinylbenzene-co-glycidyl methacrylate) microspheres are prepared by batch emulsion copolymerization[16] in the presence of o/w magnetic emulsion droplets as the seed. It is a facile method to synthesize responsive magnetic polymer composite nanoparticles. The difference between this work and that of Montagne *et al*. is that magnetic seeds with grain sizes of about 10 nm in diameter are used in this work while submicron magnetic seeds are applied by Montagne et al. The embedding of oleic acid modified Fe_3O_4 nanoparticles within polymeric matrices prevents the aggregation of Fe_3O_4 magnetic seeds in physiological media and the physicochemical properties of Fe_3O_4 magnetic seeds can be preserved. This method can control the particle size distribution and magnetic content of the composite particles. This study provides a route to prepare a new material, which might be useful in biomedical applications especially drug releasing coatings for medical devices. As a result, medical devices may be implanted or inserted into the body because magnetite nanoparticles have extensive biomedical applications due to their biocompatibility.[17,18]

Experiment

Materials

Divinyl benzene (DVB, 80%) and Glycidyl methacrylate (GMA, 98%) were purchased from Aldrich Chemical Co.Ltd.. The monomers were purified of inhibitors by washing with 5% NaOH solution before use. Ferric chloride ($FeCl_3 \cdot 6H_2O$, analytically pure grade), ferrous sulfate ($FeSO_4 \cdot 7H_2O$, analytically pure grade), sodium dodecyl sulfate ($C_{18}H_{29}NaO_3S$, SDS, chemically pure grade) were supplied by Sinopharm Chemical Reagent Co. Ltd., Shanghai, China. Oleic acid ($CH_3(CH_2)_7CH=CH(CH_2)_7COOH$, OA, chemically pure grade), potassium persulfate ($K_2S_2O_8$, analytically pure grade) and n-Octane (C_8H_{20}, chemically pure grade) were obtained from Shanghai Linfeng Chemical Reagent Co. Ltd., Shanghai, China. Ammonia ($NH_3 \cdot H_2O$, 25 wt % NH_3, analytically pure grade) was purchased from Nanjing Chemical Reagent Co. Ltd., Nanjing, China. All the chemical agents were used as-received without further purification.

Preparation of Fe_3O_4 ferrofluid

Fe_3O_4 NPs were prepared by chemical coprecipitation of Fe^{3+}: Fe^{2+} in the ratio of 1.5: 1 as described in previous reports.[19] The procedure preparing ferrofluids was showed as follows. Briefly, $FeCl_3 \cdot 6H_2O$ and $FeSO_4 \cdot 7H_2O$ were dissolved in distilled water with vigorously stirring to dissolve completely, and then heated to 70 ℃ under the protection of nitrogen atmosphere followed by adding ammonia to the flask. After 10 min, OA was added into the solution and continuously stirred at 70 ℃ for 1 h. Then, the solution was heated to 85 ℃ and kept at this temperature for 30 min in order to evaporate NH_3. After finishing the reaction, the solution was cooled to room temperature and washed with deionized water for several times. Finally, the products were dispersed in octane to get magnetic fluid with magnetite content of 8 wt %.

Preparation of epoxy-functionalized magnetic colloidal particles

The reactions were conducted by batch emulsion polymerization in the presence of o/w magnetic emulsion droplets as the seed, as illustrated schematically in Fig. 3. DVB (1.0 mL) and GMA (0.5 mL) were added in magnetic emulsion (50 mL) in the presence of KPS as initiator. The mixture was then carried out at 70 ℃ with stirring (300 rpm) under N_2 atmosphere for 24 h, and then terminated by cooling at room temperature. The obtained epoxy-functionalized magnetic colloidal particles were collected with a magnet and washed with distilled water for several times.

Characterization

The sizes and morphologies of the samples were investigated by transmission electron microscopy (TEM, Model Tecnai 12, Philips Co. Ltd., Holland). The particle size distributions of samples were determined by dynamic light scattering instrument (DLS, Zetasizer, Malvern, UK). The thermal stability of the dried sample was measured by thermogravimetric analysis (TGA, Model TA 2100, TA Instruments, USA) at a heating rate of 10 ℃/min in N_2 over the range of 50-700 ℃. Magnetic properties of the particles were detected at room temperature using vibrating sample magnetometer (VSM, Model 7410, Lake Shore Co. Ltd., USA).

Results and discussions

Characterization of sample

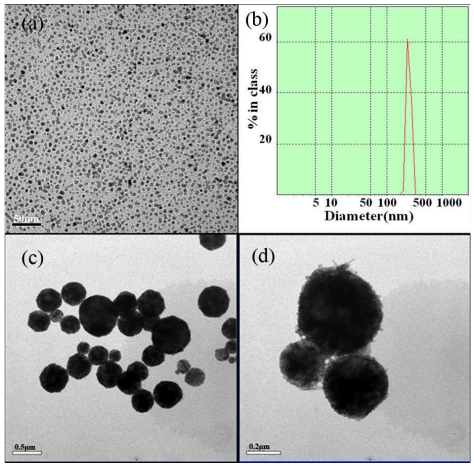

Figure 1 Transmission electron microscope images of (a) the OA modified Fe_3O_4 particles, (c, d) mPDGs and (b) dynamic light scattering graph of mPDGs.

The morphologies of the OA modified Fe_3O_4 particles and the mPDGs are investigated by TEM, as shown in Fig. 1. From Fig. 1 (a), we can see that the modified Fe_3O_4 particles can be well dispersed in octane, and the mean size of nanoparticles is about 10 nm, which is similar to our previous results.[19] In Fig. 1 (c) and (d), the TEM images present well-defined polymer microspheres with a mean diameter of about 200 nm. Fig. 1 (b) shows that the sizes of mPDGs determined by DLS are in the range of 150-350 nm, and the majority of the particles have a grain size of about 250 nm.

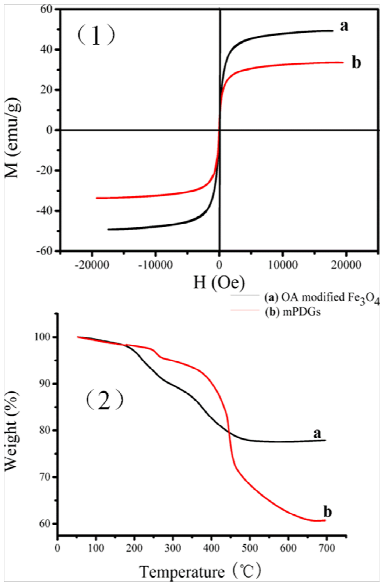

Fig. 2 VSM measurement results (1) and the TG measurement results (2) of (a) the OA modified Fe_3O_4 particles and (b) mPDGs.

Fig. 2 (1) shows the magnetic properties of the Fe_3O_4 particles before and after coating with poly(divinylbenzene-co-glycidylmethacrylate). It can be seen from Fig. 2 (1) that the saturation magnetization (M_s) value of the OA modified Fe_3O_4 particles is 48.25 emu/g while the M_s of mPDGs is 33.66 emu/g. Interestingly, ferromagnetism is preserved, demonstrating that the polymerization conditions have a little influence on the as-synthesized nanoparticles. Therefore, these magnetic materials can be easily controlled by an external magnetic field which is significant for applying to bioconjugation and biomedical fields.

The magnetic contents of the samples are evaluated by TGA. Fig. 2 (2) presents the thermal degradation curves for (a) OA-coated Fe_3O_4 nanoparticles and (b) mPDGs, respectively. As can be seen from curve a, a very moderate decrease before 150 ℃ is mainly attributed to the release of moisture entrapped by the emulsified Fe_3O_4 nanoparticles. Upon heating to 500 ℃, owing to decomposition of the organic layer, a larger loss (19.5 wt % (a) weight loss) appears, so it is concluded that OA decomposes in the range of 300-500 ℃, and this means that about 78% of the magnetite particles are coated with OA. From the curve of mPDGs, the weight of mPDGs begin to decrease rapidly at 400-700 ℃ and the residual mass percentage is 60 wt % at 700 ℃, which means a thicker polymer shell on the surfaces of the MNPs. These results demonstrate that the magnetic ferrofluids have been coated by divinylbenzene-co-glycidyl methacrylate and mPDGs can keep its structural and functional stability for further research.

Reaction procedure

The possible reaction procedure of the mPDGs by the batch emulsion polymerization method is presented in Fig. 3. The oil-soluble Fe_3O_4 ferrofluids are first dropped into lauryl sodium sulfate solution and emulsified to form Fe_3O_4 magnetic emulsion droplets as the seeds. Emulsifier molecules gather together to form emulsifier micelle when lauryl sodium sulfate is dissolved in the solvent. When KPS is added to the emulsion as water-soluble initiator, it will generate SO_4^{2-} ions in water. Some of the sulfate ions directly spread into the inner part of emulsifier micelle, inducing polymerization reaction. The others sulfate ions are captured by the double bond on the surfaces of Fe_3O_4 particles in the emulsion. They further spread into the micelle to induce polymerization between the activated double bond on the surfaces of Fe_3O_4 particles and the double bond of the hydrophobic DVB monomer in the micelle. New reactive epoxy-functionalized mPDGs are synthetized using seed emulsion polymerization of DVB and GMA monomers in the presence of Fe_3O_4 magnetic emulsion droplets as the seed. In the synthesis of reactive functional polymers, GMA contains a polymerizable double bond and a reactive epoxy group in its chemical structure, which are useful for chemical grafting of any biomolecule containing reactive functional groups.

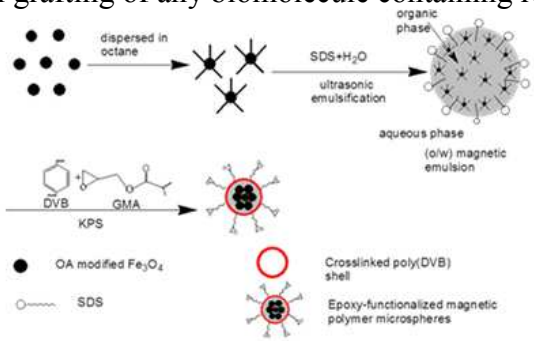

Fig. 3 Schematic illustration of the reaction mechanism of mPDGs.

Conclusion

Through the batch emulsion polymerization method, we have successfully synthesized the magnetic responsive poly(divinylbenzene-co-glycidyl methacrylate
) colloidal particles (mPDGs). The materials possess structural stability, high biocompatibility and biodegradability, and they would be a promising drug carrier. Furthermore, we have enough reasons to believe its application in the biomedical field. Further study on their biomedical application is being conducted in our team.

Keywords: Biodesulfurization, Immobilized cells, Sodium alginate, Polyvinyl alcohol.

Abstract: Immobilization of the bacterium *Agrobacterium tumefaciens UP-3*, which was isolated from soil and sewage in the Shengli Oilfield, was studied in this paper. The suitable culture condition of growth cells was determined. The effects of immobilization conditions and materials on the desulfurization performance of immobilized cells were investigated. The results showed that the immobilized cells with mixture of sodium alginate(SA) and polyvinyl alcohol(PVA) as the immobilized carrier had good biodesulfurization characteristics; The optimum operation immobilization conditions are 4° C, the concentration of SA being 3% (w), the concentration of PVA and SA being 7% (w), and the ratio of carriers (ml) and cells (g) being 20. When DBT addition is 2.7 mM, the DBT degradation rate of immbobilized cells is above 60%.

Introduction

People were forcing to develop new technology of clean fuel production. Biodesulfurization (BDS) at room temperature and atmospheric pressure could selective oxidize the sulfide due to the effect of air, water and bio-catalytic, and then remove the sulfur atom or sulfide [1]. It has advantages of low cost, mild operating conditions, no need for hydrogen and effectively desulfurization heterocyclic sulfur compounds which is difficult for hydrodesulphurization. The researcher abroad have been isolated a variety of bacteria with the ability of desulfurization [2-7]. Less research on the oil biodesulfurization has been done and the progress was quite slow. Thus there is an urgent need to strengthen the basis technical reserves for petroleum biodesulfurization.

Immobilized microorganisms has now become a research hotspot, since immobilization through regeneration and activation can significantly improve the life of biocatalytic desulfurization catalyst; maintain the original state of the enzyme; enhance the stability of the biocatalyst performance; increase the cell density and resistance to pollution; avoid the loss of cells; save the subsequent separation process of the reaction system. Highly efficient and stable biological desulfurization catalyst is the premise of the industrialization of biocatalytic desulfurization, and the immobilization of desulfurization microbe strain is one of effective ways to obtain a highly efficient and stable biological desulfurization catalyst. The research on immobilization related to the oil desulfurization microbe strain which have been reported at abroad were only Je Hwan Chang, Manabu Naito etc[4]. This article uses *Agrobacterium tumefaciens UP-3* with independent intellectual property rights of our own as the oil biodesulfurization bacterium. Its desulfurization performance and immobilized study at home and abroad have not been reported yet. In this paper, the immobilization technique of embedding was adopted to research the immobilization of *Agrobacterium tumefaciens UP-3*, and we also explored the influence of immobilization conditions and materials on the catalytic desulfurization performance of the biocatalyst.

Materials and methods

Strain

The microbe strain, identified by Chinese Academy of Sciences as *Agrobacterium tumefaciens*(named: *Agrobacterium tumefaciens UP-3*), was isolated from the oil contaminated soil and sewage of Shengli Oilfield, obtained after the process of the separation, purification, mutation, screening and rescreening.

The media

Santes medium: soybean peptone 10 g, yeast extract powder 2 g, enzymatic hydrolysis of casein, 2 g, NaCl 6g, glucose 10g, distilled water 1000ml, with NaOH adjusted to pH 7.3～7.5.

Phosphate buffer: $Na_2HPO_4 \cdot 12H_2O$ 71.36g, $NaH_2PO_4 \cdot 2H_2O$ 31.20g, deionized water 1000ml, the PH 7.5.

Basic salt solution: Na_2HPO_4 4 g, $(NH4)_2SO_4$ 2 g, $MgSO_4.7H_2O$ 0.2 g and $CaCl_2$ 0.001 g, $FeSO_4.7H_2O$ 0.001 g, distilled water 1000 ml, pH 7.0.

The other main material

Sodium alginate, polyvinyl alcohol, agar, calcium chloride, boric acid, dibenzothiophene (DBT), diatomaceous earth, activated carbon.

Strain cultivation and collection

Cultured in shaking table with a speed of 200r/min. At the temperature of 31° C, with 250 mL flask, 50 mL medium, cultured for 24 hours, then centrifuge, centrifuge operating conditions: -4 ° C, 10000r/min.

Immobilization method

When adsorption immobilized method was used, add sterilized carrier to the medium which have been cultivate for 24 hours, adsorb 15 to 18 hours, then remove, wash for standby; while for embedding immobilized method, put collected bacterium washed several times with phosphate buffer. After centrifugation, add to the dissolved immobilized carrier glue, then using a syringe drip the 4 ° C gel solution into ball under stirring condition, cross linking and precipitate 24 hours, make the strength of the immobilized ball stable, and then wash it three times with distilled water for further use.

Desulfurization test

Oil biodesulfurization technology developed earlier at abroad, and many studies used dibenzo thiophene as model compounds [4-7], Mainly because it is relatively difficult to remove the sulfur compounds of thiophene compounds (especially dibenzo thiophene and its derivatives) in the existing oil products. Similarly, we also used DBT as a model compound to conduct biological desulphurization experiment. The specific methods were as follows: adding the growth cells or immobilized cells to sterile reaction model system containing DBT concentration of 2.7 mM, putting into the constant temperature shaking table for reaction.

Determination of desulfurization effect

By using 0.8 volume of extract liquid, the remaining DBT in the culture medium after reaction was extracted. After full concussion, take 1μl of the top extraction phase into the chromatographic for the determination of residual content of DBT which could be used to calculate the effect of desulfurization. Chromatographic conditions were as follows: WCOT FUSED SILICA 30m × 0.25mm capillary column, FID detector, the initial temperature of column box : 80° C, heated up to 300° C at the speed of 20°C / min, inlet temperature 320° C, flame ionization detector temperature 325 ° C, gas flow tail-blowing 25ml/min, H_2 30 ml/min, air 300 ml/min.

Results and discussion

Desulfurization performance of growth cells

The growth of microorganisms was not only affected by the medium, but also greatly influenced by temperature, pH, pressure, ventilation status and other factors of growth environment. In the previous

study we have identified the optimum culture conditions of UP-3 as follows: atmospheric pressure, 31 °C, pH value of 7.3 to 7.5, aerobic conditions.

Resting cells refer to cells that basically stopped growing in the culture medium and with a poor nutritional status. In order to check whether UP-3 strains of resting cells could degrade DBT or not, the cells were suspended in phosphate buffer with no nutrients. The experimental results of degradation of DBT showed that the UP-3 cells in poor nutritional status had a quite limited capacity of degradation. When the DBT concentration was 2.7mM, the best degradation effect is only about 13%.

Influent of the immobilization materials on desulfurization performance

The common immobilization methods includes adsorption, embedding and cross-linking, of which cross-linking has a large impact on the activity of the microorganisms and relatively harsh operating conditions [8], thus this paper initially chose adsorption and embedding. Among them, the immobilized material is an important factor affecting the immobilized effect, and the principle of selection of the immobilized material is low cost, easy operation, high activity of immobilized microorganisms, long life and so on. We used three kinds of adsorption carrier and two embedding vectors, and the results were shown in Table 1. It can be seen that adsorption immobilization effect of the UP-3 were generally lower than the embedding method, and the adsorption effect of silica gel got the best which was still much lower than the immobilized effect of the embedding; while among the embedding method due to slower rate of cross-linking and difficult operation of PVA we improved its operability through the addition of SA and meanwhile its mechanical strength has been greatly improved as well as the drop of desulfurization activity was not very clear compared with SA immobilized ball. Then we mainly studied the immobilized cells which was based SA and PVA as the immobilized carrier.

TABLE 1 PERFORMANCE COMPARE OF IMMOBILIZATION CARRIERS

Item	Adsorption			Encapsulation	
	Active carbon	Kieselguhr	Silica gel	SA	PVA and SA
Mobilization degree	Middle	Bad	Middle	Good	Excellent
Activity	13.76	16.38	34.96	67.70	66.13
Longevity	400	400	400	600	650

Influent of the immobilization conditions on desulfurization performance. The preparation conditions include pH value, temperature, concentrations of carriers and precipitators, etc. According to the previously mentioned investigations of the cells performance, the optimum pH value of UP-3 cells is 7.3-7.5. So the preparation of immobilized cells is also operated under that pH value. In table 2, the influence of temperature on desulfurization of immobilized cells is showed. The relatively ideal temperature for the immobilization preparation is at 4 ° C when the immobilized cells perform the highest activity and the best degradation ability. It is found that the metabolism of microorganisms is slower at 4° C and the influence of preparation conditions on the performance of microorganisms is smaller, causing less activity loss.

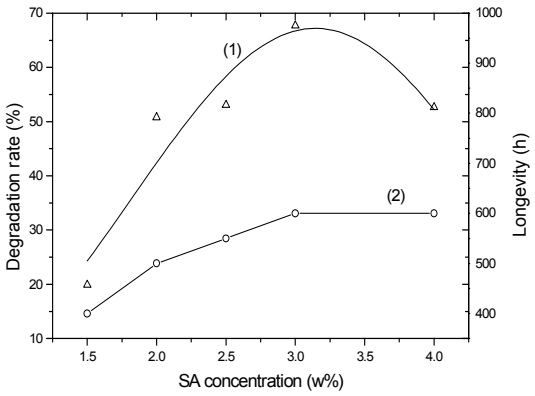

TABLE 2 INFLUENCE OF TEMPERATURE ON DESULFURIZATION OF IMMOBILIZED CELLS

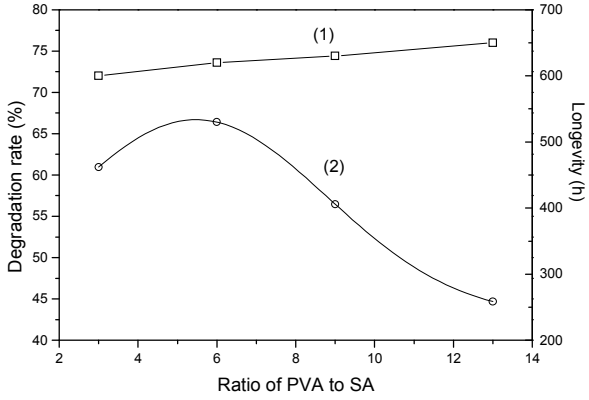
Immobilization temperature (° C)	4	15	25
First degradation rate (%)	53.10	29.46	28.40
Second degradation rate (%)	45.98	16.35	19.86

The SA aqueous solution which is a polyelectrolyte with higher charge density could experience gel transformation due to the divalent cations. PVA could also experience cross-linking reaction in the saturated boron solutions. In this paper, the higher concentration of embedding carriers results in

the greater viscosity bringing inconvenience to granulation and producing irregular balls. In addition the compact structure of immobilized balls could lead to the slow diffusion. On the other hand, the lower concentration of embedding carriers results in the lower viscosity and porous structure promoting diffusion. But during the granulation process agglomerate is likely to take place, which causes the lower strength, the easier loss of cells and the decrease of desulphurization performance. So it's necessary to select the proper concentration in order to facilitate the immobilization process and keep the better mechanical strength.

Figure 1 shows the influence of sodium alginate concentration on immobilization. It is observed that when the concentration of SA is 3wt%, the degradation ability of immobilized cells achieves the best and the longevity almost reaches the maximum. It is found that with the lower concentration of SA, the structure of granulation is looser and the pore size is larger, which reduces the fixation strength of microorganisms as well as the UP-3 cells and makes degradation affected by biochemical reaction. In addition, as the concentration of SA increases, the performance of fixation and desulphurization is gradually improved. Especially beyond a critical concentration of SA, the amount of embedded microorganisms is invariable and the degradation performance is controlled by diffusion. With the higher concentration of SA, the structure of granulation becomes much compacter while the desulphurization performance is reduced.



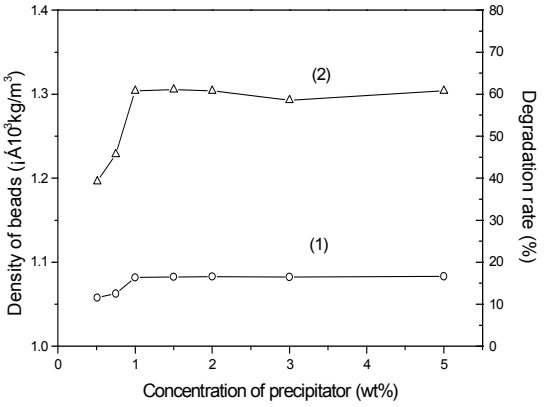


Fig 1. Influence of SA concentration on immobilization Fig 2. Influence of ratio of PVA to SA on immobilization

Figure 2 shows the influence of ratio of PVA to SA on immobilization. The total concentration of PVA and SA is 7wt%. Form figure 2, as the ratio of PVA to SA increases, the degradation rate of immobilized cells rises and then declines while the longevity keeps growing. It is found through analysis that with the lower concentration of PVA and SA, the higher SA content affects the performance of cross-linking and immobilization. Then the decrease of the concentration of SA prevents the agglomeration of PVA, reduces the influence on immobilization, and promotes granulation as well as the embedding performance of UP-3 with PVA. But when the SA concentration further reduces with PVA concentration rising, the inner structure of immobilized balls becomes much compacter, affecting the diffusion of substrates and reaction products, reducing the activity of embedded cells and the degradation performance of immobilized cells. As it is showed in figure 2, the proper concentration ratio of PVA to SA is 6.

In this part the density variation of immobilized balls and the desulphurization performance of immobilized cells are studied. Figure 3 shows the influence of precipitator on immobilization. It is observed that when the concentration of precipitator is beyond 1wt%, the concentration variation has little effect on the density of immobilized balls and the desulphurization performance of immobilized cells. It is considered through analysis that the selected carriers could be immobilized by cation exchange. So according to the stoichiometric calculations, the mass ratio of precipitator cation to carrier cation should be 1:3.92. When the carrier concentration is 3wt%, accordingly the stoichiometric concentration of precipitators is 0.77wt%. Because of the influence of inner diffusion of immobilized balls on cation exchange and the lower water content of alginate during the

granulation process, the practical concentration of carrier increases in a certain extent. As a result, even though the precipitator concentration is above 1wt%，the precipitator almost has little impact on the immobilization performance.

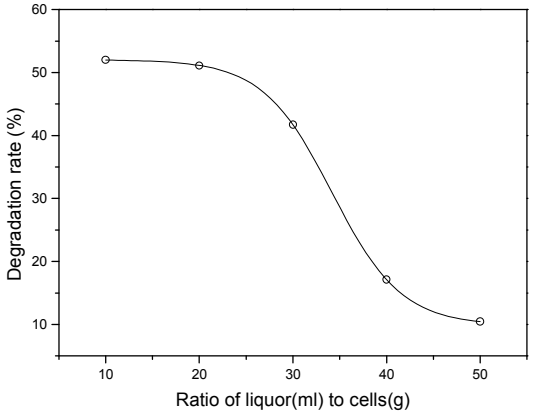

Fig.3 Influence of precipitator on immobilization Fig.4 Relationship of DBT degradation with ratio of SA and PVA

The concentration of embedded cells is another key factor to influence the desulphurization performance of the immobilized cells. Figure 4 indicates the relationship of DBT degradation with ratio of sodium alginate (ml) to cells (g). The degradation rate reduces with the increase of that ration. When the ratio is below 20, the degradation rate increases slowly with the ratio reduces. Considering the optimum usage amount and the activity of immobilized cells, the ratio of sodium alginate to cells is selected 20.

Influent immobilization conditions and materials on degradation time.

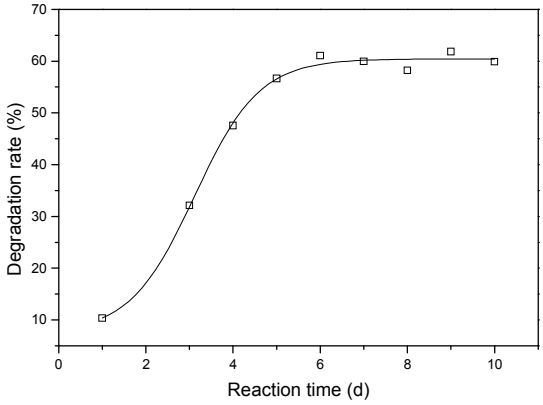

Fig.5 Relationship of DBT degradation with degradation time

The desulphurization performance obviously decreased and the desulphurization rate also slowed after UP1 cells were immobilized. Figure 5 indicates the relationship of DBT degradation of immobilized UP1 cells with degradation time. As shown, the degradation rate rises significantly when the reaction time is below 6h. And then the rate varies slightly. Those results are caused by feedback inhibition and diffusion effect during the reaction process of microorganisms. At the beginning of reactions, because of the higher activity of enzyme systems and the higher concentration of the substrates, the effect of feedback inhibition is smaller and the reaction rate is faster, which enlarges the concentration difference of products between inside and outside of colloidal particle and the diffusion driving force, leading to the easier diffusion of products into the water phase outside the colloidal particle and the faster degradation rate. With the reaction carried through, the concentration of substrates decreases while the concentration of products increases compared to that of substrates. Then the effect of feedback inhibition is enforced and reaction rate falls down, which leads to the slow

rise of degradation rate. When the concentration of products and/or substrates in water phase is equal or close to that inside the colloidal particle, the diffusion driving force is approximates zero. So products don't diffuse into the water phase and substrates in water phase also don't enter the colloidal particle. That is the end of reaction which indicates the maximum of degradation rate.

Conclusions

The immobilized research on oil biodesulfurization bacteria—*Agrobacterium tumefaciens* UP-3 have not been reported yet at home or abroad. In this article, the mixture of SA and PVA was selected, the SA and PVA as the immobilization carrier, and optimized the immobilization conditions of UP-3 so as to prepared immobilized UP-3 which had a great desulfurization performance. When the DBT concentration reaching 2.7 mM, the degradation rate reached more than 60 percent of DBT; and the optimum degradation time of the immobilized UP-3 cells was 6 d. Excellent desulfurization capacity was shown by the immobilized UP-3 cells as well as mild using conditions with a broad prospects for industrial applications.

Keywords: PLGA microspheres, in vitro release, different drugs, degradation

Abstract In this study, four model drugs, i.e., Meloxicam (MEL), Risperidone (RIS), Eprinomectin (EPR), and Bull Serum Albumin (BSA), were encapsulated in PLGA microspheres *via* solvent evaporation methods. The encapsulation efficiency and *in vitro* release profiles of different drugs with various water solubilities from medicated PLGA microspheres were investigated. The surface morphologies of microspheres were detected by scanning electron microscope (SEM). The release characteristics of the model drugs from the medicated microspheres were carried out in the phosphate buffer solution (PBS), pH7.4, at 37 °C. Studies found that the water solubility of model drugs had significant influences on their *in vitro* release profiles and the release rates of four model drugs were in the orders of BSA＞MEL＞RIS＞EPR.

Introduction

For the past few years, PLGA microspheres were widely used as the carriers of sustained and targeted drug delivery systems due to its excellent biocompatibility and biodegradation [1]. At present, eight kinds of microsphere formulations had been on market [2]. Recently, the studies of medicated PLGA microspheres were mainly concentrated on the influences of the drug-loading, encapsulation efficiency and *in vitro* release profiles under different conditions. For example, Ito and Wang improve the encapsulation efficiency of hydrophilic drugs by putting some additives into the internal water phase [3, 4]. Aamir discussed the *in vitro* release dynamics of tramadol hydrochloride-loaded microspheres [5]. However, in present literatures, people were mainly focus on the research of the *in vitro* release about a single drug from microspheres, but fewer researches take the solubility of model drugs into consideration in drug release. Fewer people make a comparative study on the release profiles of different drugs with various water solubilities. Therefore, it is meaningful to study the *in vitro* release profiles from different drug-loaded microspheres.

In this study, BSA, MEL, RIS and EPR were chosen as the model drugs and encapsulated into PLGA microspheres by solvent evaporation methods. The morphologies were observed by scanning electron microscope (SEM). The drug-loading and different release profiles of various model drugs were revealed. All experimental data might have the significance of theoretical and practical applications.

Experimental

Materials

Poly (D, L-lactide-co-glycolide) (PLGA, lactide/glycolide ratio 50:50) was obtained from Lakeshore Biomaterials. Poly (vinyl alcohol) (PVA17-99, 88% hydrolyzed) was the product of Tianjin Institute of Chemical Reagents (Tianjin, China). MEL and RIS were received from Jiangsu Nhwa Pharmaceutical Corporation Limited. EPR was purchased from Hebei Veyong Bio-Chemical

Co. Ltd. BSA (fraction V) was supplied by Shanghai Institute of Lianshuo biological science and technology. Some important information of model drugs was summarized in Table 1.

Preparation of microspheres

Model drug-loaded PLGA microspheres were prepared through solvent evaporation technology. Approximately 25 mg of model drugs (MLX, RIS, EPR) were dissolved into 10 mL of PLGA/dichloromethane solution (10 mg/ mL) to obtain a homogeneous solution. Then, 500 mL PVA/water solution (1.0 %, w/v) was added into above solution *via* an LSP01-1A micro-injection pump (Baoding Longer Precision Pump Co Ltd, China) at the speed of 0.5 mL/min. After stirring at 1200 rpm for 20 min, the stirring rate was reduced to 400 rpm for another 5 h to evaporate methylene dichloride. Subsequently, the resultant microspheres were washed three times using deionized water. The medicated microspheres were freeze-dried for 24h under the condition of vacuum, -40°C, using a LGJ-10 vacuum freeze drier (Beijing Songyuan Huaxing Science and Technology Corporation, China) for further study.

BSA-loaded PLGA microspheres were usually prepared through a double emulsion solvent evaporation method. 25 mg of BSA was dissolved into 1.0 mL deionized water using as internal water phase. Then, above solution was dispersed into 10 mL PLGA/methylene dichloride solution (10 mg/mL) and mixed with a vortex mixer (QL-861, Haimen Qi Lin Beier Instrument Manufacturing Co. Ltd, China) to obtain a homogeneous W/O emulsion. Subsequently, the formed emulsion was added into 500 mL PVA/water solution (1.0 %, w/v) using an LSP01-1A micro-injection pump at a rate of 0.5 mL/min. The following steps were carried out as the forward descriptions. All the obtained dry-microspheres were stored at -20 °C for further usage.

TABLE 1: THE PHYSICOCHEMICAL PROPERTIES OF FOUR MODEL DRUGS

Materials	Molecular mass(D)	Melting temperature (°C)	Water solubility (mg/mL)	pKa
MLX	351.40	260.00	8.10	4.50± 1.00
RIS	410.50	170.00	0.16	8.10 ± 0.10
EPR	914.10	161.00~166.00	0.02	12.40 ± 0.70
BSA	66400.00	—	≥40.00	—

Morphology of microspheres

The morphologies of the lyophilized drug-loaded microspheres were observed by an S-4800 SEM (Hitachi, Japan) after coating the dried samples with gold films under vacuum.

Drug-loading and encapsulation efficiency

For the three hydrophobic drugs, approximately 10 mg of medicated microspheres were dissolved into 2 mL dichloromethane, and then diluted with alcohol to 50 mL. The amount of drugs entrapped into microspheres were analyzed by 2400 PC UV spectroscopy (Shanghai Shunheng Corporation, China) [6-8], while the drug loading of BSA microspheres were determined by an extraction method [9]. 10 mg of medicated microspheres were dissolved into 1 mL dichloromethane for 10min and then 1.5 mL PBS was added. The mixture was vigorously shaken for 1 min in order to extract BSA into PBS from the organic solution. After centrifuging, the PBS solution was withdrawn and the BSA was extracted again. The BSA content of the solution was analyzed using BCA kit [10]. The drug loading and encapsulation efficiency was calculated as the following Eq.1, Eq.2 [11], where m_d is the weight of drug entrapped, m_s is the weight of microspheres used, E_a represents the actual drug-loading and E_t is the theoretical drug-loading. The results were reported as the mean ± SD.

$$\text{Drug-loading}(\%) = (m_d/m_s) \times 100\% \quad (1)$$

$$\text{Encapsulation Efficiency}(\%) = (E_a/E_t)\times 100\% \quad (2)$$

In vitro release profiles

Four different forms of lyophilized drug-loaded microspheres were individually placed in test tubes and suspended in 4 mL of PBS (pH 7.4) containing 0.02 % sodium azide. Samples were

incubated at 37 °C on a ZHWY-100H oscillator (ZHICHENG analytical instrument manufacturing, China) at the shaken speed of 100 rpm. At appropriate time intervals, the samples were collected and centrifuged for 10 min at 4000 r/m. 3 mL of PBS was removed and replaced with equivalent fresh medium. The concentrations of model drugs in the PBS was analyzed by 2400 PC UV spectroscopy (Shanghai Shunheng Corporation, China). All the drug release tests were carried out in triplicate and the results were presented as average.

Results and Discussion

Morphological characterization of microspheres

The representative SEM images of four kind of medicated microspheres were shown in Fig. 1 (a-d). It was clearly seen that the obtained microspheres were smooth, rounded and mono-dispersed spheres with the particle size distribution of 60-140 μm. However, the striking distinctions were observed on their surface. Some micro-pores were markedly observed on the surface of BSA/PLGA microspheres in Fig. 1 (d), while others were not found on the surfaces clearly.

The encapsulation efficiency of microspheres

The encapsulation efficiency were calculated and shown in Fig. 2. It could be seen that the encapsulation efficiencies were followed the orders of EPR > RIS > MLX >BSA. The reason mainly came from their natural characters [12]. Table 1 showed that the water partition coefficient (log P) of MLX, RIS and EPR was 2.66±0.85, 2.68±0.41 and 5.95±0.86, respectively. Some researches revealed that the substance was amphipathic when its log P was between -0.30 and 4.50. It was hydrophobic if its log P > 4.50 [13]. Therefore, MLX and RIS were the amphipathic molecules, and EPR was lipotropic. Accordingly, EPR could easily dissolve in the organic phase on the basis of the similarity-intermiscibility theory. It was hard to transfer into the water phase during the preparation. However, amphiphilic MLX and RIS could dissolve into water phase more or less, which led to a lower drug-loading. The BSA exhibited the lowest encapsulation, which was only 50.60±6.01%. The possible reason might be due to the strongest water solubility of BSA, which made serious drug-leakage during the preparation of BSA-loaded microspheres.

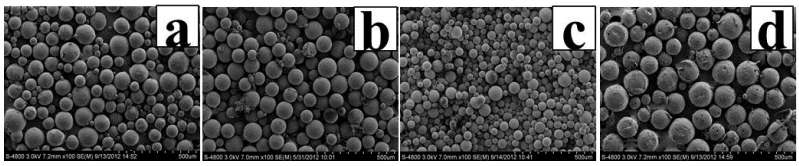

Fig. 1: SEM photographs of four types of microspheres: (a) MEL, (b) RIS, (c) EPR, and (d) BSA.

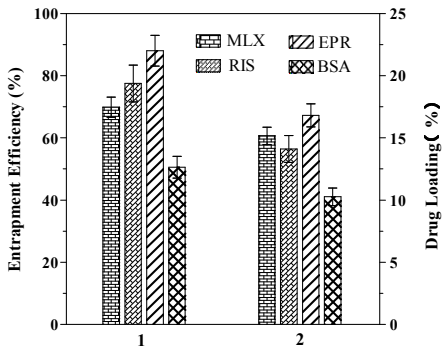

Fig. 2: Drug loading and encapsulation efficiency of four model drug-loaded PLGA microspheres, 1 was the encapsulations of four types of microspheres, 2 was the drug-loading of four model drug-loaded microspheres.

The in vitro release and degradation of microspheres

The cumulative release profiles of the four drugs were shown in Fig. 3. At 24 h, the cumulative release percent of drugs were 9.07±5.18% (MLX), 4.67±1.15% (RIS), 2.73±4.18% (EPR), and 53.03±5.10% (BSA), respectively. It was clear that BSA showed the fastest release rate. After 12 d, the cumulative release amount of BSA reached to 96.14±2.55%. MLX-loaded microspheres reached the equilibrium state of release at the 18 d with the cumulative release percent of 94.51±2.67%. In

contrast, the release of RIS and EPR were relatively slow, and the released amount of both drugs was 86.69±4.56% and 75.32±3.64%. The release rates followed the orders of BSA > MLX > RIS > EPR. The degradation of different medicated microspheres was distinguishing and it could be clearly seen that the MLX-loaded microspheres exhibited a fast erosion process in Fig. $4a_{1\text{-}3}$. In the 21st day, cracks were appeared on the microspheres, and these microspheres lost their spherical shapes in the 28th day. The degradation rate of RIS-loaded microspheres (Fig. $4b_{1\text{-}3}$) was similar to that of MLX. However, EPR (Fig $4c_{1\text{-}3}$) almost maintained its sphere without collapsing at the 28th day, and only some surface corrosion and irregularity were observed. Compared with other microspheres, the BSA-loaded microspheres exhibited the fastest degradation process. Fig. $4d_{1\text{-}3}$ showed that big and dense channels were shown on the surface of spheres in the 15th day, and it was broken into fragments in the 21st day. The differences among these release profiles might be attributed to the different physicochemical properties of drugs and the structures of medicated microspheres. The percent release of drugs from polymers, at a fixed time point, depended on the drug solubility in water, It seemed reasonable that hydrophilic drugs with high solubility might increase the rate of water diffusion into the matrix, thereby accelerating release and bulk erosion, while highly hydrophobic drugs with low solubility would inhibit water diffusion into the matrix, thereby slowing the release rate [12].

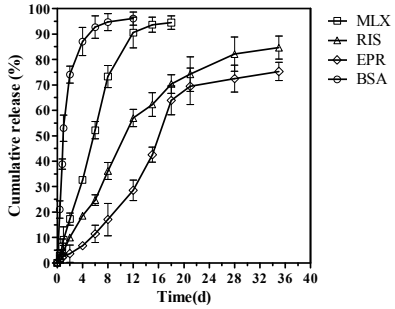

Fig. 3: Cumulative release profiles of model drugs, (a) MEL, (b) RIS, (c) EPR, and (d) BSA-loaded PLGA microspheres during 0-35 d.

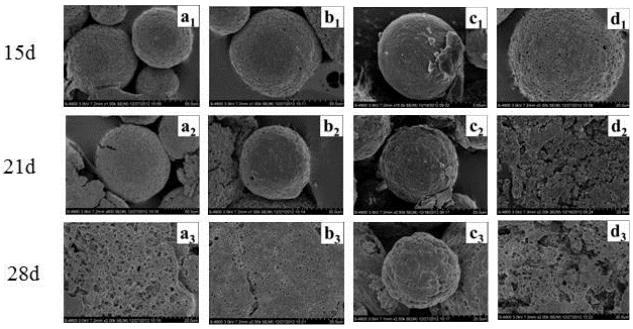

Fig. 4: Representative SEM images of the degradation of medicated microspheres on the day of 15, 21, and 28, respectively. a) was MEL-loaded microspheres, b) RIS-loaded microspheres, c) EPR-loaded microspheres and d) was BSA-loaded microspheres

Conclusions

In this study, four kinds of drug-loaded PLGA microspheres were fabricated by solvent evaporation technique. The resultant microspheres were smooth and spherical and the encapsulation efficiencies of four drugs were following the orders of BSA ＜ MLX ＜ RIS ＜EPR medicated microspheres. In addition, the release profiles of four kinds of drugs-loaded PLGA microspheres showed that the drug release rate of microspheres was BSA ＞ MLX ＞ RIS ＞ EPR. We found that the release rate were vary as the different drugs, the water solubility of drugs played an important role in drug release and the degradation of microspheres matrix. Therefore, overall drugs release profiles from medicated microspheres must take the properties of drugs into consideration.

Keywords: hydrogel microspheres, pH-sensitive, swelling behaviour, BSA.

Abstract. To accelerate the response rate of smart hydrogels to the environmental conditions, a novel pH-sensitive hydrogel microsphere with the controlled shapes and sizes were developed. Such monodispersed microspheres were synthesized *via* free radical polymerization under the protection of a multilayer stability system. The pH-responsibility of hydrogel microspheres was tested with the hydrogel bulk as a control. *In vitro* release studies were conducted in the simulated gastric fluid and intestinal juice with bovine serum albumin (BSA) as a model drug. The large specific surface areas endowed hydrogel microspheres a faster pH-responsibility than that of bulk ones. Therefore, such microspheres showed potential applications as the oral protein drugs carrier.

Introduction

The pH-sensitive hydrogel is a kind of crosslinked polymer with three-dimensional network structure, which can shrink or swell with the changing of environmental conditions [1]. As a common pH-responsible hydrogel, acrylic-based hydrogels have aroused widely attention in recent years due to their excellent pH-sensitivity, specific shape and mechanical strength [2-4]. In acid conditions (*i.e.* stomach juice), acrylic-based hydrogel shrinks and blocks model drug to leak out. On the contrary, they will swell in alkaline solutions (*i.e.* small intestine fluid) and release drug quickly. Therefore, it can be used to fixed-point release drug in intestinal tract and avoid the protein drugs to be destroyed by pepsase [5, 6]. Mariko Morishita *et al.* fabricated a pH-responsive poly (methacrylic acid) hydrogel. In the *in vivo* trial, a significant glucose reduction is observed for oral insulin delivery [7].

The previously research reveals that it takes over 10 h to reach the release equilibrium for a drug-loaded hydrogel bulks [8]. It is just meet the time of drug transfer in the small intestine, which may cause the drug released from hydrogel incompletely and influence the drug efficacy. The hydrogel microspheres have some discrepancies of small radius and large specific surface areas compared with hydrogel bulks, which guarantees them larger contact areas with release medium and a rapid drug release profile. Morishita et al. crush and sieve the hydrogel bulks into powders with diameters of < 53 μm and 212-300 μm. Results show that the smaller sized microparticles induce larger hypoglycaemic effects and the maximal hypoglycaemic effects are achieved at 4 h [7]. Now hydrogel microparticles of small size are almost obtained after processing the hydrogel bulks. It may lead to the destruction of the internal network of hydrogels.

In this study, a batch of hydrogel microspheres was developed *via* a heat-initiated suspension polymerization. The molar ratio of methacrylic acid (MAA) and Poly (ethylene glycol) methyl ether methacrylate (PEGMA475) was an important influence factor in the fabrication of monodisperse hydrogels microspheres [9]. To overcome the aggregation of hydrogel microspheres in the polymerization process, a multilayer stability system was constructed. The swelling characteristics

of hydrogel microspheres and the drug release profiles from medicated hydrogel microspheres were also evaluated.

Experimental

Materials

Before usage, MAA was purified *via* vacuum distillation to remove the polymerization inhibitor. Poly(vinyl alcohol) (PVA 1799) with an alcoholysis degree of 99% and an average polymerization degree of 1750 ± 50. PEGMA475, Triethylene glycol dimethacrylate (TRGDMA) and BSA were purchased from Sigma-Aldrich (USA). All the chemical agents were AR.

Preparation of pH-sensitive hydrogel microspheres

7.2 g PVA aqueous solution (2 wt%) and 0.05 g Tween 80 were added into a 25 mL three-necked flask equipped with a thermometer, a reflux condenser and magnetic stirring. Fixing the monomers at 3wt% (based on the total mass of reaction system), the compositions of different hydrogels were weighed according to Table 1. After adjusting the pH of above solution to 7.0, the mixed solutions were added dropwise and reacted 30 min under the temperature of 82 ± 0.5 °C. When the reaction system became turbid, uniform particle size and monodisperse hydrogel microspheres were obtained. The resulting products were centrifugal washed with the deionized water for five days. Consequently, the p(PEGMA-g-MAA) hydrogel microspheres were fabricated and preserved for the further studies.

TABLE 1: COMPOSITION OF PREPARED HYDROGEL MICROSPHERES

Sample code	Molar ratio (MAA:EG) [a]	AIBN(mg)	TEGDMA(mol%) [b]
PM1	3:1	7.5	1.50
PM2	2:1	7.5	1.50
PM3	1:1	7.5	1.50
PM4	1:2	7.5	1.50
PM5	1:3	7.5	1.50
PMT	1:2	7.5	1.25

FTIR studies

The FTIR spectra of hydrogels and raw materials were determined by a Spectrum 100 Fourier transform infrared spectrometer (PerkinElmer, China). The freeze-dried samples were tested directly after grinding and tabletting with KBr powder.

Morphology observation

The morphologies of hydrogel microspheres were observed *via* a B1 electron microscope (Motic, China). An S-4800-I SEM (HITACHI, Japan) was used to observe the morphology lyophilized hydrogel microspheres.

Swelling studies

Five copies of hydrogel microspheres (PM1, PM2, PM3, PM4 and PM5) were used to study their swelling behaviors. PBS with the pH values of 1.2 and 7.4 were used to simulate gastric fluid and small intestine fluid, respectively. The specific process was carried out following the previous study.

A certain amount of lyophilized hydrogel microspheres (PMT) was immersed into PBS (pH 7.4) for 34 h. Then, they were transferred into the PBS (pH 1.2). This swelling procedure was repeated twice. The swelling ratios were determined after sampling at certain points of time during whole process [8].

Drug incorporation

The lyophilized hydrogel microspheres (PMT) were immersed into the BSA solutions (2 mg/mL). After 24 h, they were freeze-dried, and then immersed into 30 mL PBS (pH 7.4) for 24 h. The BSA concentrations were determined by the BCA protein assay through 2400 PC UV spectroscopy (Shanghai Shunheng Corporation, China). The incorporation of BSA was calculated according to Eq. 1:

Incorporation of BSA (mg/g, w/w) $=M_i/W_{hm} \times 100\%$ (1)

Where: M_i was the amount of BSA incorporated into hydrogel microspheres,
W_{hm} was the weight of lyophilized hydrogel microspheres.

In vitro drug release

To investigate the *in vitro* release properties of hydrogel microspheres, pH1.2 (simulated gastric juice) PBS and pH 7.4 (simulated intestinal fluid) PBS were chosen for the release test. The specific process was carried out following the previous study [8].

Results and discussion

Preparation of pH-sensitive hydrogel microspheres

The hydrogel microspheres were prepared by the heat-initiated radical polymerization. The hydrogen bonds would result in the aggregation of final microspheres. To solve this problem, a multi-layers protection system of Tween-80, PVA and $-COO^-$ were constructed. Tween-80 would be adsorbed on the surface of particles, which isolated particles from agglomeration with each other. PVA could increase the viscosity of the continuous phase. The steric hindrance formed from PVA would inhibit hydrogel microspheres from gathering. Importantly, –COOH groups were ionized into $–COO^-$ by controlling the pH above 7.0. The electrostatic repulsions among electriferous microspheres would inhibit them from aggregation.

The distribution states of different hydrogel microspheres with various monomer ratios were depicted. With the molar ratios of MAA/EG changing from 3:1 to 1:3, the hydrogel microspheres gradually transited from much pieces to complete spheres, and their diameters were in the range of 20-100 μm. The obtained hydrogel was fragmented when the molar ratio of MAA/EG was 3:1. Because of MAA was a hard monomer, and higher MAA content in reaction systems made the resulting hydrogel microspheres fragile [10]. When MAA/EG was changed to 1:2 or 1:3, the hydrogel microspheres became relatively uniform spherical particles. Higher content of EG in the molecular chains made the hydrogel microspheres more flexible.

In FTIR spectra (Fig. 1), the absorption bands observed at 1680-1600 cm^{-1} in PEGMA and MAA were attributed to the stretching of C=C groups, which were disappeared in the spectrum of the hydrogel microspheres, Fig. 1(c). The sharp peaks observed at about 1700 cm^{-1} in monomers were representing the stretching vibration of –C=O groups. For the distribution of ether linkage in PEGMA, spectrum (b) exhibited the stretching vibration bands of C-O at about ~1113.1 cm^{-1}. These peaks were also observed in the spectrum of hydrogel microspheres. Accordingly, these data suggested that the hydrogel microspheres was successful prepared.

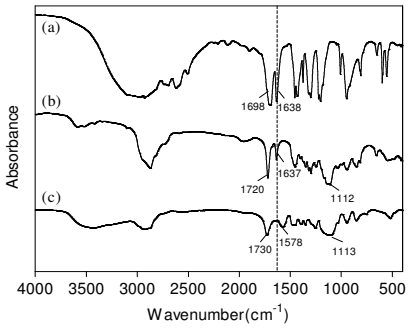

Fig. 1: FTIR spectra of (a) PEGMA, (b) MAA and (c) hydrogel microspheres.

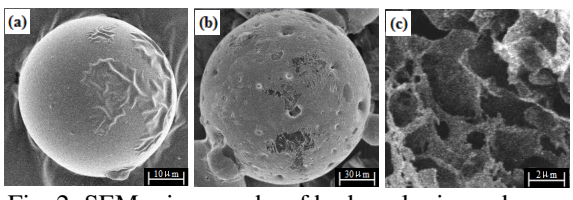

Fig. 2: SEM micrographs of hydrogel microspheres.

The SEM detection was carried out and shown in Figure. 2. As to the hydrogel microsphere (Fig. 2 (a)), its particle size was about 50 μm and the surface was slightly wrinkled. However, the size of

hydrogel microsphere was increased to 100 μm after swelling in PBS (pH 7.4). After lyophilizing, the swollen hydrogel microspheres showed some pores on its surface (Fig. 2 (b)), which might be due to the fast lose of moisture during the lyophilization. The internal structures of hydrogel microspheres were three dimensional networks, Fig. 2 (c) [8].

Swelling behaviour

PBS with pH values of 1.2 and 7.4 were used to mimic gastric juice and small intestinal juice, respectively. Five kinds of hydrogel microspheres showed above 3 times swelling ratios in pH 7.4 than those in pH 1.2, Fig. 3. A *t*-test showed that the differences between the swelling ratios in pH 1.2 and pH 7.4 were significant ($p < 0.05$) (the portion with dashed line).

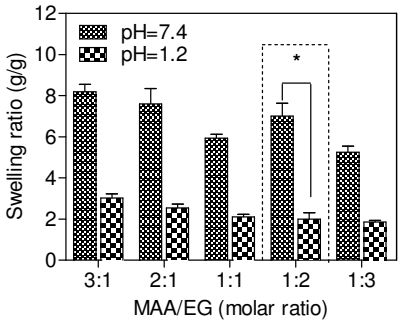

Fig. 3: Swelling ratios of hydrogel microspheres prepared with five monomers ratios in PBS with the pH values of 1.2 and 7.4.

The swelling hydrogel microspheres were shrank in the acidic buffer solutions. After swelling in alkaline buffer solution again, the swelling ratio was still high. It performed good swelling reversibility. The comparison of the swelling reversibility between hydrogel microspheres (PMT) and hydrogel bulks (TMP475) was carried out [8]. In PBS (pH 7.4), the swelling ratio of the hydrogel microspheres was about 11 times of lyophilized microspheres, and the equilibrium swelling time was only 6 h. Whereas, the swelling ratio of hydrogel bulks might increase to 35 folds of the original hydrogels with the equilibrium swelling time of 24 h. Though the swelling ratio of hydrogel microspheres was low, the equilibrium swelling was quick, Fig. 4. The hydrogel microspheres had lager special surface areas than hydrogel bulks, and the particles responded quickly to the environment stimuli. Therefore, the hydrogel microspheres with a high response rate might be useful for the quickly releasing of macromolecular hydrophilic drugs into the intestine by the oral administration.

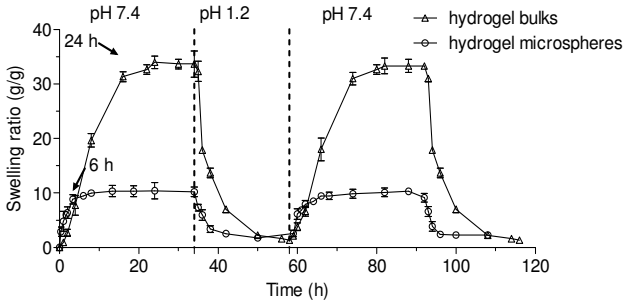

Fig. 4: Equilibrium swelling and reversibility studies of hydrogel microsphere and hydrogel bulks.

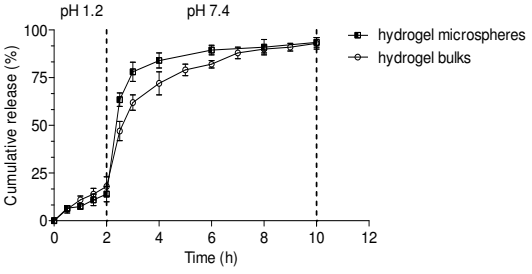

Fig. 5: The cumulate BSA released from medicated hydrogel microsphere and hydrogel bulks.

In vitro release

The BSA loading efficiency of hydrogel microspheres was 87.7 % and the hydrogel bulks' was 71.4 %. Though the hydrogel microspheres had a low swelling ratio, the BSA loading efficiency was higher than those of hydrogel bulks. *In vitro* release, less than 20 % BSA were released from the medicated hydrogels under acidic conditions (pH 1.2) at the first 2 hours, Fig. 5. In the alkaline conditions (pH 7.4), the cumulative release of BSA was reached above 75 % in 3h. Consequently, the release rate gradually slowed down and reached to the equilibrium state at 6 h. The maximum cumulative release of BSA was above 90%. Whereas, the cumulative release of BSA of hydrogel bulks was 65% in 3h. Compared with hydrogel bulks, the medicated hydrogel microspheres released smaller amount of BSA under acidic conditions, but BSA released more quickly under alkaline condition. These results indicated that hydrogel microspheres had the compact internal structure and could prevent drug leakage under acidic conditions. The characteristic of them might have potential advantages to the oral delivery of protein drugs.

Conclusions

A pH-sensitive hydrogel microsphere was developed *via* thermally initiated radical polymerization under the protection of the multilayer stability system. The monodisperse hydrogel microspheres with a good swelling property were obtained. *In vitro* release experiments revealed that the BSA-loaded hydrogel microspheres released faster than that of hydrogel bulks. The hydrogel microspheres had fast response to the environment conditions.

Study On Structure Analysis and Cell Toxicity Of Okra Polysaccharide

Min Li-jing[1]

School of Life Science, Huzhou Teachers College, Huzhou, Zhejiang 313000

Keyword: okra polysaccharide; structure; cytotoxicity assay

Abstract: The aim is to analysis okra polysaccharide component and structure, and study on the cell toxicity.[Method] In this paper, we used okra seeds as raw material, extracted okra polysaccharide by boiled alcohol sink method extraction, purified it, studied the mono-saccharide composition, and did okra polysaccharide cytotoxicity assay.[Results]The results show sugar content is 28.15% in the extracts form okra seeds, and the okra polysaccharides are composed of rhamnose, Arabian sugar, D-xylose, D - fructose and D-glucose as well as several monosaccharide composition, cytotoxicity assay shows that the cell toxicity of okra polysaccharide is similar to that of glucose. [Conclusion]This study provided experimental basis for the optimization and development of polysaccharide resources from okra. Polysaccharides are from cell wall of plants, animal cell membrane, multi hydroxyl polymer of microbial cell wall[1]. Polysaccharide is second only to coal, oil and natural gas in the world's fourth largest energy[2]. Plant polysaccharide has many physiological activities, no cytotoxicity, and become the research hotspot [1].Okra polysaccharides extracted from okra fruit has the activities of lipid-lowering, antihypertensive, anticancer, anti stress, anti fatigue activity, and etc [2].In the paper, we extracted polysaccharides from Okra Seed, puried by column purification, hydrolyzed by acid hydrolysis, and then studied its monosaccharide composition and the cytotoxicity of okra polysaccharide, to provide the experimental basis for further development of okra polysaccharide.

Reagent and Instrument

Reagents

Okra seeds, bought from the farmers market; anthrone (analytical pure), sulfuric acid (analysis purity), trifluoroacetic acid (analysis purity), methanol (analytical pure), acetonitrile (analytical pure) Shuanglin Chemical Reagent Factory; Dextran standard, rhamnose standard, D- xylose standard, xylitol standard, fucose standard, D- fructose standard, D- glucose standard, galactose mannose standard, Shanghai Xi Bao Biotechnology Co. Ltd; Sephadex HW-40C, TOSOH company; methyl thiazolyl tetrazolium (MTT), trypsin were purchased from sigma-Adrich company; DMEM was purchased from Gino biological Co. Ltd.; calf serum (FCS) were purchased from Hangzhou Sijiqing biological engineering materials Co., ltd..

SMMC-7721 cells (HCC) was cultured in 1640 containing 10% calf serum medium, which offered by Zhejiang University tumor immunity.

Phosphate buffer solution (PBS): 8.0gNaCl, 3.4785gNa_2HPO_4, 12H_2O, 2.9g NaH_2PO_4, 0.2 g KCl, 0.2 g KH_2PO_4 were dissolved in 1000mL distilled water;MTT solution: 5 mg/mL methyl thiazolyl tetrazolium was dissolved in PBS liquid, filtering, sterilizing, stored at 20℃ in dark;

Main instruments

Dialysis membrane (MW8000-14400) was purchased from Pierce company; FD-1 freeze dryer was purchased from Beijing De Tianyou Technology Development Co., Ltd.; VV1800PC scanning UV VIS spectrophotometer, Shanghai mapada Instruments Co. Ltd.; Themo Forma thermostatic shaker; Sony -80 ℃ cold box; Thermo Mulitiskan Mk3 microplate, Thermo company.

Method

Extracted and purified okra polysaccharide[3]

Okra fruits were soaked in water, counter-flow at 100℃ for 4h (×4 times), filter to obtain filtrate, combined filtrate, concentrated, dripped ethanol (v/v:1:3), 4000rmp centrifugal to obtain precipitation, added water to dialysis for 48h (MW:8000-14400), 4000rmp centrifugal to obtain supernatant, dryed to obtain crude, the crude was dissolve in water and puried from column (Sephadex, HW-40C), freeze-dried into light yellow powder.

Determined the content of okra polysaccharide with anthrone sulfuric acid method[4]

Standard curve of glucose: 0.05g glucose standard was dissolved in pure water, constanted volume for the glucose standard solution of 0.5g/L, as the stock solution. Remove stock solution to configure for the series of standard solution concentration of 5 μ g/mL, 15 μ g/mL, 40 μ g/mL, 60 μ g/mL, 80 μ g/mL. Orderly we shifted 1mL standard solution for different concentration in the colorimetric tubes, and added 4mL 2g/L anthrone-sulfuric acid solution, the ice water bath, after that bathed in boiling water for 10 min, removed to cool it at room temperature for 10min. Using distilled water as blank, measured absorbance at 621nm, and the standard working curve were obtained by the least squares method, the regression equation is: A=0.0093C+0.0312 (R^2=0.9779). As the absorbance value changes with the sugar concentration is linear, we can determine the sugar content in the samples with the external standard one point method, as for:

$$\frac{A_{s\tan dard}}{A_{sample}} = \frac{C_{s\tan dard}}{C_{\mathrm{x}}} \qquad (1)$$

$$\text{sugar content}\% = \frac{C_{\mathrm{x}}}{C_{\text{stoste}}} \times 100\% \qquad (2)$$

$A_{s\tan dard}$: standard absorbance: Abs; A_{sample} : sample absorbance: Abs;

$C_{s\tan dard}$: standard concentration: μg/mL; C_{x} : okra polysaccharide concentration of sample: μg/mL;

C_{stoste} : okra polysaccharide apparent concentration of sample: μg / mL.

Okra polysaccharide powder was dissolved in water into 100mL volume, removed 1mL this solution to determine the sugar content operated as above.

Gel permeation chromatography (GPC) determination of okra polysaccharide molecular weight

The molecular weights were 10500, 43200, 76900, 188000Da of the standard products of dextran as standard, GPC determination of retention time, as the standard working curve were obtained by the least squares method, the regression equation is: y=-1.5319x+21.653 (R^2=0.9955).

Chromatographic conditions were: Agilent 1100, SEDEX75 type evaporative light scattering detector (ELSD), detector sensitivity: 7, atomization temperature: 55℃, atomization pressure: 3.06bar,: Tsk-GeL 3000PWXL column (7.8 × 300mm), column temperature: 30℃, mobile phase: water /N_2, flow rate: 1mL/min.

Acid hydrolysis of polysaccharide chain

Some okra polysaccharide sample was added 2mL2.0mol $L^{-1}CF_3COOH$, , constant temperature oil bath at 110°C, reflux for 2h, taken a sample every 0.5h to 8h after hydrolysis and then low concentration at 45°C , the HPLC tests components.

Chromatographic conditions were: Agilent 1100, SEDEX55 type evaporative light scattering detector (ELSD), detector sensitivity: 5, atomization temperature: 40 ℃, atomization pressure: 3.0bar chromatographic column: HypersilNH25 μm (4.6mm × 250mm), column temperature: 25 ° C, mobile phase: acetonitrile water (v:v = 82: 18), flow rate: 1mL/min, injection volume: 10 μ L.

HPLC analysis monosaccharide composition

Chromatographic conditions were: Agilent 1100, SEDEX55 type evaporative light scattering detector (ELSD), detector sensitivity: 5, atomization temperature: 40℃, atomization pressure: 3.0bar chromatographic column: HypersilNH25 μm (4.6mm × 250mm), column temperature: 25°C, mobile phase of methanol: acetonitrile water (v:v = 85: 10:5) ,flow rate: 1mL/min, injection volume: 10μL.

cytotoxic assay

Cos-7 cells were inoculated into 96 well plate, 5000 cells / well, culture 24h., absorbed the old culture each bore liquid. Okra polysaccharide and glucose standard in 10%FCS containing DMEM were prepared into solution concentration gradient is 0.01, 0.025, 0.05, 0.1, 0.25, 0.5 and 1mg/mL. Each hole was added 0.15mL this solution, 4 holes for 24h cocultured with cell culture liquid sugar, suction to the old, then added serum free DMEM per hole 100 μ L containing 5 μ g/mLMTT (5mg/mL MTT10mL into 90 μ LDMEM), cultured for 4H at 37 ℃. Turning plate method to discard the liquid, each hole was added with 100 μ LDMSO 10min, concussion, determined the OD value at the wavelength of 570nm in the ELISA detecting instrument. At the same time for the cell alive and cell death were all control, all 6 holes.

$$\text{cytotoxicity}\ (\%) = \frac{X - X_{0\%}}{X_{100\%} - X_{0\%}} \times 100\% \tag{3}$$

X： the value of OD after cocultured with okra polysaccharide; $X_{0\%}$： the value of OD cell death control;

$X_{100\%}$： the value of OD cell alive control.

Results and analysis

Determined the content of okra polysaccharide with anthrone sulfuric acid method

TABLE 1 DETERMINED THE CONTENT OF OKRA POLYSACCHARIDE WITH ANTHRONE SULFURIC ACID METHOD

No	stoste Concentration（μg/mL）	absorbance（Abs）	sugar concentration（μg/mL）	sugar content（%）	Average（%）
standard	30	0.2142			
1	188	0.3747	52.48	27.91	
2	188	0.3802	53.25	28.32	28.15
3	188	0.3790	53.08	28.23	

Gel permeation chromatography (GPC) determination of okra polysaccharide molecular weight

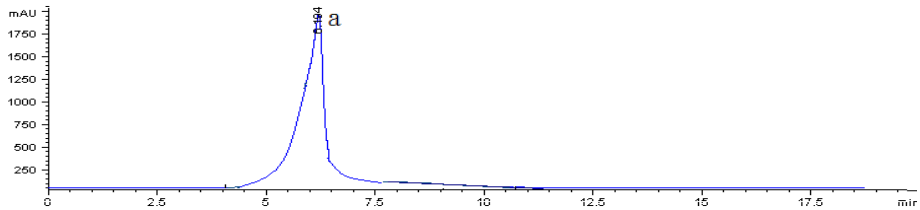

Fig1 Gel permeation chromatography (GPC) determination of okra polysaccharide molecular weight

The spectrogram showed that retention time of okra polysaccharide wsa 6.194min, so it's molecular weight was 191,838.9Da.

Acid hydrolysis of polysaccharide chain

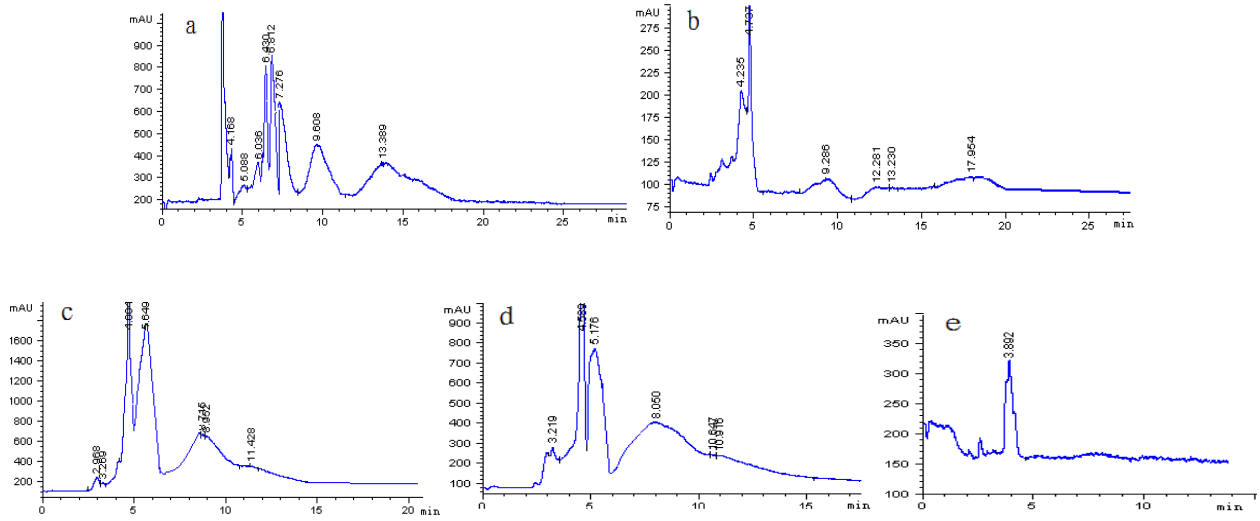

Fig2 The chromatograms of the sample of Okra polysaccharide in different hydrolysis time

a 2h；b 2.5h；c 3h；d 3.5h；e 8h

Observation of okra polysaccharide hydrolysis series map, we found that the hydrolysis products became more and more simple along with the hydrolysis time, this may be due to residual damage acid with the degradation of hydrolysate hydrolyzed liquid, especially in the hydrolysis of 8h

hydrolysis products had all degradation. And the selection should be relatively mild, hydrolysis time shoulds not be too long hydrolysis for okra polysaccharide, generally the best choice of the hydrolysis time was 2h for the best effect. The change in retention time between 11-13min peak displacement, may be D – glucose was shaped into in enolate anion, and then converted to the mixture of fructose, mannose and glucose in the action of dilute acid.

The retention time of CF_3COOH was 2.4-2.9min, while around 4.9min was the peak of CH_3CN. There was no disaccharides in liquid solution of polysaccharide, all ingredients were monosaccharides.

HPLC analysis of monosaccharide composition

Taking retention time may influence on each other after mixing the monosaccharide standard into account, so we determined their retention time of each component after the monosaccharide mixed, basing on determination retention time the monosaccharide standard single injection.

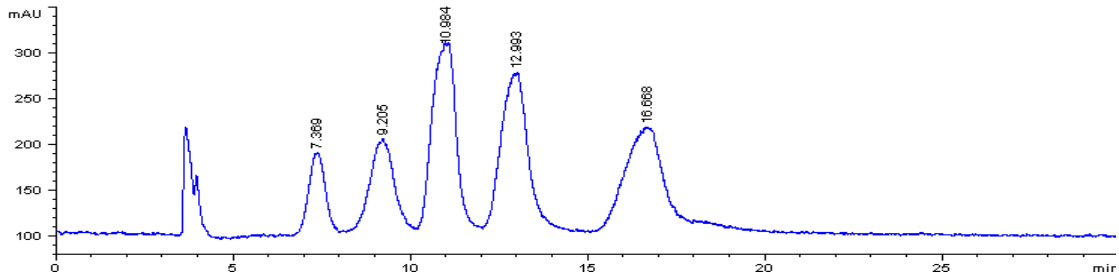

Fig3 The retention time of each component in mixed monosaccharide standard

We added methanol in the mobile phase in the monosaccharide composition analysis, because the time interval sampling data in okra polysaccharide acid hydrolysis liquid, we found that each component had adhesion retention time, to decrease the mobile phase polarity, component retention time shiftted, the retention time was about 3.3-3.9min for CF_3COOH solvent peak, about 5.0min was mobile phase CH_3CN peak. We found of existence of rhamnose, arabinose, D-xylose, D-fructose and glucose monosaccharide in okra polysaccharide acid hydrolysate.

TABLE 2 THE RETENTION TIME OF EACH MONOSACCHARIDE COMPOSITION OF OKRA POLYSACCHARIDE ACID HYDROLYSATE

retention time (t_R/min)	monosaccharide compositio
7.014	rhamnose
8.754	arabinose
9.957	D-xylose
12.490	D－ fructose
15.084	D－glucose

Cytotoxic assay

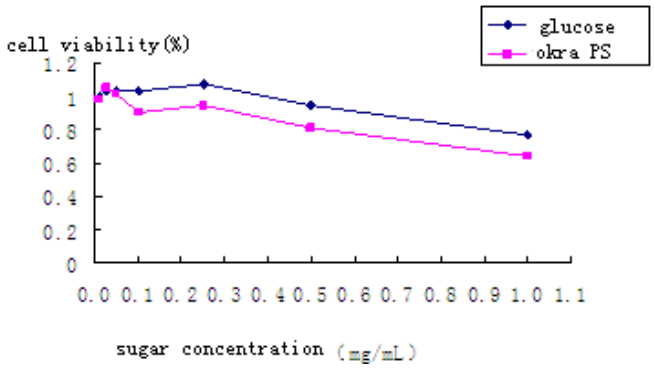

Fig4 The data of cytotoxic assay

Figure4 shows the observed cytotoxicity, okra polysaccharide and glucose similar, belong to low toxicity materials, good biological compatibility. These results provide an experimental data support for the further development and utilization of okra polysaccharide.

In this paper, okra polysaccharide was extracted from okra seeds, and is mainly composed of rhamnose, glucose, xylose, D-Arabia, D- fructose and glucose, several kinds of monosaccharide composition, and the material of low cytotoxicity, good biological compatibility, is expected to develop the use of depth.

Keywords: Resveratrol; SMEDDS; Development; Optimization

Abstract. We developed a SMEDDS to enhance the oral delivery of resveratrol by using high performance liquid chromatography, a pseudo ternary phase diagram and a central composite design (CCD). We found that the optimal formulation of 12.69% greoil gtcc, 62.29% Cremophor EL, and 25.02% Labrasol. We characterized the particle size and zeta potential of the final SMEDDS.

Introduction

Resveratrol is a polyphenol occurring naturally in several plants [1, 2]. Previous studies have shown that resveratrol has many physiological properties, such as cardio protective actions, cancer preventive and therapeutic effects [3]. It also has the potential as an anti-obesity compound and a potent new antioxidant in skin care formulations [4, 5]. However, the oral delivery of resveratrol is very low in humans [6]. Therefore, a drug delivery system to improve oral delivery is crucial.

In recent years, many researchers have focused on SMEDDS to improve oral delivery of some drugs. SMEDDS is a mix of oil, target drugs, surfactant and cosurfactant that emulsify under gentle agitation [7]. A SMEDDS can improve oral delivery because it offers a large inter facial area for drug diffusion with nano size [8]. SMEDDS has been successfully established in improving the oral bioavailability of cyclosporine, coenzyme Q10, tacrolimus and oridonin [8-12]. However, only few studies have described the use of SMEDDS for resveratrol.

Generally speaking, it is important to optimize the SMEDDS. And it is easier to conduct investigations by changing one variable while keeping all others constant. However, this approach was difficult to determine interactions among the variables. One common way is to use CCD [13]. The CCD is a composite of the factorial experiment, axial points, and centre point, and it is widely used for the response variable that abolishes the need for a complete three-level factorial experiment [14]. CCDs have been used in the optimization of formulations such as the nanostructured lipid carrier system for econazole nitrate, α-tocopherol-loaded solid lipid nanoparticles [15, 16].

In this study, a high performance liquid chromatography (HPLC) method was established for the determination of the solubility of resveratrol in different oils, surfactants and cosurfactants. The effects of the surfactants, cosurfactants, and oils on the microemulsion were investigated using the pseudo ternary phase diagrams. A CCD was used to study the effect of formulation variables (oil content and Km value) on the response variables, including droplet size, polydispersity index (PI) and drug loading. The optimal preparation was characterized preliminarily

Materials and Methods

Materials

Resveratrol (purity: 98%) was purchased from Tianjin Jianfeng Natural Product R&D Co., Ltd, China. Cremophor EL and Cremophor RH 40 were supplied by BASF, Germany. Labrasol, Maisine 35-1, Peceol, Lauroglycol 90, Labrafil M 1944CS, Plurol OleiqueCC497, and Plurol Diisostearique were obtained from Gattefosse, France. Greoil gtcc, 1,2-propanediol, oleic acid, propylene glycol esters offatty acid, Tween 80, and PEG400 were provided by Beijing Fengli Jingqiu Commerce and Tarde Co., Ltd, China. HPLC grade methanol and acetonitrile were supplied by DikmaPure, China. All other chemicals used were of analytical grade and were commercially available products. MilliQ water was used in all the experiments.

Solubility of resveratrol

Excess amount of resveratrol was placed in dark brown screw-capped bottles with 1 mL different vehicles and mixed by vortexing. Mixtures were allowed to agitate on a shaker (Zhicheng ZHWY-103D, China) at 37 °C for 48 h. After that, the samples were centrifuged at 10000 rpm for 15 min. The supernatant was diluted with methanol and then passed through 0.45 μm membrane filters (Millipore, America). And an HPLC 1200 system (Agilent, America) with an Agilent Extend C18 column (5 μm, 4.6×250 mm) was used. The mobile phase was a mixture of water and acetonitrile (73:27, v/v) at a flow rate of 0.8 mL/min. The resveratrol concentration was quantified at 306 nm, and the column temperature was 30 °C. The inter- and intra-day variance was within the acceptable range. The solubility studies were repeated three times.

Preparation of SMEDDS formulations

SMEDDS of resveratrol were prepared by dissolving resveratrol into the mixture of surfactant, cosurfactant and oil. And it was vigorous vortexing adequately in a water bath at 37 °C. All formulations were stored at room temperature before use.

Construction of pseudo ternary phase diagrams

Pseudo ternary phase diagrams of the selected compositions of SMEDDS were constructed by titration of homogenous liquid mixtures of oil, surfactant and cosurfactant with 0.1 M HCL. And they were used to identify the self-microemulsifying regions and to find the preliminary optimal component concentrations. With Km values of 3, 2, 1, 1/2 and 1/3 (w/w), the surfactant and cosurfactant mixture was warmed and then mixed with oil. The ratio of oil to surfactant varied as 1:9, 2:8, 3:7, 4:6, 5:5, 6:4, 7:3, 8:2 and 9:1 (w/w). These mixtures were slowly titrated with aliquots of 0.1 M HCl at 37 °C until they became turbid. Clear and isotropic samples were deemed within the self-microemulsifying regions [17]. All experiments were repeated three times, and similar observations were made across all replications.

CCD. In our study, the oil content and Km value were identified as the studied factors of SMEDDS. And the droplet size, PI and drug loading were the responses. The CCD was created by Design Expert 8.0. The three responses were suitable for a second order polynomial model (Eq. 1). In the equation, X_1 and X_2 correspond to the studied factors, Y represents the measured response, A_0 is an intercept, and A_1–A_5 are the regression coefficients. The signal to noise ratio, adeq Precision, was employed to validate the resulting model. A ratio greater than 4 is desirable.

$$Y=A_0+A_1\times X_1+A_2\times X_2+A_3\times X_1^2+A_4\times X_2^2+A_5\times X_1\times X_2. \quad (1)$$

The desirability function is used to treat the multicriteria problem as a single criterion problem. The response to be minimized is Eq. 1. In the two equations, Y_{min} represents the lowest possible value, Y_{max} represents the highest possible value, and Y_i indicates the experimental value. As a global desirability function, an overall desirability (D) is calculated using the geometric mean.

$$d=\begin{cases} 0 & (Y_i \geq Y_{max}) \\ \dfrac{Y_i - Y_{min}}{Y_{max} - Y_{min}} & (Y_{min} < Y_i < Y_{max}) \\ 1 & (Y_i \leq Y_{min}) \end{cases} \quad (2)$$

$$d=\begin{cases} 1 & (Y_i \geq Y_{max}) \\ \dfrac{Y_{max} - Y_i}{Y_{max} - Y_{min}} & (Y_{min} < Y_i < Y_{max}) \\ 0 & (Y_i \leq Y_{min}) \end{cases} \quad (3)$$

Characterization of SMEDDS

Prior to the droplet size, PI and zeta potential measurement, SMEDDS of resveratrol was diluted with water 200 times and gently stirred. They were determined using a Malvern Zetasizer ZS90 (Malvern Instruments, UK). Each sample was analysed in triplicate.

The drug loading of SMEDDS was determined with the blank SMEDDS (absence of the drug). And the experiment method was the same with the investigation of solubility of resveratrol.

Results and Discussion

Solubility Studies

The solubility of resveratrol in various materials is presented in Fig. 1. The solubility of resveratrol was very low in the oil phase for the oils tested compared to some surfactants and cosurfactants. Therefore, the solubility of resveratrol can be increased by SMEDDS. Finally, greoil gtcc was selected for the oil phase because it is widely used in the pharmaceutical and food industries. Among the surfactants, Cremophor EL showed the highest solubility for resveratrol. Labrasol was selected as a cosurfactant for its high resveratrol solubility and for its improved intestinal absorption of drugs [17].

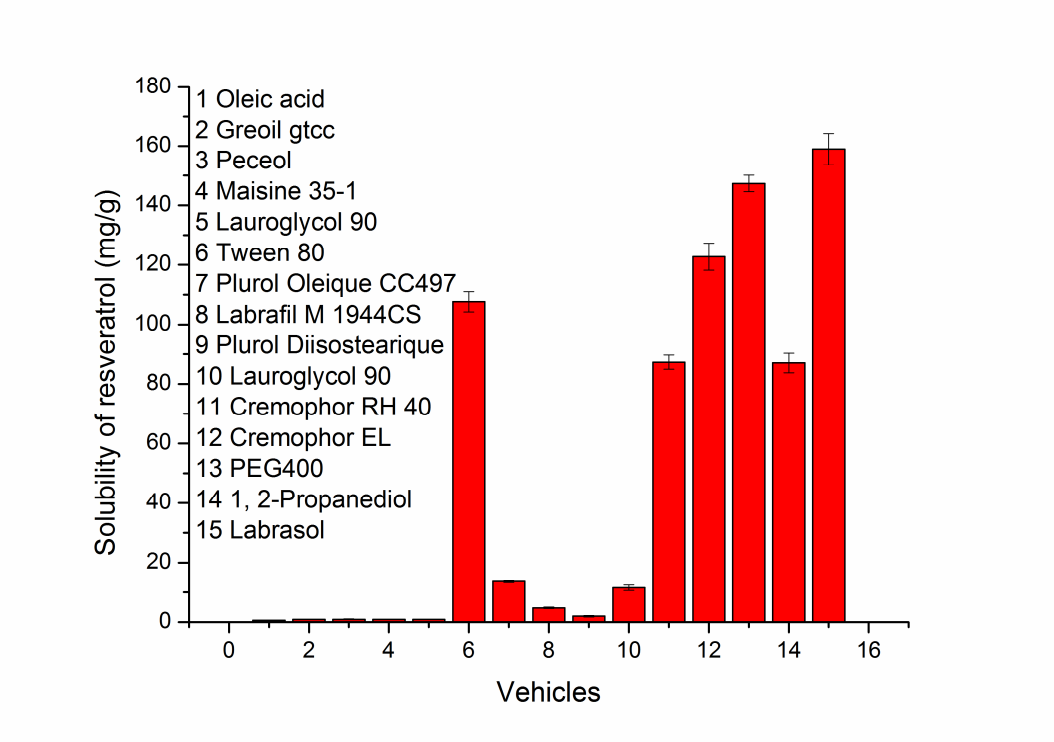

Fig. 1 The solubility of different vehicles

Construction of pseudo ternary phase diagrams

As Fig. 2 shows, the self-microemulsifying region expands as the Km value increases, with the maximum self-microemulsifying region at the Km value of 3, indicating that the Km values are effective for a stable and efficient SMEDDS formation. The appropriate formation and the specific formulation could not be determined and confirmed in this experiment. Therefore, some formulations were selected and used for the CCD experiment.

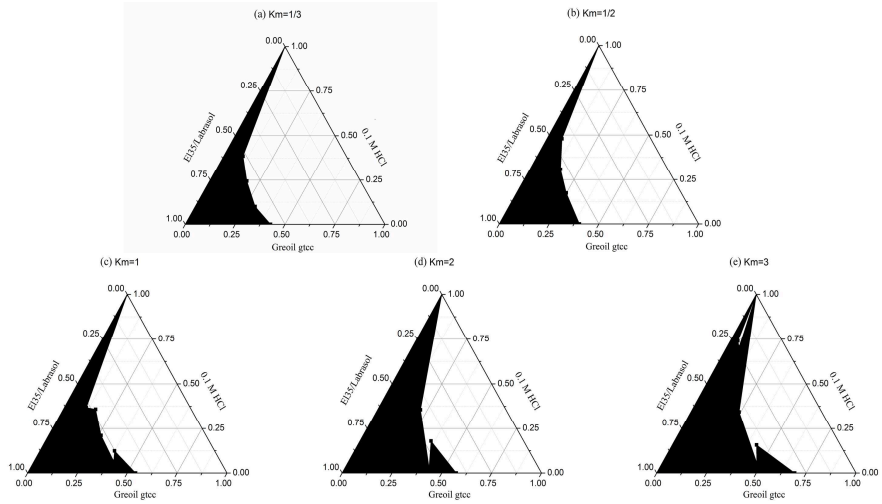

Fig. 2 The pseudo-ternary phase diagrams of greoil gtcc, 0.1 M HCl, Cremophor EL and Labrasol

CCD. The responses for oil content (X_1), Km value (X_2), droplet size (Y_1), PI (Y_2) and drug loading (Y_3) were included in the CCD, and the three responses Y_1–Y_3 were significant for assessing the SMEDDS's quality. Among these objectives, Y_1 and Y_2 were minimized, while Y_3 was maximized. D was calculated for each run. Design Expert was used to fit these responses using Eq. 1. The fitting parameters are shown in Table 1. The Adeq Precision of the responses and the desirability indicated that the model was significant and could be used to navigate the design spaces.

TABLE 1: THE FITTING PARAMETERS OF THE RESPONSES AND THE DESIRABILITY

	A_0	A_1	A_2	A_3	A_4	A_5	Adeq Precision
Droplet size	5.40	4.11	5.13	-0.055	-7.99	0.21	20.46
PI	0.35	-0.0077	-0.037	0	0	0.0028	11.18
Drug loading	119.72	-2.21	-9.10	0.030	0.95	0.011	25.88
Desirability	0.53	-0.0016	0.0011	0	-0.088	-0.0031	11.58

A 3D colour map of the three responses and D was drawn using Origin 8.5 (Fig. 3). Fig. 3a shows the 3D colour map for droplet size and reflects the relationship between the droplet size and the two factors. A droplet size smaller than 50 nm could be observed in the domain containing an oil content of less than 20%. When the oil content was more than 30% and the Km value was less than 2, the droplet size was greater than 80 nm.

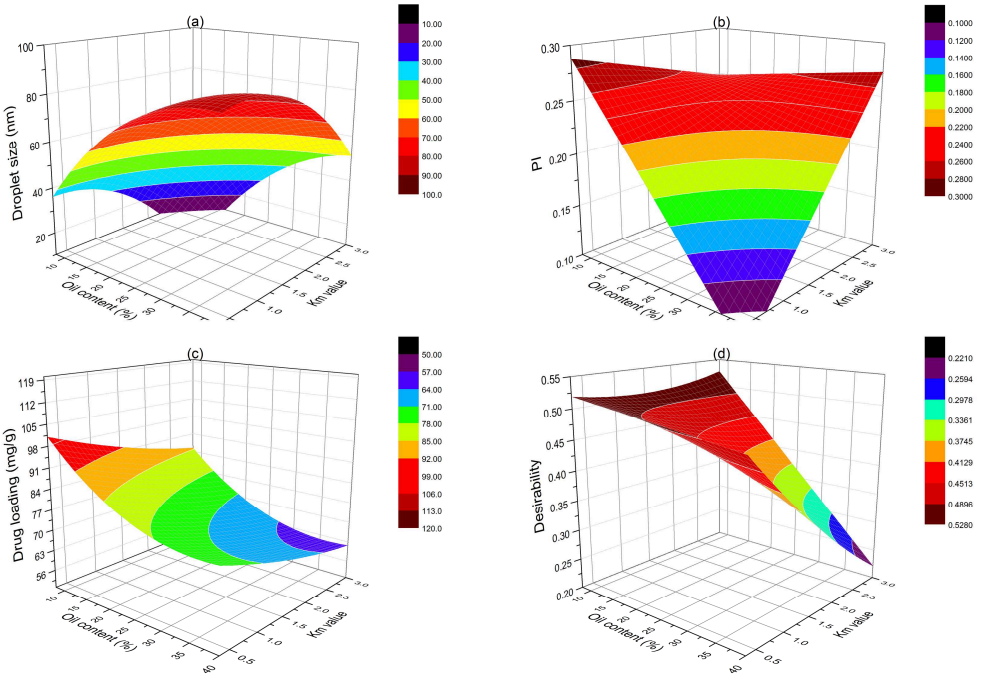

Fig. 3 The 3d colour map of the three responses and the desirability

The PI reflects the size distribution generated by the SMEDDS dispersion in an aqueous media. The optimal oil content was greater than 25% for achieving a minimum PI within a Km value less than 1.5 (Fig. 3b). As shown in Fig. 3c, the effect of the oil content on the drug loading was critical. When the Km value remained constant, the increase in oil content resulted in decreased solubility.

For further optimization of the formulation, D function was used to optimize the three responses simultaneously. The 3D colour map for D is shown in Fig. 3d. D was greatly affected by the oil content, which was important to maintain the stability of the formulation. The solution for the cosurfactant looked better than the solution for the surfactant, indicating that the Km value was responsible for dissolving more resveratrol. The final formulation that was chosen by the Design-Expert software was X_1=12.69%, X_2=2.49, and D = 0.541. Thus, the final optimal formulation of the SMEDDS was 12.69% greoil gtcc, 62.29% Cremophor EL and 25.02% Labrasol.

Characterization of SMEDDS

The droplet size was 20.51±0.63 nm, PI was 0.241±0.016, and drug loading was 76.45±3.23 mg/g. The zeta potential was -1.12±0.21 mV for the formulation.

Conclusion

We developed a potentially useful method for local delivery of orally ingested resveratrol. The selection of the optimal SMEDDS composition for resveratrol might offer an advantage as an alternative oral dosage form. The optimization of the SMEDDS formulation for resveratrol was conducted using CCD combined with a desirability function. And it was efficient for modelling and optimization of resveratrol in a SMEDDS as well as for understanding how the formulation factors influence the properties of a SMEDDS.

Keywords: Hip joint endoprosthesis, ceramic head, shape deviations, cone contact areas, tensile stress, failure probability.

Abstract: The paper deals with the problems of ceramic head of hip joint endoprosthesis destructions, and with assessing the impact of shape deviations of conical surfaces on the tensile stress under ISO 7206-5 loading. The failure of the hip joint endoprosthesis ceramic head has always traumatic consequences for the patient, since a part of or even the whole endoprosthesis has to be reoperated. Hence, it is desired to reduce the number of implant re-operations to the minimum. Therefore the computational modelling of the stress of the head was realised. The shape deviations of the ideal contact cone areas of the head and stem are parameters that significantly influence the tensile stress in the head and its reliability. The assumed shape deviations of the head's and stem's cones are macro shape deviations (different cone taper) and micro shape deviations (unevennes) measured using the IMS-UMPIRE equipment. The stress state in the ceramic heads was solved using the FEM and head's failure probability is based on the Weibull weakest link theory [4, 5 and 9].

Introduction

One of the most frequently operated joints of the human body is the hip joint [1]. In young patients, the operation is mostly aimed at reconstructing the joint's pathologically developed geometry [6]. In older age, operations prevail in which the patients are provided with partial or total endoprostheses [8, 13]. These may be of different design solutions, with various materials being used in the endoprosthesis' individual parts. In a design solution which used ceramic heads, the destruction of the

Fig. 1. *In vivo* destructed ceramic heads

head has occurred in vivo. In one hospital of the Czech Republic, more than 1 % of applied endoprostheses had to be reoperated (Fig. 1). That is why the state of stress and the reliability of ceramic heads of total endoprosthesis is being intensively analysed by means of computational modelling.

The analysis of the head fracture surface orientation showed that the meridionally oriented fracture surfaces prevail (Fig. 1). Since ceramics is a material characterised by the limit state of brittle strength, the cohesion failure starting in directions perpendicular to the direction of the maximum principal tensile stress, then the stress responsible for the failure of head cohesion should be the hoop stress [3]. An effective method of solving the problem of reliability is computational modelling combined with experiments. For solving the strain/stress states in the head, the finite elements method was used, namely the ANSYS program system.

Computational modelling

The topology of the elements of the total hip joint endoprosthesis follows from Fig. 2 with the basic macro-dimensions of elements. Computational modelling of the strain/stress states in the head was implemented on a system whose elements were parts of the stem and the head.

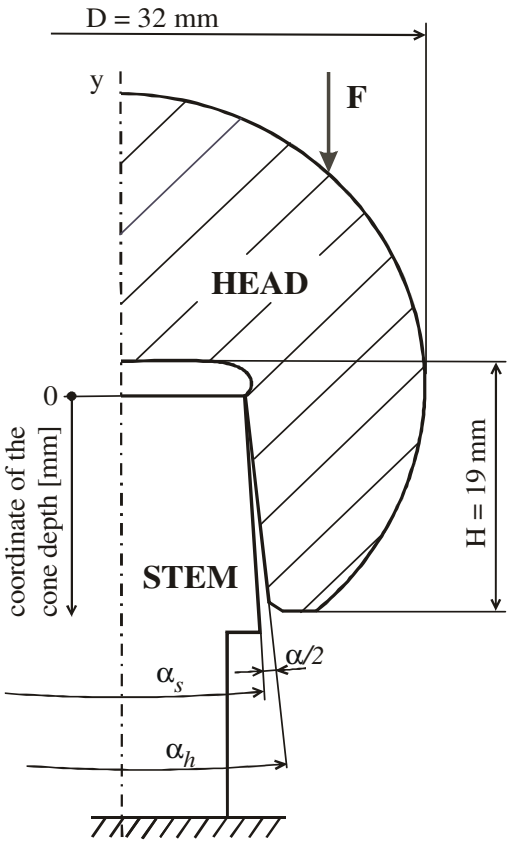

Fig. 2. Topology and macro shape deviation

Fig. 3. Measure device IMS-UMPIRE

In order to implement computational modelling of the impact of shape deviations of the cones of stems and heads of hip joint endoprostheses, which has a stochastic character, the measurement of these deviations was carried out using the IMS-UMPIRE measuring equipment (Fig. 3). The quality of the measured contact surface of both cones can be expressed by macro-parameters (deviations) – the most important is angle of the taper of the head and the stem and straight line character), and micro-parameters (deviations) – local micro-unevenness of surface. As regards the inclination angles of the elements of ruled surfaces (degree of taper) one can say that the manufacturing documentation permits only an alternative in which the vertex angle of the head (angle α_h) is greater than the vertex

angle of the stem (angle α_s) – Fig. 2 (the value of the angle α can be found from zero to 10'), and the circularity of the individual sections (perpendicular to the y-axis) is less than 10 µm [2 and 7].

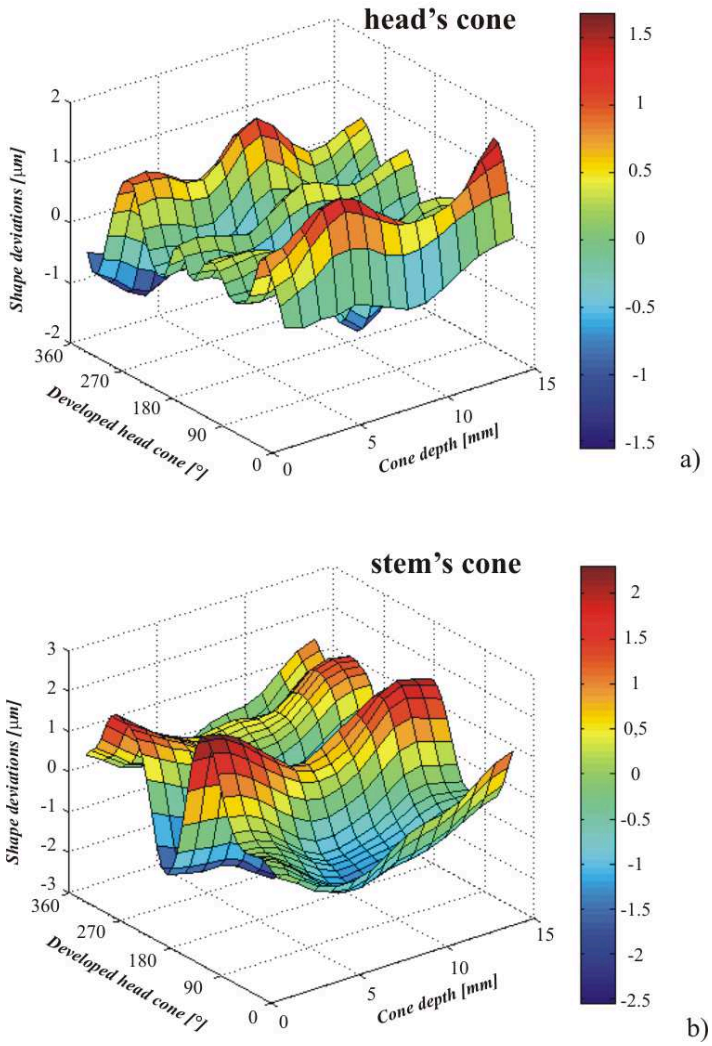

Fig. 4. Micro shape deviation of the: a) head cone and b) stem cone

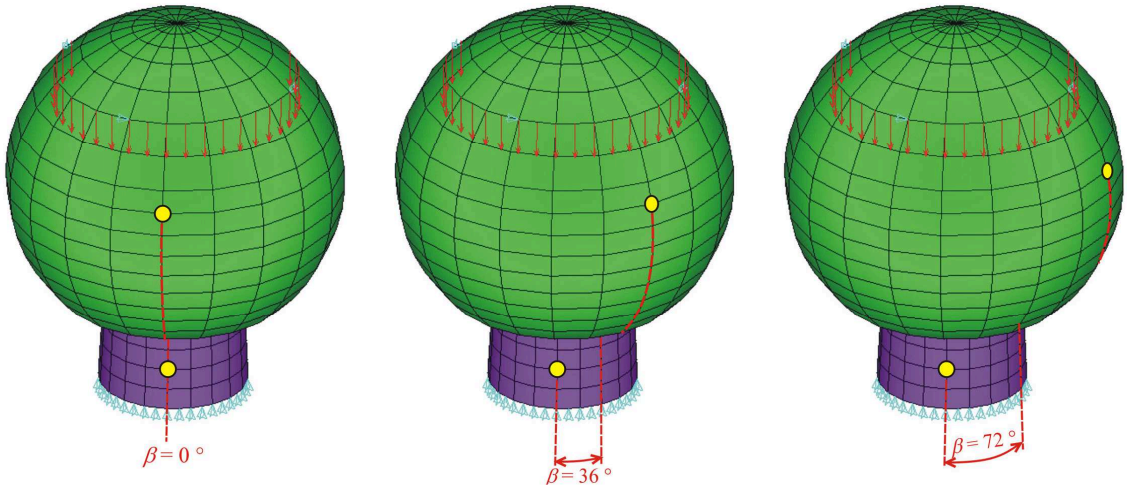

Fig. 5. Representation of various head to stem positions - angle β

The measured micro shape deviations from the ideal conical shape for cone of head are illustrated by the developed cones in Fig. 4a (from -1.5 to 1.5 μm). The micro shape deviations of the stem cone are show in Fig. 4b (from -2.5 to 1.5 μm). The mentioned head with macro and micro shape deviations was put and loaded on the stem cones under ISO 7206-5 loading (Fig. 2).

The state of stress of the ceramic head of endoprosthesis can be strongly affected by the process of endoprosthesis implantation, when the surgeon fits the head on the cone of the stem. The fitting of the head on the cone of the stem is a random process, in view of the mutual position of the head to the stem (in sense of the head's slight turning around the y-axis, defined by angle β – Fig. 5) [10, 11]. The question is, whether the local shape deviations of the cones, in case of random completing, can produce high tensile stresses that might reduce the reliability of the head. For this reason, a series of computations will be made for each pair and for various positions of the head towards the stem.

For computational analyses of the head's cohesion failure, the head was loaded with linear forces acting on a circle, the carrier of the resulting force F being identical with the axis of the stem, Fig. 2. This way of loading complies with the ISO 7206-5 standard, according to which the reliability of ceramic heads is tested for failure of cohesion.

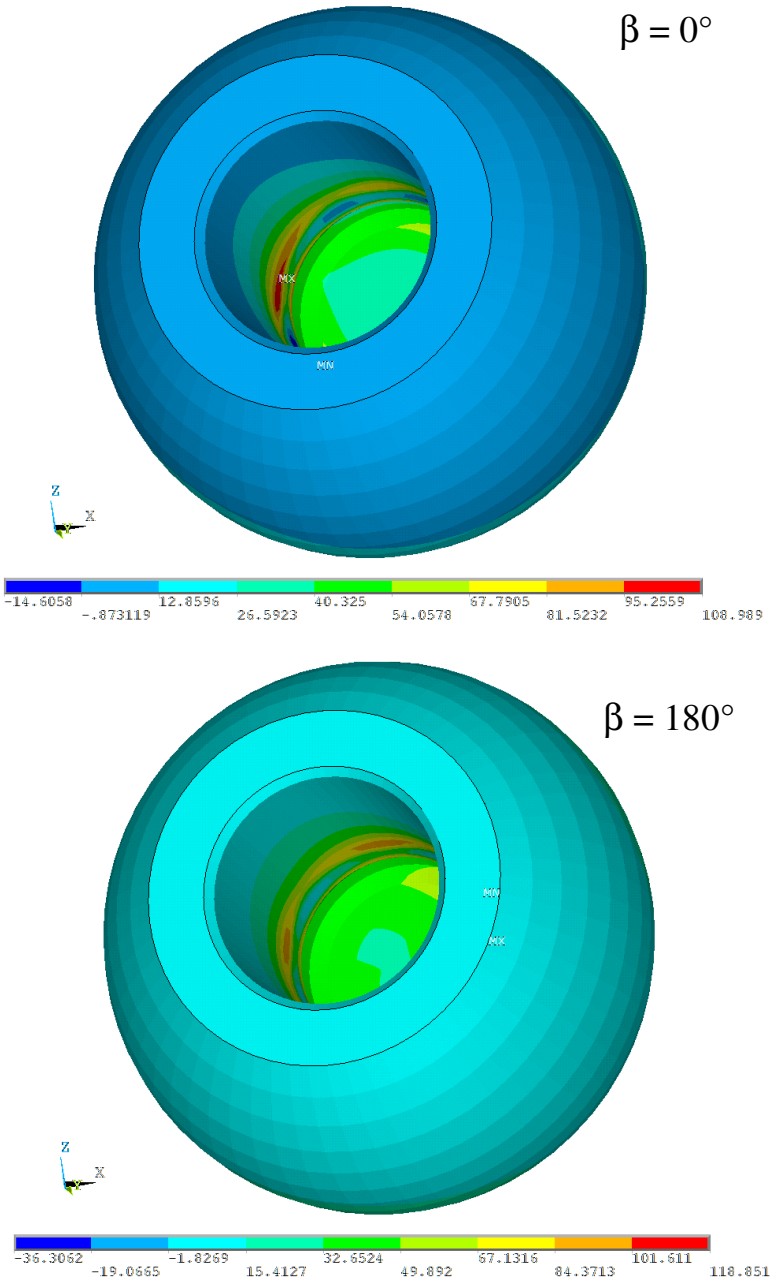

Fig. 6. First principal stress isolines (in MPa) for loading F = 4 kN and α = 10’ and for two different angles β

The material of the head and the stem was considered to be a linear isotropic continuum. The stem was made of steel and the following constitutive characteristics were taken into account in the calculation: E = 210 GPa μ = 0.3. The material of the head was ceramics on the basis of aluminium oxide Al_2O_3, for which the following constitutive characteristics were considered: E = 390 GPa, μ = 0.23. Contact between the head and the stem is modelled as elastic Coulomb friction with coefficient of friction f = 0.15 [7, 8 and 12].

Results and Discussions

The negative behavior of the ceramics is the brittleness and therefore the tensile stresses in the ceramic head will be analysed in detail [8]. The maximum tensile stress in the head is located on the contact surface near the contact region. The size of the contact region is influenced of the position of micro shape deviations of the stem and the head cone. Fig. 6 shows the isolines of the first principal stress in the head

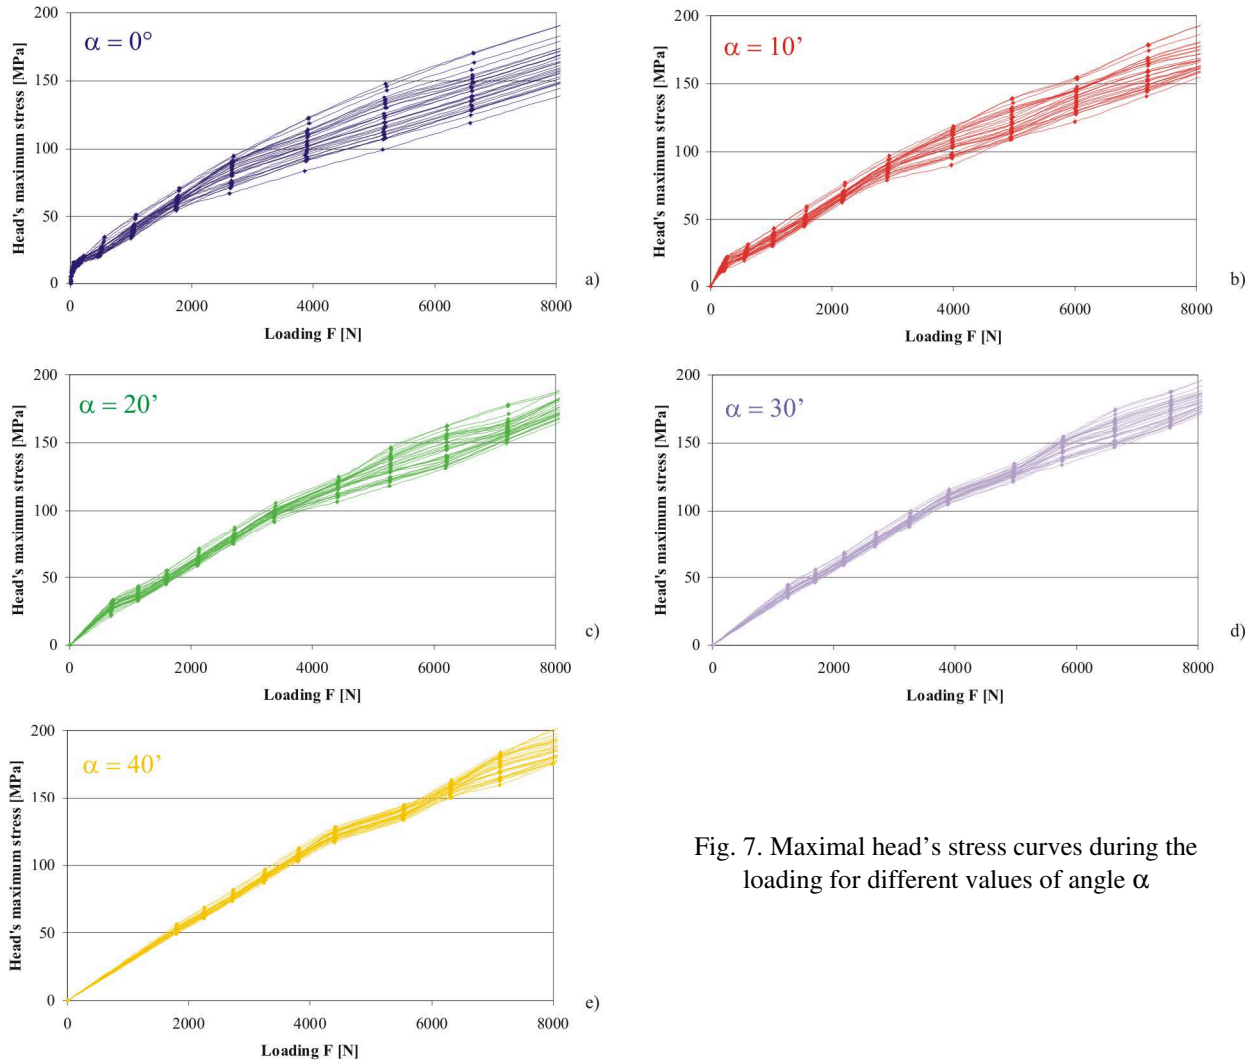

Fig. 7. Maximal head's stress curves during the loading for different values of angle α

(F = 4 kN and α = 10') for different position of the head and the stem (β = 0° and β = 180°). The location of the maximum tensile stress and the shape of the isolines are different for both analysed angles β due to the relative location of the micro deviations of the head's and stem's cones.

The distribution of maximum values of tensile stresses in the ceramic head (σ_{max}), in dependence on the value of the head's load and on value of the α, is shown in Fig. 7a-e. The width of the curves is decresed with increasing angle α. This is due to the fact that in case the zero angle α (ideal case when the cone angle of the head and stem is the same) is in the contact local shape deviations on the entire tapered surface. Increasing of the angle α value caused the reduction of the contact area and this contact area is localized to the area of the smallest diameter of the cone. Then the smaller number of the local shape deviations are in contact and extreme tensile stress in the head has a smaller variance (width of curves in Fig. 7).

Conclusions

By computational modelling it has been proved that the character and the size of micro and macro shape deviations on a conical contact area between the stem and the head of hip joint endoprosthesis have a pronounced influence on the character and the value of stress in the head and, hence, on the probability of the head's cohesion failure. The increasing of the stress and the failure of cohesion of ceramic heads illustrate how the ignorance of the influence of micro-dimensions on macro-behaviour of parts may have negative and even traumatising consequences.

Keywords: Amphiphilic copolymer, RAFT, Polymerization, Methyl methacrylate

Abstract： A novel, well-defined, amphiphilic block copolymer was synthesized by RAFT copolymerization of 2-(dimethylamino) ethyl methacrylate (DMAEMA) and methyl methacrylate (MMA). The polymer structure was characterized by ^1H *NMR* , GPC and TEM. It was found that the stable spherical micelles with core-shell structure are formed and good solubility in water. The copolymer would have great potential in drug delivery systems.

Introduction

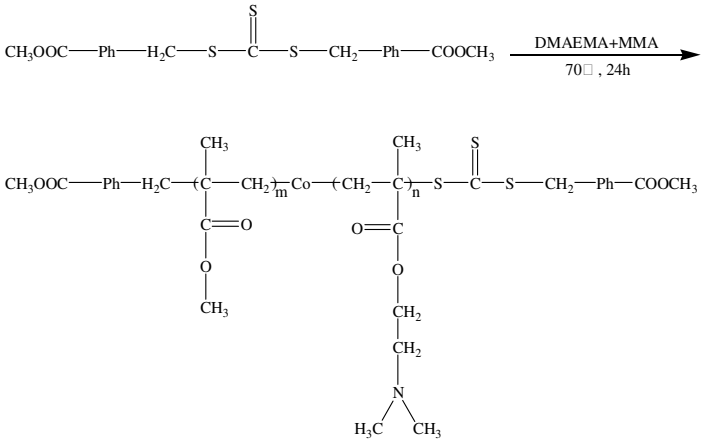
Amphiphilic copolymers are able to self-assemble into micelles having a hydrophobic inner core and a hydrophilic outer shell. In recent years, polymeric micelles used as nanoscale drug carriers have attracted much attention for their pharmaceutical or diagnostic applications [1] and a variety of anticancer drugs, such as paclitaxel [2] and doxorubicin [3, 4] were incorporated into the hydrophobic inner core for the controlled release. The precise control of polymer architectures as well as the properties of self-assembled micelles is of great importance for drug delivery [5-8].

Poly[2-(dimethylamino) ethyl methacrylate] (PDMAEMA) is a special polymer containing tertiary amino groups and exhibits pH-sensitivity which can be protonized in acidic solution [9-11]. Due to the unique property, a series of pH responsive copolymers have been synthesized from PDMAEMA for application as controlled drug delivery system [12-14].

In this study, a novel amphiphilic block copolymer(Poly (DMAEMA-co-MMA) was synthesized by RAFT and the structure was characterized by ^1H *NMR* , GPC and TEM. The amphiphilic copolymers are able to self-assemble into micelles having a hydrophobic inner core (MMA) and a hydrophilic (DMAEMA) outer shell. The results suggest that the micelles would have great potential in drug delivery systems.

Experimental

Materials



Trithiocarbonate RAFT agent had been synthesized in our laboratory according to the literature [15]. DMAEMA(Tianjin Fuchen Chemicals,China) and MMA(Tianjin Fuchen Chemicals,China) were dried over CaH_2 and distilled under reduced. All other reagents and solvents were used as received without further purification.

Measurements

Fourier transform infrared spectra were recorded on a Nicolet 670 spectrometer. The ^{1}H-NMR and measurements were obtained with a Mercury Plus AS400 spectrometer at room temperature in $CDCl_3$. GPC measurements were conducted on an Alli-ance GPCV2000 instrument (Milford, MA, USA) with THF as the eluent. TEM images were obtained using a JEM 1200 EX transmission electron microscope.

Copolymer Synthesis

The Amphiphilic copolymer Poly (DMAEMA-co-MMA) was synthesized by RAFT polymerization of 2-(dimethylamino) ethyl methacrylate (DMAEMA) and methyl Methacrylate (MMA). The reaction process as shown in Scheme 1.

Scheme 1 Synthesis of the Amphiphilic Poly(MMA-co-DMAEMA)

TEM Experiments

Transmission electron microscopy (TEM) was performed on a JEM 1200 EX, a drop of sample solution was placed onto a copper grid coated with carbon. Water was allowed to evaporate from the grids at room temperature.

Results and Discussion

1H NMR

The ^{1}H-NMR spectra of Poly(MMA-co-DMAEMA) is shown in Fig.1. The characteristic chemical shifts of polymer are clearly assigned: 0.871-1.291(-CCH_2C$\underline{H}_3$), 1.419-1.989(-CC$\underline{H}_2$CH_3), 2.01-2.364(-N(C$\underline{H}_3$)$_2$), 2.614(C$\underline{H}_2$N(CH_3)$_2$), 3.583 (-OCOC$\underline{H}_3$), 4.055 (-OCOC$\underline{H}_2$-), The ^{1}H NMR result is thus consistent with the structure of the copolymer.

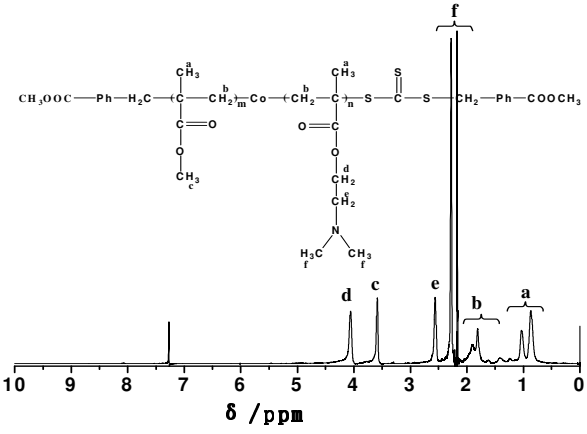


Fig. 1 ^{1}H-NMR spectra of the amphiphilic Poly(DMAEMA-co- MMA) in $CDCl_3$

GPC

The number-average molecular weight were determined by GPC with polystyrene standards to be 1.83×10^4 , weight-average molecular weight (Mw) / number-average molecular weight (Mn) =1.15. The GPC trace (Fig.2)of the graft copolymer showed a unimodal shape. This further indicated that the polymerization was completed successfully and that there was no homopolymer in the reaction product.

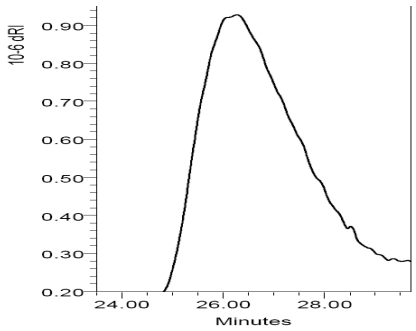

Fig. 2 GPC curve of the copolymer

TEM

The morphology of copolymer in aqueous solution was studied by TEM at room temperature are show in Fig.3. At a concentration of 1.0×10^{-4} g·mL^{-1} (Fig. 3a)， the micelles are globular, with the micellar size varying from 150 to 170 nm. Further increasing concentration, the micelles size start to increase, at a concentration of 3.0×10^{-4} g·mL^{-1}, the micelles are globular , with the micellar size varying from 300 to 320nm in Fig. 3b.

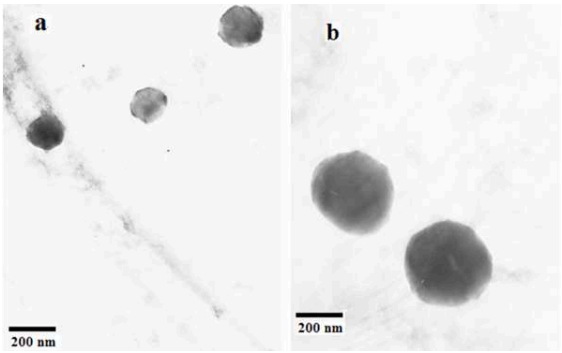

Fig. 3 TEM image of copolymer micelles in aqueous solution

Conclusions

In this study, a novel amphiphilic block copolymer Poly(MMA-co-DMAEMA) was successfully synthesized by RAFT copolymerization. The polymer structure was characterized by ^1H *NMR* , GPC and TEM. The results show that Poly(MMA-co-DMAEMA can form stable micelles in queous solution, the sizes of micelles was found to be related with the copolymer concentration, the sizes increased with concentration. More attention will be paid to the study of the supramolecular self-assembly behavior of the copolymer in aqueous solution and organic solvents in the future.

Keywords: antibacterial, essential oil, Eugenol

Abstract. Essential oils are produced by plants for many reasons including protection against various bacterial and fungal. This study provides a dose-response analysis for antibacterial activity assessment using *Escherichia coli* DH5 as indicator microorganism. In this work it has been shown that it is possible to extract antibacterial activities using a simple process.

Introduction

The essential oils are volatile liquids extracted from various plants that generally grow in tropical countries [1]. Plant essential oil is reported to be a rich source of bioactive compounds like benzalde-hyde, carvacrol, carvone, cineole, cinnamaldehyde, citral, cymene, estragole, eugenol, geraniol, limonene, menthol, pinene, terpenene,terpineol, thymol and vanillin. These bioactive compounds of plant origin exhibit antibacterial, antifungal, antigiardia and antioxidant. Plant essential oils are potentially useful sources of naturally derived antimicrobial compounds. They not only have pleasant fragrances, but also possess many useful biological activities [2-5]. The essential oils from a number of aromatic crops are extracted through steam distillation, with each plant species often having a distinct temperature and duration of the distillation process. The steam distillation of any aromatic crop results in four products: (i) essential oil; (ii) steam-distilled (residual) plant material; (iii) residual water; and (iv) hydrolat. Eugenol (4-allyl-2- methoxyphenol) is the major constituent of several important essential oils such as clove, pimento berry, bay, nutmeg and cinnamon oil. It is commonly used as a fragrance and flavoring agent in a variety of cosmetics, and food products. Eugenol has shown antimicrobial, antioxidant, anti-inflammatory, antispas- modic, antidepressant, antigenotoxic, and anticarcinogenic properties [1, 6] .

The essential oils from plants play an important role in medicine and cosmetic industry. Since their discovery, antimicrobial drugs have proved remarkably effective for the control of bacterial infections. The antimicrobial compounds from plants may inhibit bacterial growth by different mechanisms than those presently used antimicrobials and may have a significant clinical value in treatment of resistant microbial strains. Examples of some microorganisms that gained resistance to antimicrobials are: *Escherichia coli* and *Streptococcus faecalis.* This study provides dose-response relations which are regularly used in antibacterial activity, as a quantitative analysis to show the criteria of 50% effective concentration EC_{50} [7]. The principle of antibacterial activity indicated that for all materials there is a minimum concentration. In this study, the essential oil extraction technique was used steam distillation; the aim of this work was to evaluate the influence of essential oil and eugenol of antibacterial activities.

Materials and Methods

Fresh plant (200 g) was placed in a flask which was connected to a boiler. The steam was produced in the boiler by electrical heating of distilled water. As the water started to boil, the vapor from the boiler went through the fresh plant. Then the vapor and the essential oil extracted from the plant passed through the cooler, where both the oil and water were condensed and collected (Fig. 1). The operation lasted 2 h.

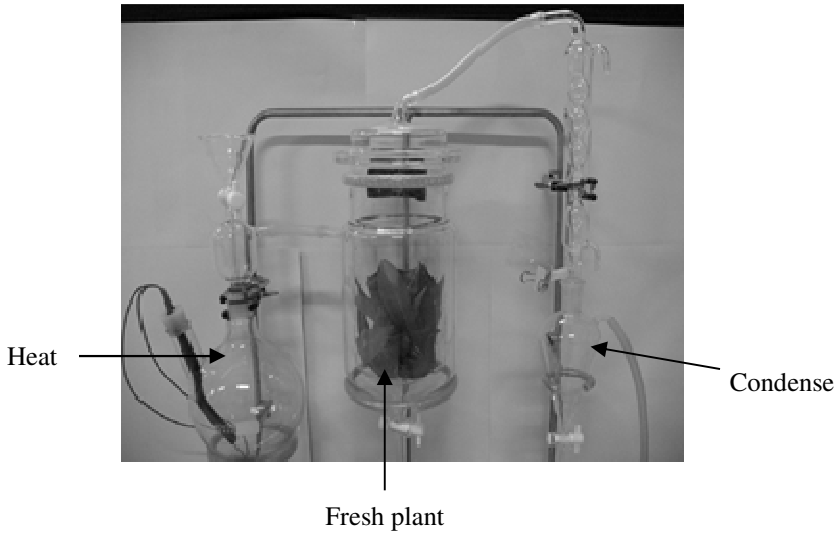

Fig. 1 Experiment equipment

As E. coli is commonly found in the lower intestine of human body, we intentionally selected E. coli as an indicator microorganism to reveal preliminary screening of antibacterial activity of plant extracts. The E. coli DH5α used in this study was provided by Professor Bor-Yann Chen, NIU, Taiwan. E. coli DH5α was pre-cultured in Luria-Bertani (LB) broth (10 g/L tryptone, 5 g/L yeast extract, 10 g/L NaCl) at 37 °C, 125 rpm for 12 h. All the essential oils used in this study were high-purity liquid from steam distillation method. Each essential oils was diluted to various concentrations, and mixed with sodium citrate buffer solution, 0.5× LB, and deionized water to formulate essential oil solutions ranging between 0 mg/L and 2000 mg/L. Subsequently, cultured E. coli DH5α solutions were added to each essential oil solution at a volume ratio of 1:100. The E. coli DH5α concentration was then determined by measuring the of the cell solution optical density (OD) value every 30 min for the initial 5 h, and then every 1 h up until 24 h. The cell solution OD value was measured at 600 nm (OD600) in a spectrophotometer (GENESYS 20, Thermo Scientific) using cultured broth as the blank cuvette [8-9].

Results and Discussion

Probit analysis [10] was adopted to reveal dose response curves of various metal ions. The probit model postulates that the tolerance capacity of individuals in response to toxic material in a given population is Log-normal distribution. A semilogarithmic plot of metal concentration versus the provoked response is assumed to reveal a linear relation. The probit model converts sigmoid-shaped dose-response curve into a linear normal equivalent deviation scale. For example, the 50% and 84.1% response correspond to the NED scale in 0 and 1, respectively. In addition, a probit unit in the model equals NED scale plus 5. The conversion formula are shown as follows:

$$Y = A + B \log_{10} Z$$

$$P = \frac{1}{2}\left\{1 + erf\left(\frac{Y-5}{\sqrt{2}}\right)\right\}$$

$$erf(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-\xi^2} d\xi$$

where A and B denote the intercept and slope of dose–response relation, Z and Y are metal concentration (mg/l) and probit unit, respectively; P is the response (%) corresponding to administered metal, erf(x) is an error function. Note that the response variable is normalized to be located between 0 and 1. The conversion relation between the probit unit and provoked response is listed in Table 1. For example, 55 and 85% of response correspond to probit unit of 5.13 and 6.04, respectively. The responses for antibacterial activities are determined by $1-\mu/\mu_0$ and $1-L_0/L$, respectively, where μ and L denote the maximum specific growth rate and the adaptation lag time. [8-9].

TABLE 1. CONVERSION RELATION BETWEEN ANTIBACTERIAL ACTIVITIES RESPONSE (%) AND PROBIT UNIT

%.	0	1	2	3	4	5	6	7	8	9
0	2.60	2.67	2.95	3.12	3.25	3.36	3.45	3.52	3.59	3.66
10	3.72	3.77	3.82	3.87	3.92	3.96	4.01	4.05	4.08	4.12
20	4.16	4.19	4.23	4.26	4.29	4.33	4.36	4.39	4.42	4.45
30	4.48	4.50	4.53	4.56	4.59	4.61	4.64	4.67	4.69	4.72
40	4.75	4.77	4.80	4.82	4.85	4.87	4.90	4.92	4.95	4.97
50	5.00	5.03	5.05	5.08	5.10	5.13	5.15	5.18	5.20	5.23
60	5.25	5.28	5.31	5.33	5.36	5.39	5.41	5.44	5.47	5.50
70	5.52	5.55	5.58	5.61	5.64	5.67	5.71	5.74	5.77	5.81
80	5.84	5.88	5.92	5.95	5.99	6.04	6.08	6.13	6.18	6.23
90	6.28	6.34	6.41	6.48	6.55	6.64	6.75	6.88	7.05	7.33
100	8.10									

Probit unit of 2.60, 4.16 and 5.00 correspond to the threshold (bottom; EC0), EC20 and median effective response (EC50), respectively. (Chen et al., 2004, 2006).

The conversion relation between the probit unit and response could be calculated from Eqs. (1)-(3) and simulated results were listed in Table 2. As indicated in Table 2 for antibacterial activities of essential oils, EC_{20} and EC_{50} values all point to the essential oils series being *Eugenol* > *Melaleuca alternifolia essential oil* > *Basil essential oil*.

TABLE 2. CRITICAL EFFECTIVE CONCENTRATIONS OF 'ANTIBACTERIAL ACTIVITIES' PREDICTED FROM THE PROBIT MODEL

	EC_{20}(mg L^{-1})	EC_{50}(mg L^{-1})
Eugenol	718.7	1463.5
Basil essential oil	987.2	1724.3
Melaleuca alternifolia essential oil	930.4	1682.6

Summary

In recent years, the essential oils and the herbal extracts from various plants have attracted a great deal of scientific interest due to their potential as a source of natural agents to increase the safety and shelf life of cosmetic active compounds. In this work it has been shown that it is possible to extract antibacterial activities using a simple process (steam distillation extraction). Based on these conclusions, future investigations will focus the research on the in extraction techniques and on chemical identification of the antimicrobial ingredients.

Keywords: cellulose fibers; β-cyclodextrin; FTIR; CP-MAS NMR; antibacterial activity

Abstract: Cyclodextrins (CDs) can form inclusion complexes with a variety of molecules making them very attractive in different areas, such as pharmaceutics, biochemistry, food chemistry and papermaking. In this communication the preparation of β-cyclodextrin-grafted cellulose fibers was carried out by reacting β-cyclodextrin with cellulose fiber via citric acid (CA). Both fourier transform infrared (FTIR) and cross polarization magic angle spinning solid state nuclear magnetic resonance (CP-MAS NMR) indicated that β-CDs had been chemically attached to cellulose backbone through the formation of ester bonds. Furthermore, the β-CD-grafted cellulose fibers formed inclusion complexes with ciprofloxacin hydrochloride (CipHCl). And the β-CD-grafted cellulose fibers loaded with CipHCl showed excellent antibacterial activity against *E.coli* and *S.aureus*.

Introduction

β-Cyclodextrins (β-CDs) are cyclic oligosaccharides containing seven D-glucose units linked by α-1, 4 glycosidic bonds and they contain a hydrophobic cavity which can entrap small molecules. β-CDs can also be grafted onto macromolecules with cross-linkers to make the substrate functionalized by hosting some small agents [1,2].

Cellulose is the abundant natural polymers on earth. It is virtual and inexhaustible source of raw materials for environmentally friendly, biocompatible, renewable and modifiable polymers which makes it one of the most promising feedstocks for industry in the future [3]. In order to increase the functionality of cellulose, synthesis procedures have been developed. In fact, the modification and functionalization of nature fibers with CDs is being implemented. A number of cross-linking agents are utilized to graft β-CD onto cellulose, such as epichlorohydrin, cyanuric chloride, N-methylol acrylamide, polycarboxylic acids [4-6]. In this paper, β-CD was grafted onto the cellulose fiber with citric acid as cross-linkage, and the modified cellulose fibers were characterized by means of FTIR spectroscopy, solid-state NMR, TGA and SEM. Moreover, ciprofloxacin hydrochloride was loaded into grafted β-CD to obtain the antimicrobial cellulose fiber and the inhibition activities of β-CD grafted cellulose fibers containing the antibiotics against gram-negative and gram-positive bacteria were also investigated.

Experimental Procedure

β-cyclodextrin citrate (CA-β-CD) was prepared firstly by semidry reaction between β-CD and citrate acid [7]. The obtained CA-β-CD (0.3g) and SHP (0.1g) was dissolved in distilled water (10mL), followed by adding cellulose fiber (1.0g) and cured at 160℃ for 15 min. FT-IR (Vector 33; Bruker) and solid-state CP/MAS ^{13}C-NMR (AVANCE 300; Bruker) was applied to characterize the structures of modified cellulose fibers. Thermal analysis was performed using TGA (Q500, TA Instruments) and the morphology of modified cellulose fibers was investigated by SEM (S3700, Hitachi).

β-cyclodextrin-grafted cellulose fibers (1g) were immersed into CipHCl aqueous solution (100mg/g oven dry fiber) for 4h. The obtained samples were washed with distilled water and dried at 60℃ for 24h.

The inhibition efficiency of the cellulose fibers with antibiotics against *E.coli* was assessed with a shaking flask method [8].

Results and Discussion

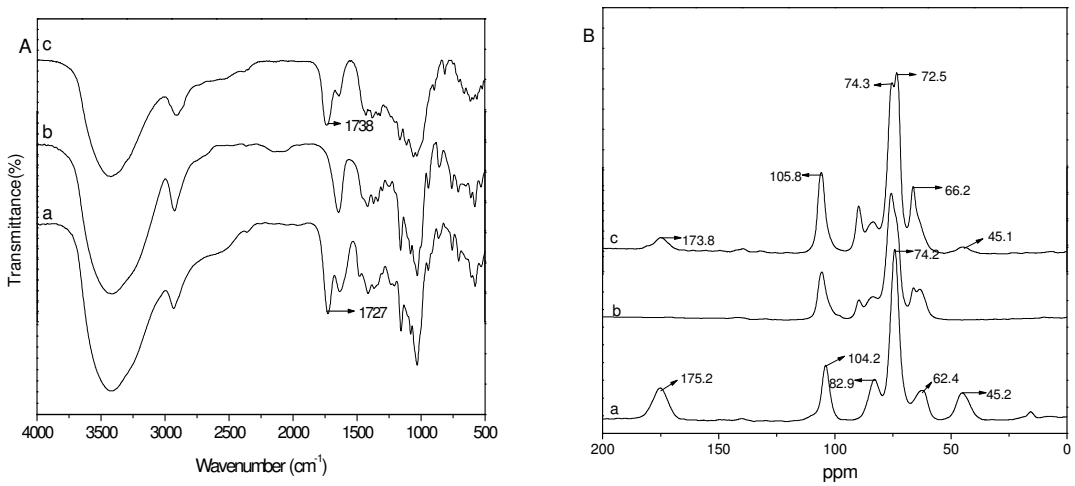

Fig. 1 FT-IR spectra (A) and solid-state CP/MAS ^{13}C-NMR spectra (B) of CA-β-CD (a), native cellulose fibers (b) and β-CD-grafted cellulose fibers (c)

The FT-IR spectra of CA-β-CD, native cellulose fibers and β-CD-grafted cellulose fibers are shown in Fig. 1A. For the free β-CD, the adsorption at 3404, 2933, 1416, 1370, 1180, 1029 cm^{-1} are an indicative of β-CD [9]. Comparatively, the bands in CA-β-CD are qualitatively the same except a new vibration at 1727cm^{-1}, which is indicative of ester group, suggesting that esterification reaction occurred between β-CD and CA. From the spectra of unmodified and modified cellulose fibers, A new vibration at 1738 cm^{-1} can be observed in modified cellulose fibers and assigned to a C=O stretching vibration mode characteristic for an ester bond. This suggests that the carboxylic acid from CA-β-CD forms ester bonds with the hydroxyl groups from cellulose fiber at elevated temperature. The results showed that β-CD had been successfully grafted onto cellulose fiber by this approach.

The esterification has also been confirmed by solid-state CP/MAS ^{13}C-NMR spectra (Fig.2 B). It has already been shown that the spectra of the free β-CD is relatively poorly resolved due to the presence of multiple resonances for the C-atoms of the glucose unites (C2, C3, C3,C4, C5 and C6), which can be ascribe to the co-existence of different structural arrangements induced by partial

hydration of the sample [10]. The signals between 55 and 110ppm are assigned to the C-atoms, and the assignments of each carbon were made with reference to the literature [11]. Compared with the free β-CD, a significant signal is present at 175.2ppm assigned to carbonyl group, indicating that the esterification reaction occurred between β-CD and CA. For the cellulose fibers，the signals between 55 and 110 ppm are attributed to carbon in the carbohydrate, while the small signal peaks between 110 and 160ppm are assigned to carbon of lignin. The next two peaks at 74.8 and 72.5 ppm are from cellulose C2 and C3. Finally, the peak at 105.8 ppm is due to the C1 of cellulose. Comparatively, a new signal at 173.8 ppm is assigned to the carbonyl group of modified cellulose fibers for an ester bond which confirms the reaction between carboxylic acid from CA-β-CD and hydroxyl groups from cellulose fibers. In addition, an obvious signal at 45.1 ppm is due to $–CH_2$ from CA. This also confirmed the reaction between CA-β-CD and cellulose, therefore β-CD was grafted onto cellulose fibers with citric acid as a bridging.

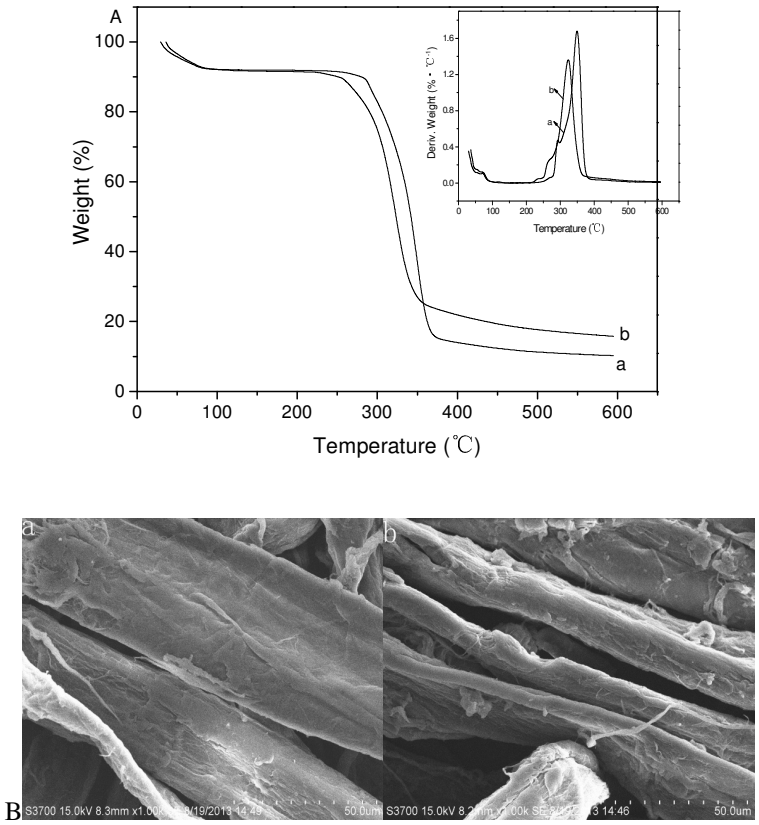

Fig. 2 TG and DTG (A) profiles and SEM (B) of native cellulose fibers (a), β-CD-grafted cellulose fibers (b)

The thermogravimetric behaviors of native cellulose fibers and cellulose fibers grafted with β-CD are illustrated in Fig. 2A. Two degradation steps can be observed up to 600℃: the first one at a temperature around 100℃ is due to the loss of water evaporation, while the second one is due to the start decomposition of various compositions in samples. The remainder weights at 600℃ were 11% and 13% for native cellulose fibers and β-CD-grafted cellulose fibers, respectively. Moreover, the temperatures at the maximum degradation rate (T_{max}) of all samples were determined from the maximum of DTG curves. The peaks corresponding to the maximum weight loss rate were present 350℃ with 60% weight loss for native cellulose fibers, while at 292℃ with 15% weight loss and 348℃with 63% weight loss for cellulose fibers grafted with β-CD. The incorporation of β-CD into cellulose fibers lead to a decrease in the T_{max}, which might be attributed to the presence of β-CD and an increase in the disorder of cellulose molecular packing.

Fig. 2B shows the morphologies of cellulose fibers before and after modification. The morphology of cellulose fibers after esterification is similar with unmodified cellulose fibers because of the occurrence of chemical modification on the surface of cellulose fibers and no serious disruption inside.

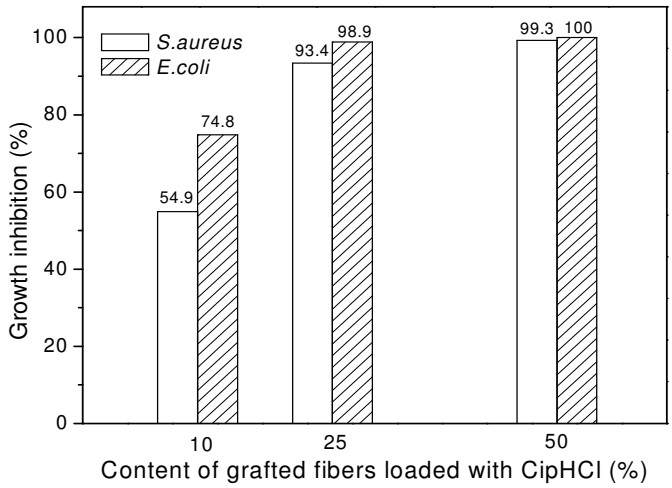

Fig. 3 Effect of β-CD grafted fibers loaded with CipHCl content on the growth inhibition of sheets against E.coli and S.aureu

The effect of modified cellulose fiber content on the growth inhibition of sheets with the shaking flask method is shown in Fig. 3. With the increasing of modified cellulose fiber content, the growth inhibition against *E.coli* and *S.aureu* both increase. The growth inhibition against *E.coli* and *S.aureu* both reach about 100% when modified cellulose fiber content is 50%, suggesting that all the bacteria were killed. Moreover, the growth inhibition of sheets against *E.coli* is higher than that against *S.aureu*, probably due to the difference in walls between Gram-negative and Gram-positive bacteria.

Conclusion

Cellulose functionalization is still a hot topic. FTIR and solid-state CP/MAS ^{13}C-NMR showed that β-cyclodextrin had been successfully grafted onto cellulose fibers. And the β-CD grafted fibers loaded with CipHCl exhibited excellent antibacterial activities against *E.coli* and *S.aureus*. This approach opens the way to develop antibacterial paper products that may be useful to prevent wound and nosocomial infections in medical and packaging fields.

Abstract: Adsorption performances of activated carbon Norit RO 0.8, neutral resin Amberlite XAD-7, anion resin Dowex 1x4 and cation resin Dowex 50wx4 were investigated in detail for artificial liver support devices. Firstly, equilibrium adsorption experiments of these adsorbents to albumin, creatinine, bilirubin, tryptophan and cholic acid were conducted respectively. Then their adsorption capacities were obtained by curve fitting. The results indicate that activated carbon Norit RO 0.8 and anion resin Dowex 1x4 are two better adsorbents for removing toxins. Lastly, adsorption rate constants of activated carbon Norit RO 0.8 and anion resin Dowex 1x4 to all above solutes were studied with pseudo-first and second-order kinetic adsorption models. The results show that the toxin adsorption rate of anion resin Dowex 1x4 is faster than that of activated carbon Norit RO 0.8. The systematical experimental results in this paper are very important references for researchers in the field of blood purification based on adsorption technology.

Introduction

Adsorbents are key parts of artificial liver support devices. They dominate the clearance of toxins in patients with liver failure. Therefore, the selection of adsorbents is very crucial. Since the concept of adsorption is introduced into artificial liver devices, many efforts have been focusing on the selection/search of adsorbents with specific adsorption, high adsorption capacity and good biocompatibility.

Activated carbon is a widely used adsorbent in artificial liver support devices [1-3]. Generally, powdered activated carbon, because of its large surface area, can removed more toxins than granular activated carbon; however, it easily causes a large pressure drop across the detoxifying column [4]. In order to improve biocompatibility, activated carbon usually is coated with albumin or cellulose [5]. Activated carbon is a non-specific adsorbent. It removes not only harmful toxins but also useful substances. In order to improve specificity, lots of resins are being tried. There are three types of resins: anion, neutral and cation. In general, anion exchange resin are used to remove protein-bound toxins, e.g. bile acids; cation exchange resins are for ammonium [6]; neutral resins are for the adsorption of water-insoluble substances, e.g. aromatic amino acids [7]. As ammonium can be removed by dialysis, cation exchange resin could be of no major benefit to the liver therapy [6]. Currently, Molecular Adsorbent Recirculating System uses activated carbon and anion exchange resin whereas Prometheus System uses neutral and anion exchange resins [8, 9]. Although various adsorbents are investigated in/for artificial liver support devices, the study of the measurement of the basic adsorption parameters of these adsorbents is scattered and also is relatively little in the literature.

The measurement of adsorption parameters of adsorbents to toxins is a basic and important research. It not only can estimate the use or regeneration time of adsorbent cartridges for artificial liver support devices, but also can facilitate the development of mathematical models to predict the adsorption efficiency of artificial liver support devices. In this paper, based on the literature, four typical adsorbents i.e. activated carbon Norit RO 0.8, neutral resin Amberlite XAD-7, anion resin

Dowex 1x4 and cation resin Dowex 50wx4 were chosen as candidates because of their highly frequent appearance in removing harmful substances or drugs. Then, adsorption parameters i.e. adsorption capacities and kinetic adsorption rate constants of these adsorbents to albumin, creatinine, bilirubin, tryptophan and cholic acid were studied systematically.

Materials and Methods

Bovine serum albumin (Cohn fraction V, MW = 66,000), creatinine, tryptophan, cholic acid, dimethyl sulfoxide (DMSO, ≥99.5%), sodium carbonate (anhydrous, ≥99.95%), activated carbon (Norit® RO 0.8), resins Amberlite XAD-7 Dowex 1x4 and 50wx4 were bought from Sigma-Aldrich, USA. Bilirubin (MW = 584.68) was from VWR, USA. Hydrochloride acid (1.0N) was purchased from Chemistry Store at the University of Washington. The hemodialyzer was Gambro® Phoenix™.

Batch experiments were performed to determine all adsorption parameters. Each adsorption experiment generally includes five steps: adsorbent preparation, solution preparation, equilibrium/kinetic adsorption, concentration test, and data analysis. All kinetic adsorption experiments almost were the same as equilibrium experiments except that the real-time samples were taken from flasks quickly. Take the case of bilirubin adsorption onto activated carbon, detailed operations are as follows:

Activated Carbon Preparation

Before experiments, a given amount of activated carbon (dry), e.g. 0.5g, was weighed and placed in a 50 ml plastic tube flask. Dialysate, prepared from the Gambro machine, was added into the tube and the tube was placed for at least 48h to remove air bubble and then was washed to remove carbon ash and small debris. Generally, for each case, at least 5 concentration situations were considered, so 5 activated carbon samples were prepared. Sometimes 5 concentrations were not enough to determine the adsorption parameters. Under this situation, multiple concentrations were conducted.

Bilirubin Solution Preparation

First, dialysate was produced by the hemodialysis machine. Second, it was used to prepare the bilirubin mother solution with 2% albumin and 200mg/l bilirubin (During the process, DMSO was added into the weight boat to dissolve the bilirubin powder, 0.25M Na_2CO_3 solution was used to help dissolution, and 1.0N HCl solution was added drop by drop to adjust the pH value of the solution to about 7.3). Third, according to the experimental requirement, the bilirubin mother solution was diluted step by step to obtain serial concentrations with the 2% albumin solution, e.g., 200, 150, 100, 50, 10mg/l.

Bilirubin Adsorption

Before experiments, dialysate in each sample tube was carefully sucked out using pipettes. Then, for each solution, take one sample for testing the initial concentration and add the given volume (usually 25ml) into one tube. Finally all tubes were horizontally placed on an oscillator shaker with 60rpm (KJ-201BJ). Samples were taken after 24 hours in equilibrium experiments or at desired time in kinetic experiments. All experiments were repeated at least 3 times.

Bilirubin Concentration Test

The spectrophotometer (Spectra Max 190) was used to test all concentrations of solutes. All samples were tested in 3 days. Albumin (BCG), creatinine and total bilirubin (Diazonium Salt) reagents were from Fisher Scientific, USA. All methods for testing solute concentrations were from the product specifications or [10]. Each sample was tested at least 3 times and an average value was used.

Equilibrium Isotherm

The Langmuir isotherm is a simple model frequently used to understand adsorption under a variety of situations. Although one might like to use other adsorption isotherms such as the Freundlich isotherm and the Toth isotherm to describe the adsorption phenomena, in all cases except bilirubin in this study, the Langmuir isotherm is good enough. The Langmuir equation is expressed as $q_e=ac_e/(1+bc_e)=q_mbc_e/(1+bc_e)$, where, q_e (mg/g) is the toxin adsorbed by an adsorbent at equilibrium,

c_e (mg/l) the toxin concentration at equilibrium, q_m (mg/g) the maximum value of the toxin adsorbed by an adsorbent (on the first layer), a the fitted constant, and b the fitted constant.

Regarding the bilirubin adsorption, the Langmuir isotherm is used under the condition of low bilirubin concentrations [11]; however, in the broad range of bilirubin concentrations, the experimental results could be apt to BET isotherm [12]. The Langmuir isotherm is a monolayer model whereas the BET isotherm is a multilayer adsorption model. In this study, the modified BET isotherm for the liquid phase adsorption was used [13]: $q_e=q_m k_s c_e/[(1-k_l c_e)(1-k_l c_e+k_s c_e)]$, where, k_l and k_s are constants.

Kinetic Adsorption

Several kinetic models can be used to examine the mechanism of adsorption process. In this study, pseudo-first-order and pseudo-second-order equations, which derive from chemical/reaction kinetics, were used. The pseudo-first and second-order equations [14, 15] are expressed as $dq_t/dt = k_1(q_e-q_t)$ and $dq_t/dt = k_2(q_e-q_t)^2$, respectively, where, q_e and q_t are the toxins adsorbed at equilibrium and time t, respectively, k_1 and k_2 the fitted rate constants of pseudo-first and second-order adsorptions, respectively.

Results and discussion

Adsorption capacity is an important parameter for artificial liver support devices. In this study, equilibrium adsorption experiments were conducted. Fig.1 shows two typical examples of equilibrium isotherms with respect to different adsorbents. Equilibrium adsorptions of all solutes except bilirubin can be described by the Langmuir isotherm. Compared to the cholic acid adsorption (Fig.1, left), the bilirubin adsorption isotherms are more complicated (Fig.1, right). The results show that when the resin Dowex 1x4 or 50wx4 is used, the experimental adsorption curve agrees with the Langmuir isotherm. However, when activated carbon or resin XAD-7 is used, it is apt to the BET isotherm.

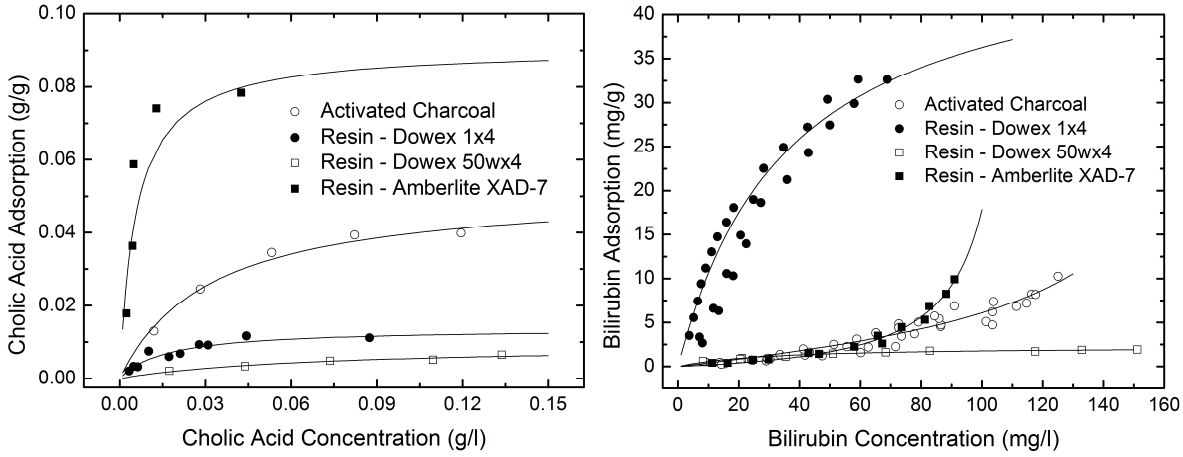

Figure 1 Equilibrium adsorption of cholic acid (left) and bilirubin (right)

Bilirubin is a specific albumin-bound toxin. Comparing to tryptophan and cholic acid, its solubility is relatively low. Without the help of albumin, it is hard to be dissolved. Therefore, the adsorption of bilirubin strongly depends on albumin conditions. Activated carbon or resin XAD-7 can absorb albumin molecules only in large pores. In the space with small pores, almost no carriers, i.e. albumin molecules appear. For free bilirubin molecules in the internal space, they have two possible directions to go. One is to arrive at the void site in small pores; the other is to reunite with bilirubin already adsorbed on the surface and form multilayer adsorption. The tendency depends on affinity. Possibly, the affinity between bilirubin and activate carbon or resin XAD-7 is weaker than that between bilirubin molecules. As time goes on, the bilirubin multilayer adsorption becomes more and more notable. Finally, the adsorption isotherm is similar to BET. The affinity between bilirubin and resin 1x4 could be stronger. Then, the adsorption of bilirubin onto resin 1x4 is close to the Langmuir isotherm.

Adsorption capacities of all adsorbents were obtained by curve fitting, which are listed in Tables 1 and 2. The results indicate that creatinine is only adsorbed by activated carbon. Resin XAD-7 adsorbs a lot of albumin whereas others slightly adsorb albumin. Tryptophan is mainly adsorbed by activated carbon. For the removal of cholic acid, activated carbon and resin XAD-7 are better choices. With respect to bilirubin, the best adsorbent is resin 1x4.

Albumin is a very important protein in carrying non-water-soluble toxins. The loss of albumin is not expected during the treatment with artificial liver support devices. Therefore, the adsorbent which adsorbs fewer albumin molecules is better. Resin XAD-7 can remove more cholic acids; however, it also loses more albumin molecules. So, resin XAD-7 is not an ideal choice. Resin 50wx4 can remove tryptophan, cholic acid and bilirubin, but the capacities are relatively low. Considering all aspects, activated carbon and anion resin Dowex 1x4 are two better choices. Then, in the following kinetic adsorption, only activated carbon and resin 1x4 are used.

TABLE 1 EQUILIBRIUM ADSORPTION PARAMETERS FOR CREATININE, ALBUMIN, TRYPTOPHAN AND CHOLIC ACID

Solute	**Adsorbent**	**a**	**b**	q_m **(g/g)**	$\mathbf{R^2}$
Creatinine	Carbon	16.273	0.0763	0.2132	0.9964
Albumin	Carbon	0.0762	1.9199	0.0397	0.9285
Albumin	Resin 1x4	0.0368	2.6189	0.0141	0.9602

Cholic Acid	50wx4	0.1344	14.666	0.0092	0.9282
Cholic Acid	XAD-7	15.823	174.76	0.0905	0.9691

TABLE 2 BILIRUBIN EQUILIBRIUM ADSORPTION PARAMETERS

Adsorbent	k_l	k_s	q_m **(mg/g)**	$\mathbf{R^2}$
Carbon	4.86E-03	7.47E-03	5.316	0.9134
XAD-7	8.68E-03	5.41E-03	2.936	0.9872
Adsorbent	**a**	**b**	q_m **(mg/g)**	$\mathbf{R^2}$
Resin 1x4	1.3563	0.02740	45.504	0.9231
50wx4	0.0791	0.03495	2.2619	0.9902

Adsorption rate constant is another important parameter in evaluating the performance of adsorbents. Small adsorption rate constant means that it takes long time for toxins to be removed. In order to reduce the toxin level in patients to normal range, the treatment time would have to been prolonged. In clinic, it is not acceptable because long treat time means high risk.

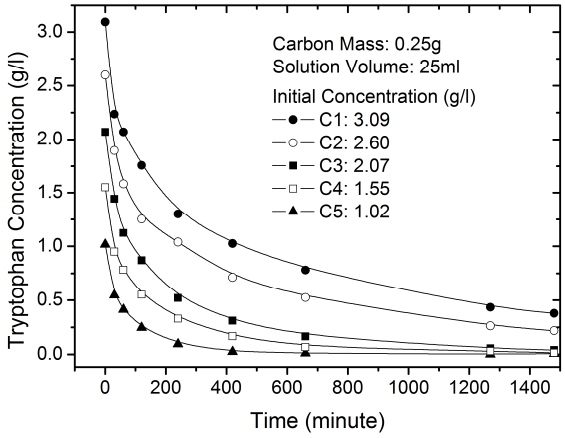

Figure 2 Tryptophan kinetic adsorption onto activated carbon

In the kinetic adsorption experiments, five different initial concentrations were used. Fig. 2 shows curves of tryptophan kinetic adsorptions onto activated carbon. The results show that the concentration of tryptophan decreases as time increases. According to these data, pseudo-first and second-order kinetic adsorption parameters can be obtained by curve fitting, which are listed in Tables 3 and 4, respectively.

Generally, the smaller the molecule is, the faster the adsorption is. Take the case of activated carbon. Among all solutes, creatinine molecule weight is the smallest, so the adsorption is the fastest. Tryptophan is the second solute regarding adsorption rates. Both bilirubin and cholic acid adsorption rates are close for their molecule weights are close. In addition, the adsorption rate constant could depend on the initial concentration because the experimental results indicate that the adsorption rate constant increases as the initial concentration decreases (in Tables 3 and 4, the initial concentration decreases from C1 to C5). This is especially obvious when the pseudo-second-order kinetic is used. The results also show that the toxin adsorption rate of resin 1x4 is faster than that of activated carbon.

TABLE 3 PSEUDO-FIRST-ORDER KINETIC ADSORPTION PARAMETER (UNIT: 1/MIN; VALUE: ×10-3)

Adsorbent	Solute	C1	C2	C3	C4	C5
Carbon	Creatinine	53.6	49.8	51.5	60.9	50.6
Carbon	Bilirubin	6.06	5.48	5.32	6.60	6.72

Resin 1x4	Cholic Acid	9.88	13.6	17.5	12.6	19.5

TABLE 4 PSEUDO-SECOND-ORDER KINETIC ADSORPTION PARAMETER (UNIT: G /(MG · MIN); VALUE: $\times 10^{-3}$)

Adsorbent	Solute	C1	C2	C3	C4	C5
Carbon	Creatinine	0.352	0.322	0.402	0.646	0.640
Carbon	Bilirubin	1.868	2.414	2.143	2.970	1.107
Carbon	Tryptophan	26.35	34.52	55.14	97.43	281.4
Carbon	Cholic Acid	74.70	157.2	225.9	463.9	1681
Resin 1x4	Bilirubin	16.56	18.07	23.03	23.20	24.80
Resin 1x4	Tryptophan	468.4	570.9	547.6	839.9	1215
Resin 1x4	Cholic Acid	895.9	1389	2547	3206	12082

Theoretically, for a given situation, the adsorption rate should be a constant. However, in practice, it is related to the operation. For example, the adsorption rate constant is affected by stir speed. In our experiments, the speed 60rpm guarantees the solution mixed well; however, it is hard to know if 60rpm is an optimal rotation speed or not. One might increase rotation speeds, but have to take the risk of solution stability or the carbon debris, which could consequently result in the fake increase of toxin adsorption rates. In this study, all kinetic adsorption experiments were done under the same conditions. The speed 60rpm is an eclectic protocol, which balances all pros and cons.

Conclusions

In this paper, the equilibrium adsorption experiments of activated carbon, resin Amberlite XAD-7, resin Dowex 1x4 and resin Dowex 50wx4 to albumin, creatinine, bilirubin, tryptophan and cholic acid were conducted respectively. Then, adsorption capacities of different adsorbents to different solutes were obtained by curve fitting. Based on adsorption capacities, Norit RO 0.8 activated carbon and Dowex 1x4 anion resin are better for artificial liver support devices. After the equilibrium adsorption experiments, the kinetic adsorption experiments were performed. Kinetic adsorption rate constants of creatinine, bilirubin, tryptophan and cholic acid onto activated carbon and resin Dowex 1x4 were obtained by curve fitting. The results show that the toxin adsorption rate of anion resin Dowex 1x4 is faster than that of activated carbon Norit RO 0.8. Because the systematic measurement

of the basic adsorption parameters in the area of blood purification based on adsorption technology is relatively little in the literature, the systematic results in this paper are important references for researchers in their future work.

Abstract. FNR (fumarate nitrate reduction regulator) is an important oxygen regulation protein, which plays a major role in altering gene expression between aerobic and anaerobic conditions. In this study, the tertiary structure of FNR protein in *Klebsiella pneumoniae* was established using homology modelling. The model was modified and optimized using molecular mechanics and molecular dynamics simulations. In addition, Support Vector Machines (SVMs) was applied to predict the possible binding sites patches of FNR. The residues conservations were further analyzed and it was found that the Asn138-Ser162 region of FNR protein was the putative dimerization interface.

Introduction

1,3-propanediol as a monomer of polyesters, polyehters or polyurethanes can be produced by glycerol in *Klebsiella pneumoniae* under anerobic and aerobic conditions[1]. The oxygen regulation mechanism has attracted increasing interest. Fumarate & nitrate reduction (FNR) was the primary oxygen sensor. It controls the physiological switch between aerobic and anaerobic growth conditions [2]. Although some researches about FNR in *Escherichia coli* were reported[3], little information is known about the oxygen regulation mechanism in *K. pneumoniae*. Shaw et al [4] presented that *K. pneumoniae* FNR gene showed high similarities to *E. coli* FNR gene (98% amino acid identity), which brought great help to study the oxygen signaling systems of *K. pneumoniae*. FNR was predicted consisting of a C-terminal DNA-binding domain, which recognizes specific binding sites within FNR-controlled promoters, and an N-terminal sensory domain containing four cysteine residues (Cys20, Cys23, Cys29, and Cys122) ligated with the $[4Fe\text{-}4S]^{2+}$ cluster [5]. Under anaerobic conditions, FNR exists as a homodimer, with each monomer containing a $[4Fe\text{-}4S]^{2+}$, which promotes dimerization, site-specific DNA binding and the gene regulation. Upon a switch to aerobic conditions, the $[4Fe\text{-}4S]^{2+}$ cluster is converted to a $[2Fe\text{-}2S]^{2+}$ cluster, triggering conformational changes that induce monomerization, preventing DNA binding and hence productive interactions with RNA polymerase [6]. The oxygen regulation mechanism of FNR is not very clear and the FNR structure has not been known. The FNR structure of *E. coli* lacking the parts of N and C terminals was modeled by Moore and Crack based on the CRP structure [7]. Therefore, it is important to build the complete structure of FNR monomerization. FNR is an active homodimer in the absense of oxygen, it is necessary to analyze the dimerization interface. Several studies about protein-protein interactions had been reported, which could be helpful to find the dimerization interface of FNR protein[8,9].

In this work, the complete FNR structure of *K. pneumoniae* was constructed using homology modelling, then the model was modified and optimized using molecular mechanics and molecular dynamics simulations. The possible binding regions of FNR dimmer were predicted by Support Vector Machines (SVMs). In addition, residues conservation were analyzed, it was suggested that Asn138-Ser162 residues region was the dimerization interface.

Materials and Methods

Model Building. The FNR protein amino acid sequence of *K. pneumoniae* was obtained from the SWISS-PROT protein sequence database. The homology modelling of FNR tertiary structure was performed using Swiss-Model based on the CRP and endonuclease Ⅲ as the templates.

The function domain of FNR is similar with CRP, and the identity between FNR protein and CRP protein was 29%. However, it only showed residues Ile30-Asp237 homologous structure of FNR protein. The position of residue Cys122 was known and could be connected to one Fe atom of $[4Fe\text{-}4S]^{2+}$ cluster, but Cys20,Cys23 and Cys29 were not sure how to be connected to the rest Fe atoms of $[4Fe\text{-}4S]^{2+}$ cluster. Jervis et al[10] presented that endonuclease III structure was known and had the iron-sulfur clusters ligated by an FNR-like CysXXCysXXXXXCys motif. Then residues Cys20-Cys29 structure of FNR bounding with a [4Fe-4S] cluster was modeled by SWISS-MODEL Server using endonuclease III as a template.

Residues Met1-His19 and Leu238-Ala250 tertiary structures of FNR protein were modeled by Insight II MODELLER module, according to the results obtained from secondary structure prediction ExPASy Server. The parameters in calculations were used as the default values unless the special illustration.

Model Refinement and Validation. The molecular mechanisms and molecular dynamics were performed for the FNR model obtained from homology modeling using the DISCOVER module of Insight II and a CVFF force field. Firstly, the model was put through energy minimization for 20000 steps of the steepest descent method. Then, the model was further subjected to energy minimization for 7000 steps of the conjugate gradient technique that led to refined structure of FNR with RMS deviation less than 0.001kal/mol. Next, a water layer was set up and the molecule was positioned at the centre of the layer by defining a 1nm distance between the protein and the layer edge. FNR model was subjected to molecular dynamics run at 300K for 500000 fsec with 1 fsec each step. The output conformers were collected at every 5000 fsec. The energy profile was analyzed using Analysis module of Insight II. The reliability of the model was verified by assessment with PROCHECK.

Interface Prediction. The interface residues of FNR monomer were predicted by PPI-Pred server combined with interface analysis. The electrostatic potential of the model was calculated using the Delphi module implemented in Insight II using the continuum dielectric approach to solve the Poisson-Boltzmann equation by the finite difference method. In the calculations, the dielectric constants for FNR and the solvent were taken to be 2.0 and 80.0, respectively. The radius of solvent was 0.14nm and the specific force field PROTEIN FORMAL in Delphi was applied. In addition, the hydrophobic interaction was analyzed using Insight II.

Results and Discussion

Description of the FNR model. The optimized FNR model was illustrated in Fig. 1. The model is mainly comprised of 8 helices, 13 β-sheets, 20 coils and a [4Fe-4S] cluster. The [4Fe-4S] cluster in FNR protein is equivalent to the oxygen-responsive molecular switches[7]. A theoretical conformational analysis of [4Fe-4S] cluster was carried out. Relevant structural parameters(i.e., φ and ψ dihedrals, α angles, and distances involving the topology of the Fe atoms) were shown in Fig 2 and summarized in Table 1. The dihedral ψ (C^{α}-C^{β}-S^{γ}-Fe) varied between -23.79° and 113.40°, and the angle α (C^{β}-S^{γ}-Fe) ranged from 105.14° to 121.92°. On the other hand, the distances d_1(C-Fe) and d_2(S-Fe) showed only minor deviations from an average value of 4.19Å and 2.29Å, respectively. The dihedral φ showed nearly a *trans* conformation for coordinating Cys20, Cys23, Cys29 and Cys122. Obviously, all cysteine residues were oriented by adopting a low-energy conformation for their side-chain-torsion.

MD Simulation and Quality Assessment of the Model. The change of potential energy with time was shown in Fig. 3. It was seen that the potential energy decreased quickly in the first 100 ps, then decreased slowly to around 7010Kcal/mol after 200ps. The conformation at 500 ps was chosen as the final 3D structure for the further study.

The model was analyzed using PROCHECK program. The Ramachandran plot was shown in Fig. 4. It was seen that 94.4% residues were in the most favoured regions, 4.5% residues were in additional allowed regions, 0.4% residues were in generously allowed regions and 0.4% residues were in disallowed regions respectively. The model is considered as a high quality model as the ratio of the residues in the most favoured regions to all residues is more than 90%. This revealed that the main chain structure modeling of FNR protein was reasonable.

Determining the Dimerization Interface of FNR Protein. The binding sites patches of unbound FNR monomer structure were predicted by PPI-Pred server combined with interface analysis. Three possible interaction binding sites patches were predicted by PPI-Pred Server. The amino acid sequences corresponding to the three different patches were shown in Fig. 5. The highest scoring patches which were most likely to be part of the protein-protein binding sites were indicated in red, and the second highest scoring patches and the third highest scoring patches were indicated in blue and green, respectively. It was found that the green patches were close to N terminal and the blue patches were close to C terminal of the FNR, respectively. The red patches were mainly located on the middle parts of the FNR amino acid sequences. In the following part, residues conservations were used to find the interaction binding sites of the dimerization interface.

Fig. 5 The possible binding sites of FNR were colored differently to show the location of three patches on the amino acid sequences.

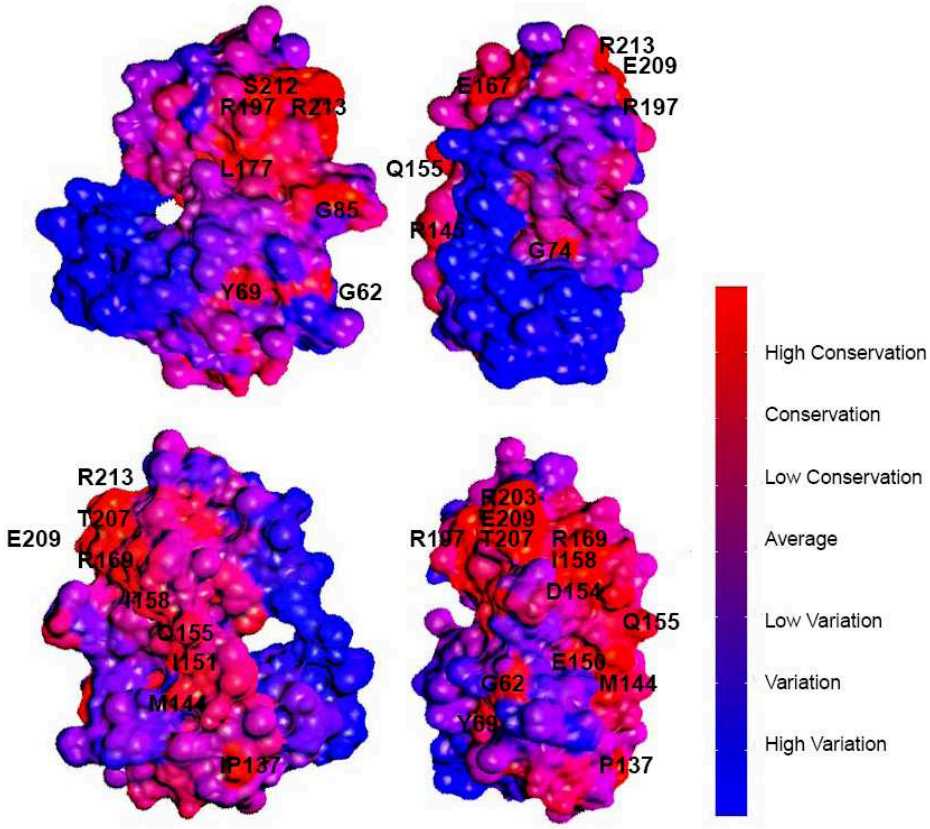

Fig. 6 The surface models of residues conservation of FNR protein predicted by PPI-Pred Server, the four views were rotated about vertical axis by 90°. Highly conserved residues were shown in Red and residues without conservation were shown in blue.

Conservations. Compared to surface residues, residues in the interface region are thought to be evolving at a slower rate. So evolutionary conservation of the residues is an important property of

the interface regions[11]. It was found that residues at the interface were more conserved than those occurring elsewhere on the protein surface in homodimer[12]. The residues conservation of FNR protein was predicted by PPI-Pred Server (Fig.6), it was observed that the highly conserved residues including: Gly62, Tyr69, Gly74, Gly85, Glu87, Asp137, Met144, Arg145, Glu150, Ile151, Asp154, Gln155, Ile158, D156, I158, Glu167, Arg169, Leu177, Arg180, Thr196, Arg197, Thr207, Glu209, Arg213, Phe218. However, not all the above residues were the residues in the interface.

The four residues of Thr207, Glu209, Arg213, Phe218 were located on the helix-turn- helix region which was the sites binding with DNA. So, the four residues were rejected. The five residues of Gly62, Tyr69, Gly74, Gly85, Glu87 were located on the ninth β-sheets region. The two residues of Tyr69 and Gly74 were not possible the residues in the interface as they were in the molecule inside. The nine residues of Met144, Arg145, Glu150, Ile151, Asp154, Gln155, Ile158, D156 and I158 were located in the α4 region. The residual residues of Glu167, Arg169, Leu177 and Arg180 were located in the α5 region. In general, the interface of dimer was big and planar. The number of conserved residues on the β-sheets was little and the interface was small and uneven. Although the interface of α5 region was planar, it was not the possible interface as the number of conserved residues was little and the α5 region was blocked by α8. The number of conserved residues on the α4 region was the most and the interface was big and planar. The residues Asn138-Ser162 of FNR were analogous to the residues of the CRP α-helix which promotes subunit interactions through formation of a coiled coil. Therefore, it was predicted that the α4 region including Asn138-Ser162 was the most probable dimerization interface.

Conclusion

In this work, the tertiary structure of FNR in *K. pneumoniae* was modeled using homology modeling and was refined by using molecular mechanics and molecular dynamics. The refined structure was validated to be reliable by using of protein validation tools. The interaction binding sites patches were predicted by PPI-Pred server. It was suggest that the Asn138-Ser162 region was the putative dimerization interface.

Keywords: Potassium Dichromate($K_2Cr_2O_7$), Surface Modification, hydrophilicity, PLA,PGLA.

Abstract: PLA and PGLA, as biodegradable polymers, are widely used in the biomedical field, such as in surgical sutures, drug delivery devices, and tissue engineering research and so on. However, the lack of hydrophilic groups on their surfaces limit their application. For improving hydrophilicity of PGA and PGLA fibers, and preserving fiber mechanical property at the same time, PLA and PGLA fibers were modified by potassium dichromate solution for different processing time for optimizing modification parameter. Breaking strength and water contact angle were tested to observe the change of properties, differential scanning calorimeter (DSC) and fourier transform infrared spectrometry (FTIR) were used to analyse the change of molecular structure and functional groups. Experimental results showed that 6min was the most suitable time for improving hydrophilicity of PLA and PGLA fibers and preserve fiber mechanical property.

Introduction

Poly-lactic acid (PLA) and poly-lactide-co-glycolide(PGLA) are thermoplastic polymers with hydrolytically labile aliphatic ester linkages[1].Their most notable includes its excellent fiber-forming ability, biodegradability and controllable hydrolytic degradation. Because of excellent properties, they are widely used in the biomedical field, such as in surgical sutures, drug delivery devices, tissue engineering research and so on[2].

However，their existing properties, such as hydrophily, can not meet the demands of tissue engineering[3]. The lack of hydrophilic groups on their surfaces also influences their biocompatibility.Therefore many researchers focus on surface modification on these materials[4,5]. Some researchers used PGLA microparticles surface-attached with TNF-related apoptosis-inducing ligand(TRAIL) to incorporated doxorubicin for inhalation treatment of metastatic lung cancer[6]. Cationic, anionic or nonionic PLA microspheres were prepared with different surface charges surfactants, and embedded on PLA membranes. The modified PLA membranes could improve the cell compatibility[7]. Some researchers grafted β-cyclodextrin(β-CD) on PLA to obtain a copolymer, which had better hydrophilicity than PLA homopolymer[8]. However, these approaches were either decreased the mechanical properties of the polymer, or too complex.

In the recent study, we attempted an easy operating and effective method to encourages the surface property of PLA and PGLA fiber, meanwhile maintains the good mechanical performance. The ester backbone can hydrolyze under the acidic condition, and the terminal hydroxyls may be oxidized. These reactions may improve hydrophilic functional groups on the surface. In this study, the mixed solution of potassium dichromate($K_2Cr_2O_7$) and sulfuric acid(H_2SO_4) was attempted to encourage hydrolyzation and biocompatibility of PLA and PGLA fibers.

Experimental

Materials

Fibers of PLA, PGLA (GA:LA=90:10) are provide by Shanghai Tianqing Biomaterial Co., LTD. The basic properties were shown in Table 1.

TABLE1 THE BASIC PERFORMANCE OF PLA AND PGLA FIBERS

Sample	Linear density[dtex]	Breaking strength[cN]	Elongation[%]
PLA	5.19	15.72	39.68
PGLA(90:10)	2.75	16.23	42.39

Potassium dichromate ($K_2Cr_2O_7$) and sulfuric acid (H_2SO_4) were analytically pure and used without further purification.

Potassium Dichromate Surface Modification

Both mass fraction of $K_2Cr_2O_7$ and H_2SO_4 solution is 10%. $K_2Cr_2O_7$ and H_2SO_4 solution were mixed with volume ratio 1:6. Samples were dipped into mixed solution for deferent period: 2min, 4min, 6min, 8min, 10min, then cleaned by deionized water three times, and dried in a vacuum frozen dryer for 2 hours.

Tensile Properties

The tensile test was made with an electronic single fiber strength tester(LLY06E, Laizhou electron instrument co.,LTD, China). Gauge length was 10 mm, stretch speed was 20mm/min. The sample number was 30.

Water Contact Angle

Water contact angle measurements of unmodified and modified fibers were undertaken by the sessile drop technique using a contact angle goniometer(JC2000A, Shanghai Zhongchen, China) under standard condition.

DSC Analysis

Fiber samples(3~5mg) were placed in crucible, tested their thermodynamic performance by Differential Scanning Calorimeter (DSC,Pyris-1, PerkinElmer, US). Samples were kept warm for 2 min at 40℃, then heated up from 40℃ to 250℃ with a heating rate of 20℃/min. The DSC automatic calculated thermal melting point (Tm) and crystallinity.

FTIR Analysis

Fibers were tested by FTIR spectrometer (NEXUS 670, Thermo Nicolet Corporation, US) in the range of 400-4000 cm-1 with a resolution of 1 cm^{-1}.

Results and Discussion

Breaking Strength of Fiber

The relationship between fiber breaking strength and $K_2Cr_2O_7$ surface modification process-time was shown in Fig.1.

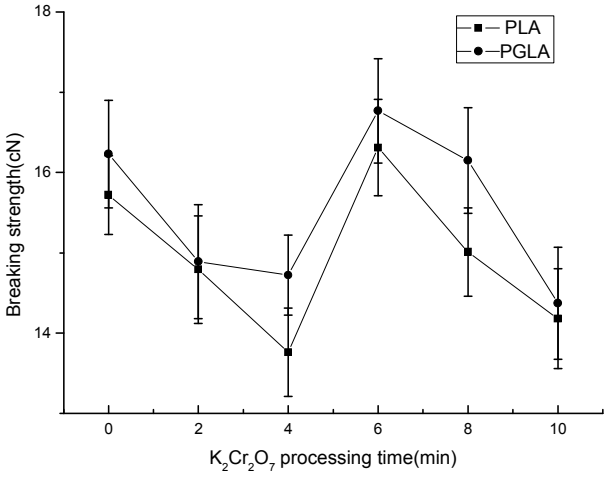

Fig.1 Change of fiber breaking strength with deferent $K_2Cr_2O_7$ process-time

Overall, the value of breaking strength had not change a lot. It indicated $K_2Cr_2O_7$ surface modification had little impact on fiber breaking strength. The breaking strength curve of PLA and

PGLA fibers dropped at the processing time of 2min and 4min. Curves reached their peak at 6min, then dropped again. That may be because joint effect of fiber molecular chain and fiber inner structure. On one hand, fiber surface molecular chain breaking caused dropping of breaking strength. On the other hand, swelling changed fiber inner structure and made it uniform. In swelling process, water molecules got inside of fibers, enhanced the fiber intermolecular distance, decreased the difference between crystalline region and amorphous region, thus made fiber inner structure uniform. Uniform structure may decrease inside stress and increase fiber breaking strength. The joint effect of two factors made breaking strength curve fluctuation.

Water Contact Angle of Fibers

The relationship between fiber contact angle and $K_2Cr_2O_7$ process-time was shown in Fig.2. Totally, contact angles of PLA were larger than PGLA. It can be seen that the contact angles of PLA and PGLA fiber increased after 2 min treatment. With the passage of time, contact angles of PLA and PGLA fibers were decreasing until 6min, then it increased once again. The lowest point of contact angle curve appeared at 6 min. Overall, appearance of two kind fibers was similar.

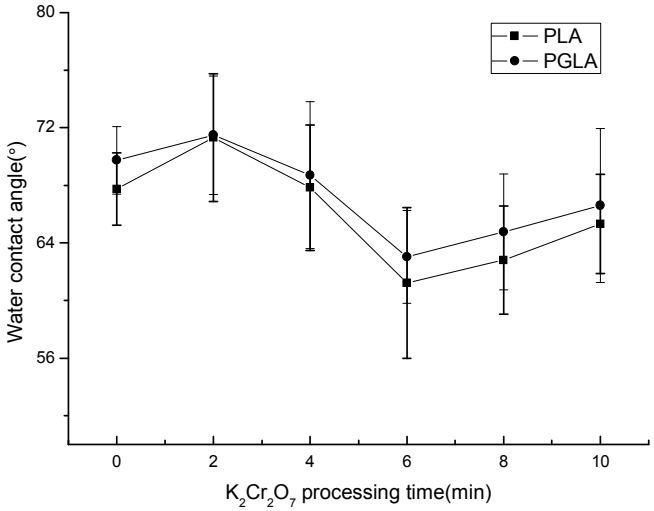

Fig.2 Change of fiber contact angle with deferent $K_2Cr_2O_7$ process-time

Under the same test method and condition, two important influencing factors of material contact angle were material surface morphology and surface molecule polarity[5]. Molecule of PLA was more lyophobic than PGLA, so contact angle of PLA fiber was higher than PGLA fiber. Furthermore, surface modification can promote ester bond hydrolysis and increase of polar groups. This was beneficial to reduce the water contact angle. On the other hand, fiber surface roughness should increase because of the chemical reagent erosion. However, the swelling effect had a contrary and made fiber surface smooth. To a certain extent, the increase of surface roughness can reduce the water contact angle. Due to the joint effect, the contact angle curves with deferent process-time of PLA and PGLA showed fluctuation. At the beginning, the chemical reagent just reacted, and the polar groups produced by reaction were very limited. At the same time, the swelling effect made fiber surface roughness decreased and played a main role, so the contact angle increased. As time passing, many polar groups were produced and surface roughness increased, so the contact angel decreased gradually. However, the reaction stopped after the reactant completely consuming. Meanwhile, the swelling was going on.So the contact angle increase once again.

Because decreased of contact angle means improving of hydrophilicity, 6min treated PLA and PGLA got the best hydrophilicity. In consideration of fiber breaking strength, controlling process-time as 6min seems reasonable.

Thermal Melting Point (T_m) and Crystallinity

Results of the thermal melting point (T_m) and crystallinity of PLA and PGLA fiber after 6min surface modification were compared with untreated samples in Table 2. It's obviously that T_m of PLA and PGLA almost had no change after treated, as the crystallinity decreased clearly, especially PLA dropped about 27.41%. This experimental result of maintaining of T_m indicated that the change of fibers chemical constituents was very limited, and might concentrate on surface. The sharp decrease of crystallinity showed that structure of fibers had changed obviously. It seems $K_2Cr_2O_7$ surface modification had less impact on crystallinity of GA-component than PLA or LA-component. Decreased of fiber crystallinity means increasing of amorphous region, which was beneficial to absorb moisture. This change may have positive effect on improving of hydrophilic.

TABLE 2 THE THERMAL MELTING POINT (TM) AND CRYSTALLINITY BEFORE AND AFTER K2CR2O7 TREATED

Samples	Untreated		$K_2Cr_2O_7$ treated	
	T_m[℃]	Crystallinity[%]	T_m[℃]	Crystallinity[%]
PLA	176.53	86.52	176.27	59.11
PGLA	206.27	44.66	206.90	34.88

FTIR Spectrometry

FTIR spectrum of PLA before and after $K_2Cr_2O_7$ treated was shown in Fig. 3.

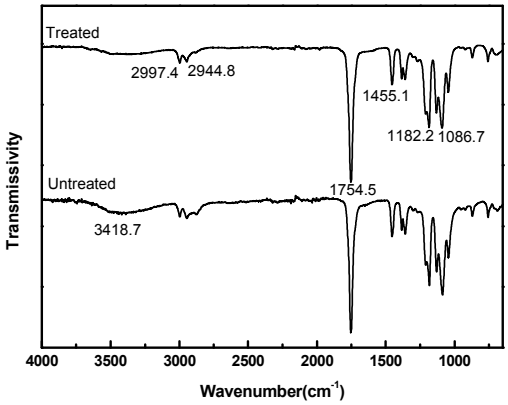

Fig.3 FTIR spectrum of PLA before and after $K_2Cr_2O_7$ treated

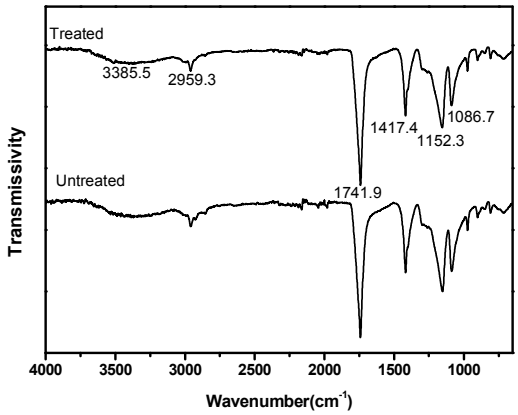

Fig.4 FTIR spectrum of PGLA before and after $K_2Cr_2O_7$ treated

The main change was the intermolecular hydrogen-bonding O-H absorption peak at 3418.7 cm^{-1} region reduced. It means that O-H hydrogen-bonding broke, and probably formed free O-H groups. As one kind of polar groups, the free O-H groups can improve the hydrophilicity of material.

FTIR spectrum of PGLA was shown in Fig.4.Before and after $K_2Cr_2O_7$ treated, infrared spectrum of PGLA fiber had no many change, besides remarkable decrease of absorption peak at 1086.7 cm^{-1} (lactone C-O-C stretch) and 1152.3cm^{-1}(bridge ester C-O-C stretch).The change means amount of

ester bond linkages decreased. It indicates the ester bond linkage of PGLA fibers were partly hydrolyzed, and might cause the increase of molecular-end polar groups.

Conclusion

In this article, $K_2Cr_2O_7$ and H_2SO_4 mixed solution was used to surface modify PLA and PGLA fibers with different time, then modifying parameter was optimize. Consideration of fiber hydrophilicity and breaking strength, the best potassium dichromate surface modification processing time was 6min. The crystallinity decreased clearly, which meant structure of fibers had changed. It meant increasing of amorphous region, which was beneficial to absorb moisture, and it's a positive change for hydrophilic. The FTIR spectrum shown that ester bonds of PLA and PGLA fibers surface were hydrolysis, and PGLA macromolecules end-groups may be oxidized. In conclusion, this modified method can improve the hydrophilicity of PLA and PGLA fibers and preserve fiber mechanical property.

Preparation and Photocatalytic Performance Study of La-WO_3 Co-doping TiO_2

Xianzhen Diao, Dong Zhou

Chemistry and Chemical Engineering College, Chongqing Institute of Science and Technology, Chongqing 401331,China
xianzhen81@126.com

Keywords：titanium dioxide; photocatalytic properties; La;WO_3; sol-gel method

Abstract：Butyl titanate as titanium source, anhydrous ethanol as solvent, glacial acetic acid as inhibitor, La-WO_3/TiO_2, La/TiO_2, WO_3/TiO_2 and pure TiO_2 photocatalysts were prepared through sol-gel method; At the same time, both of which were characterized by infrared spectrometer and uv-vis spectrophotometer; With methyl orange as simulated target degradation material, heat treatment temperature, different dopants, etc. on photocatalytic performance influences of TiO_2 were studied by spectrophotometer. Experimental results show that doping can improve obviously the photocatalytic activity of TiO_2. When calcination temperature is 500 ℃, dosage of catalyst is 0.25 g, pH is 1, and methyl orange concentration is 10 mg/L, La-WO_3/TiO_2 photocatalytic effect is best, and degradation rate is 46.18%.

Introduction

With rapid development of industrial production and a lot of industrial waste gas pollutants discharged into nature unceasingly, it makes human survival environment deteriorated, in which water environment problem is acute particularly. More than one million tons of synthetic dyes, pigments are produced and used in printing and dyeing industry each year in the world. Scientists have expected about 10% with the waste water discharged, which contain a lot of biological refractory materials, such as polycyclic aromatic hydrocarbon, polychlorinated biphenyls(PCBS), etc. Because their biological toxicity is bigger, there is a serious threat to human health and life security. Improving the environment condition and eliminating the organic pollutants in the water are current major problems to be solved to the human.

Photocatalytic materials has been the hot topics in the study of catalytic science and material science in recent years. Titanium dioxide as a kind of important inorganic semiconductor material has important application prospect in the solar water splitting, sewage treatment, etc. However, because anatase TiO_2 forbidden band width is large (Eg-3.2ev), solar energy utilization rate is low, and there is light composite problems such as electrons and holes, TiO_2 surface catalytic technology is limited in the practical application[1,2]. A lot of research experiments show that doping, precious metal deposition, semiconductor compositing[3-6] can improve effectively photocatalytic activity of TiO_2, broaden its range of light response, further improve its sun light energy use efficiency. In this paper, butyl titanate as titanium source, anhydrous ethanol as solvent, La, WO_3 doped TiO_2 photocatalysts were prepared by sol-gel method, and its photocatalytic activity was studied using uv-vis spectrophotometer and infrared spectrometer.

Experiments

La-WO_3 co-doped TiO_2 photocatalyst preparation

Under vigorous stirring, a certain amount of butyl titanate was added to 20mL anhydrous ethanol and 2.0 mL glacial acetic acid mixture slowly, stirring after 30 min, getting light yellow uniform transparent solution A; Soluble metal salt lanthanum nitrate and sodium tungstate mixture were added into 7mL anhydrous ethanol and 1.8mL distilled water mixed solution, adjusting the solution pH value(pH=2), getting the solution B. Then under the intense mixing, B liquid was added to A liquid dropwise, continuing to stir 2 h until the transparent sol. the sol was aged at room temperature for 1 d, getting silvery white gel. After the gel dried 12 h under 100 ℃ in the oven, dry gel powder was got after grinding. In the end, titanium dioxide powder was heated treatment 2h under 500 ℃ temperature in the muffle furnace, cooling, pure TiO_2, La doped TiO_2, WO_3 doped TiO_2 and La-WO_3 co-doped TiO_2 were got.

Infrared spectrum study

Molecular structures of samples analysed by German Bruker company's Equinox 55 type Fourier infrared spectrometer, scope of its wave number: 4000-400cm^{-1}; Accuracy of wave number: ≤4cm^{-1}(4000-2000), ≤2cm^{-1}(2000-400); Resolution: 1.5 cm $^{-1}$; Through the rate of accuracy: ±0.2%T; l_0 line straightness:≤±2%T.

Photocatalytic performance study

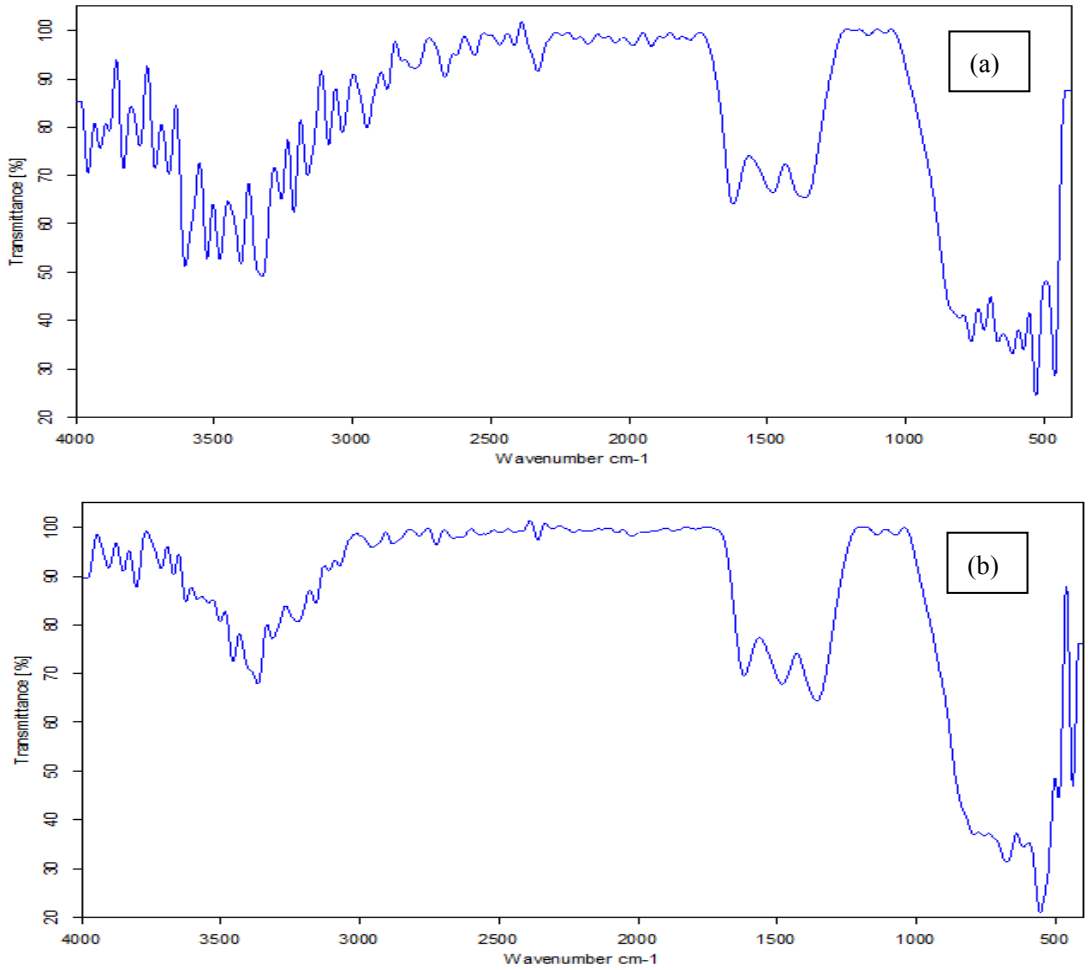
Configuration 500 ml10mg/L methyl orange solution, and measuring 60 ml methyl orange were poured into with 0.1g pure TiO_2, La doped TiO_2, WO_3 doped TiO_2, La-WO_3 co-doped TiO_2 in the beaker respectively; Stirring after 5min, dark treatment for 20min,under the irradiation of ultraviolet lamp at 30w, and liquid level 10cm from the light source, then every 30 min sampling, centrifugal separation, taking the supernatant fluid, and measuring its absorbance. The absorbance(A) of maximum absorption wavelength of 465nm was measured with visible spectrophotometer, and thus the degradation rate was calculated .

At low concentration range, it is directly proportional to the concentration and absorbance of the methyl orange solution(the concentration of methyl orange solution for 10 mg/L in this experiment), so photocatalytic degradation rate of sample can be represented as Eq. 1.

$$D=[(A_o-A_1)/A_o]\times 100\%. \quad (1)$$

In the formula, D for degradation rate; A_o for initial absorbance of methyl orange solution;A_1 for the absorbance of methyl orange solution after photocatalysis.

Results and discussion



Infrared spectrum analysis

Fig.1 are infrared spectrograms of pure TiO_2, La-WO_3/TiO_2 powders after 500 ℃ calcination.The visible on the drawing, a wide absorption peak in the vicinity of 3380cm^{-1} appears from all samples, corresponding to the stretching vibration peak of the TiO_2 surface hydroxyl. In photocatalytic oxidation reaction, the amount of catalyst surface hydroxyl and light catalytic

reactivity is directly related[17], because it not only can easily generate hydroxyl free radical (·OH) by capturing the hole, but also can improve O_2's ability to capture electron to generate more ·OH. Other, absorption peak near 1640cm^{-1} is free water H-O-H bending vibration peak, which explains the surface of samples have already been hydroxylated. Between 800-420cm^{-1} wide absorption peak attributable to Ti-O keys vibration of amorphous TiO_2[19]. And 500-800^{cm-1} appears a broad peak of Ti-O stretching vibration absorption peak. In 2440cm^{-1}, 2380cm^{-1}, 1320 cm^{-1} and 1260cm^{-1} more wide absorption peaks may be the interaction of TiO_2 and W, La formed Ti-O-W, Ti-O-La, La-O-Ti-O-W keys and appear the peaks. Also can be seen that the presence of TiO_2 makes the surface hydroxyl peak wider and stronger, and doped catalysts have more abundant surface hydroxyl. This may be due to the presence of metal ions to improve the properties of TiO_2 catalysts specific surface area, etc. And in the photocatalytic degradation organic matter molecular reaction, ·OH is the main active species of oxy-genated. Therefore, after the compound TiO_2, photocatalytic performance will be improved.

Photocatalytic performance analysis

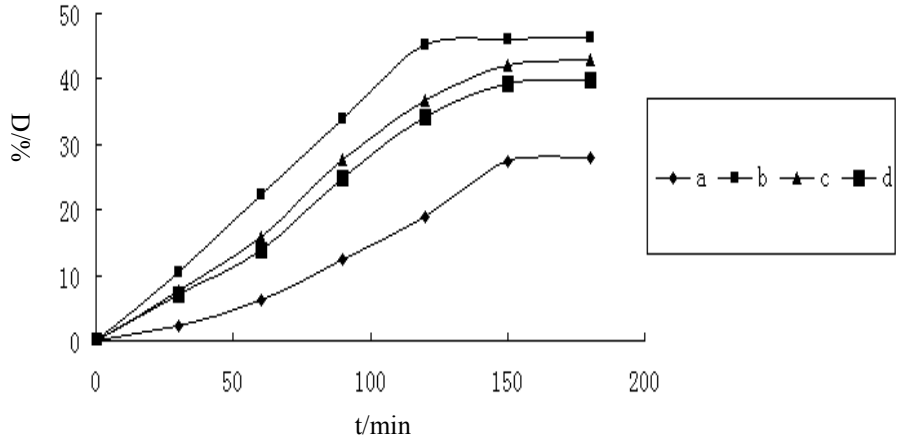
(a) pure TiO_2 (b)La-WO_3/TiO_2

Fig.1 The infrared spectrograms of TiO_2

0.25g, pH for 1. Fig.2 shows that illumination after 150 min, the degradation rates of La-WO_3/TiO_2 at 300 ℃, 400 ℃, 500 ℃, 600 ℃ heat treatment after 2h are 21. 27%, 34. 30%, 46. 18%, 36. 05% respectively. Because in low temperature calcination, TiO_2 is amorphous structure and

exists defects more, a lot of defects become the center of electrons and holes in the compound, electron and hole structure is difficult to reach surface involved in photocatalytic reaction, thus TiO_2 has lower light catalytic activity; With the increase of calcination temperature, the degree of crystallization and the density of surface structure are improved, its internal fewer defects become the center of electrons and holes in the compound, thus TiO_2 has higher photocatalytic activity. When calcining temperature is too high, however, grain growth, the effective surface area of TiO_2 is reduced, REDOX ability is reduced, TiO_2 surface active hydroxyl amount is reduced, and high temperature calcining can make the crystal structure of TiO_2 from anatase to rutile type, so its photocatalytic activity also decreases.

Fig.3 is pure TiO_2 powder, single doped and co-doping titanium dioxide powder photocatalytic degradation rate figure in10mg/L methyl orange solution,0.25g photocatalyst, pH=1, at 465nm. From figure 4.9 can be seen, as the growth of the illumination time, TiO_2 samples to methyl orange degradation rate increased gradually. At the same time, doping can improve obviously the photocatalytic activity of TiO_2, the degradation efficiency from big to small order for: La-WO_3/TiO_2>La/TiO_2>WO_3/TiO_2>pure TiO_2. Therefore, photocatalytic effect of co-doping titanium dioxide is better than single doped and pure TiO_2. Lanthanum doped with tungsten trioxide improve photocatalytic activity of TiO_2 is caused by their synergism. Because lanthanum metal ion



(a) 400℃ (b) 300℃ (c) 500℃ (d) 600℃

Fig.2 Heat treatment temperature on the influence of La -WO_3/TiO_2 photocatalytic degradation rate

radius is bigger than titanium, lanthanum can enter the lattice of TiO_2 rarely.When doping lanthanum quantity is small, lanthanum of entering lattice of TiO_2 is +3 valence. According to the band theory of solid state physics, La^{3+} doped into TiO_2 can replace Ti^{4+} lattice position, TiO_2 crystal lattice will lack an electron, which can strengthen tungsten-titanium system charge imbalance, and reduce electronic-hole composite risk, improv its photocatalytic performance.

In addition, also can be seen from the figure, photocatalytic activities of single lanthanum doped and tungsten trioxide doped TiO_2 are higher than that of pure TiO_2, the reason is that doping metal ions could enter titanium dioxide lattice, change TiO_2 crystal lattice distortion, and lead to phase transformation, make absorption wavelength of TiO_2 extending to the visible light region.

(a) pure TiO_2 (b) La-WO_3/TiO_2 (c) La/TiO_2 (d) WO_3/TiO_2

Fig.3 Different dopant on the influence of TiO_2 photocatalytic degradation rate

Conclusions

Butyl titanate as titanium source, anhydrous ethanol as solvent, glacial acetic acid as inhibitor, La-WO_3/TiO_2, La/TiO_2,WO_3/TiO_2 and pure TiO_2 photocatalysts were prepared through sol-gel method in this paper; At the same time, photocatalytic performance of /TiO_2 was studied by infrared spectrometer and spectrophotometer; With methyl orange as simulated target degradation material, heat treatment temperature, dopant, etc. on photocatalytic performance of TiO_2 affect were analysed. Experimental results show that doping can improve obviously the photocatalytic activity of TiO_2. When calcination temperature is 500 ℃, dosage of catalyst is 0.25 g, pH is 1, methyl orange concentration is10 mg/L, La-WO_3/TiO_2 photocatalytic effect is best, and degradation rate is 46.18%.

Keywords：titanium dioxide; photocatalytic properties; sol-gel method; doping

Abstract：Butyl acetate titanate as precursors, no water ethanol as solvent, pure TiO_2 and different doping ratio of F/TiO_2 photocatalysts were prepared through sol-gel method; And F doping amount on photocatalytic activity of TiO_2 influences were analysed systematically through uv-vis spectrophotometer, infrared spectrometer, etc. Experimental results show that photocatalytic activity of TiO_2 is better when the mole ratio of F is between 10% and 20%; When F doping amount is 20%, catalyst amount is 25g, the photocatalytic degradation rate of F/TiO_2 can reach 85.74% in10%wt methylene blue solution under 250W high-voltage mercury lamp illumination after 2 hours and the area of illumination $6.94\times10^{-3}m^2$. In the same way, the photocatalytic degradation rate of pure TiO_2 is just 35.39 %. It proves that F/TiO_2 catalyst of doping amount 20% presents the best photocatalytic activity.

Introduction

Along with the increasingly serious environmental problems and the demand of new energy, because its application and prospect in environmental pollution purification, energy regeneration is very broad and photocatalytic technology has been attracted much attention. Photocatalytic technology has some unique properties, which can use directly sunlight at room temperature to all kinds of organic pollutants completely mineralized and no secondary pollution, and it become a kind of ideal environmental pollution control technology, so it has become one of the most active area of research at home and abroad in recent years[1].Nano TiO_2 photocatalyst as a kind of excellent performance has many advantages of suitable width of forbidden band, large specific surface area, high photochemical stability, and high catalytic efficiency, non-toxic, low cost. It is of great significance to reduce running costs, protect the environment, maintaining ecological balance, and realizing the sustainable development, so it has a broad and attractive prospects in the control environmental pollution and so on many fields [2,3].But TiO_2 sunlight utilization rate is low and raw electronic light- hole is easy to composite, which results in the decrease of the photocatalytic efficiency. So how to improve the range of spectral response and catalytic efficiency of TiO_2, shorten the reaction required time is the emphases and difficulties and development direction of the current research.Researches show that nonmetal doping modification TiO_2[4-7]can significantly improve the photocatalytic activity of TiO_2.

In this paper, butyl titanate as precursor, anhydrous ethanol as solvent, the F/TiO_2 light catalyst was prepared by the sol gel method, and its photocatalytic activity was studied using the uv-vis spectrophotometer, infrared spectrometer, etc.

Experiments

F-doped TiO_2 powder preparation

Chemical pure butyl titanate/Ti $(OC_4O_9)_4$ as raw material, anhydrous ethanol as solvent and glacial acetic acid as inhibitor, a certain amount of distilled water, anhydrous ethanol, a small amount of nitric acid and NH_4F solutions were mixed, fully stirring, mixing, as A solution; A certain amount of acetic acid, butyl titanate and glacial acetic acid were slowly added to in 60 ml anhydrous ethanol under the magnetic force agitator, as B liquid. Under the magnetic force agitator the A solution was slowly dripped into to the B solution, got uniform transparent solution. After waiting for gel formation, stopped stirring, placed in the air, then aged 12h above; Under the condition of 120 ℃constant temperature dried about 2h, got yellow crystals; The white powder after crystal grinding would put into the muffle furnace, high temperature calcination 2h, and white fluorine doped TiO2 nano powder was got.

Catalyst characterization

Samples of components were analysed by the Germany Tensor-27 Fourier infrared spectrometer (FT-IR) ; Samples of light absorption performance and light catalytic degradation performance were tested by UV1102 ultraviolet-visible spectrophotometer of Shanghai day science co., LTD production .

Photocatalytic performance study

Research of photocatalytic performance is to use 250 w of straight pipe shape uv high pressure mercury lamp (wavelength of 253.7nm) irradiation TiO_2 degradation methylene blue solution completion. A certain amount of titanium dioxide photocatalyst was dipped to 20 ml, 10 mg/L of methylene blue solution under ultraviolet light (light source only 20 cm from the surface, the area light is $6.94*10^{-3}$ m^2), then was measured the absorbance at 464 nm every 30min, recording data, degradation rate of measured target degradation solution under uv irradiation was got by absorbance data calculated as Eq. 1.

$$D=(1-A_t/A_0)\times 100\%. \quad (1)$$

Among them: D for degradation rate; A_t for the of target degradation solution after the reaction; A_0 for the absorbance of target degradation solution before the reaction.The photocatalytic degradation rate of samples was got by the formulas.

Results and discussion

Infrared spectral analysis

Figure 1, figure 2 are pure TiO_2, F/TiO_2 infrared spectrograms. From figures illustrates that the wide and strong absorption peak in 400 ~ 1000 cm^{-1} is caused by TiO_2 crystals on the surface of Ti - O key stretching vibration.Relative to the pure TiO_2, waves obviously increases a lot after doping F. Because the F-O key antisymmetric stretching vibration absorption peak are between 1000 ~ 1700 cm^{-1}, so it can be thought that 1637 cm^{-1} , 1407 cm^{-1} peaks are infrared absorption peaks of F atom surface chelation in the TiO_2 and double complexing adsorption. It can be concluded the F element is doped in the TiO_2 catalyst effectively.

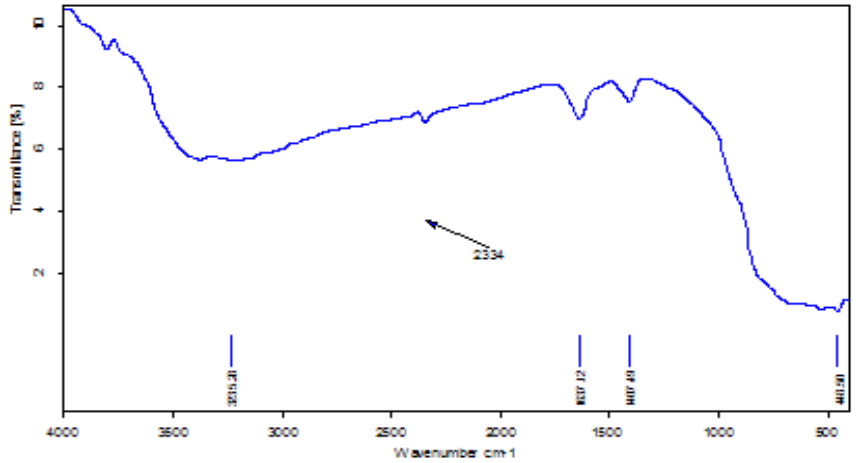

Fig.1 Pure TiO_2 FT-IR spectra

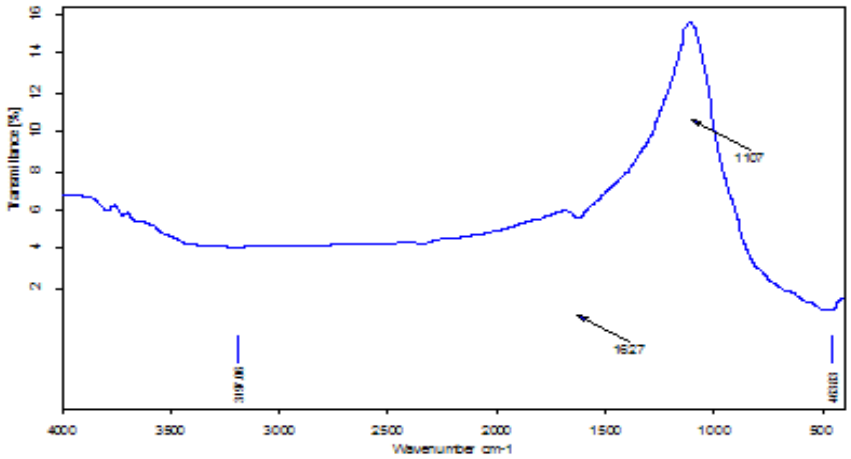

Fig.2 F/TiO_2 FT-IR spectra

Absorption spectrum analysis

Fig.3 is the uv-visible absorption spectrum of TiO_2 catalyst under the condition of PH = 2, 400 ℃, F doping amount respectively 0%, 5%, 10%, 20%, 30%.

Can be more intuitive to see from the figure, the samples of TiO_2 doped fluoride absorption sideband is more pure TiO_2 obvious red shift; With the increase of fluorine doping amount, TiO_2 nanoparticles of spectral response range expands to visible light area, and absorption of visible light increases. When fluorine doping amount increase to 20%, the ultraviolet absorption spectrum sideband from pure TiO_2' 400nm expands to 450 nm, the red shift phenomenon is more obvious. At the same time also can be seen from the picture, along with the increases of the doping amount, TiO_2 sample absorbance value also increase. When the mixing amount of fluoride is 20%, absorbance values is the most biggest; But continuing to increase the fluorine doping amount, its absorbance reduces. Thus fluorine doping amount of TiO_2 is greatly influenced by light absorption performance.

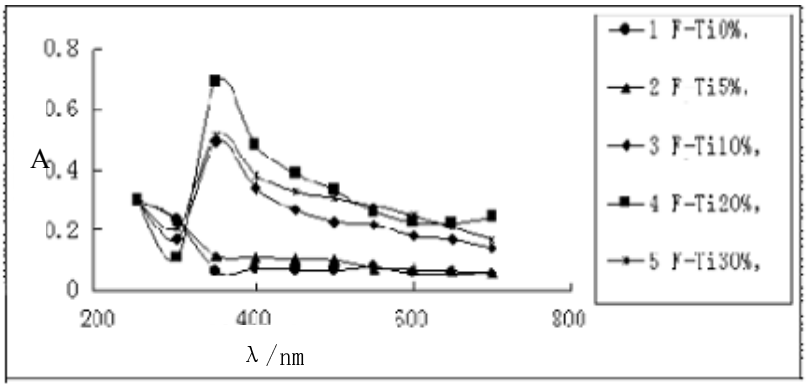

Fig.3 Uv visible absorption spectra of different doping amounts F/TiO_2

Photocatalytic Activity Analysis

Fig.4 shows 25g F/TiO_2 photocatalytic degradation rate change over time under the condition of 400 ℃, PH = 2, F doping amount respectively 0%, 5%, 10%, 20%, 30% .

The figure shows that doped fluoride of titanium dioxide photocatalyst of degradation rates increased significantly, and with the increase of illumination time, photocatalytic effect is more and more better. Doping ratio for 10% and 20% of F/TiO_2 photocatalyst of degradation rate after two hours sunlight were 82.64% and 82.64% respectively; But pure TiO_2 of degradation rate is 35.39% under the same condition. It can be attributed that F element doping can reduce light electrons and holes in the compound, restrain grain growth, and improve photocatalytic degradation rate[8]. Therefore, fluorine doping amount of TiO_2 photocatalyst has a great influence on photocatalytic degradation rate.

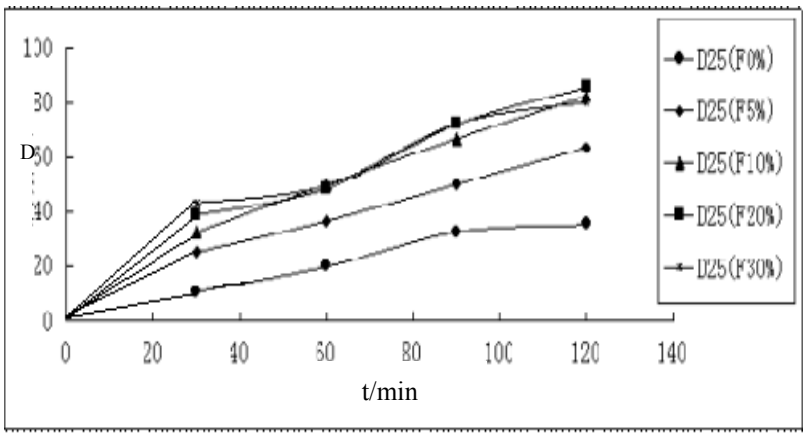

Fig.4 TiO_2 photocatalytic degradation rate chart of different F doping amount

Conclusions

Butyl acetate titanate as precursors, no water ethanol as solvent, pure TiO_2 and different doping ratio F/TiO_2 photocatalysts were prepared through sol-gel method. By means of uv-visible absorption spectrum and photocatalytic activity of study of TiO_2, results show that fluorine doping make the absorption spectrum of TiO_2 photocatalyst moving towards long wave, and within the scope of the visible light absorption enhancement; And photocatalytic degradation performance has increased significantly. When fluorine doping ratio is 20%, light time are two hours, TiO_2 catalyst for degradation rate of methylene blue solution can reach 85.74%, photocatalytic degradation effect is better.

Keywords: TiO_2; sol-gel method; photocatalytic degradation

Abstract. Cu-N co-doped TiO_2 powder was prepared by sol-gel method. The Powder was characterized by X-ray diffraction (XRD) and UV-Visible absorbance spectroscopy (UV-Vis). The X-ray results indicated that Cu-N co-doped has no effect on its anatase type. The UV-Vis results show that the absorb threshold has extend to visible-light, the absorbility of co-doped TiO_2 is higher than that of pure TiO_2, and the Photocatalytic activity has been increased.

Introduction

In recent 20 years, more and more researchers pay their attention to nanometer TiO_2, since TiO_2 has many advantages, for example, better chemical stability, highly reactive, nontoxicity, cheapness and making direct use of solar energy, it is a promising material in photoelectric conversion, chemical synthesis and photodegradation of organic pollutions in water and air. However, TiO．only absorb ultraviolet light, and it has a low utilization ratio of the sunlight (3%~4%). So, it is meaningful if the absorb threshold of TiO_2 can be extended to visible light.

A lot of researches show that dopant can improve visible light absorbility of TiO_2. At present, there has many essays about doping metallic or nonmetallic elements into TiO_2 to extend its absorb threshold. But doping metallic and nonmetallic elements at the same time is not much to see.

In this paper, metallic and nonmetallic elements co-doped TiO_2 were prepared by sol-gel method, the result of characterization and photocatalytic of co-doped TiO_2 is good.

Experimental Details

Chemical Reagent

Tetrabutyl titanate, absolute alcohol, glacial acetic acid, secondary water.

The Synthesis of Samples

Solution A: acetic acid(4ml) and tetrabutyl titanate(4ml) were added to the absolute alcohol(20ml) and stirred them strongly in the same time. Solution B: acetic acid(2ml), secondary water(2.5ml),$Cu(NO_3)_2.3H_2O$(0.0361g)and $CO(NH_2)_2$(0.5231g) were added to absolute alcohol(10ml) , dissolved them by means of ultrasonic dissolution. In conditions of strongly stirring, added B into A slowly and stirred for about 3 hours, we got stable gel after left them stand for 24h, the gel turned into dry glue after dry them at temperatures 80℃, then , the Cu-N co-doped TiO_2 powder was prepared by roasting the dry glue in muffle burner at 450℃ for 3h. For compassion, pure TiO_2 was prepared under the same conditions.

Characterization of Samples

The crystal construction of samples was characterized by using **X**-ray diffraction (D/max2500VL/Pc) with CuKa radiation, the angle of diffraction was 2θ，the step was 0.02℃, scan speed was 5℃/min, the voltage was 40 KV, the current was 50mA. Ultraviolet/visible/near infrared spectrograph (Cary5000) made by Varian Corporation was applied to Uv-Vis diffuse reflectance spectroscopy , Standard BaSO4 board was used to adjust the instrument baseline.

Photocatalytic Activity Test

The center light of photochemical reactor is 500W high-pressure mercury-arc lamps outside is circulating water cooling trap, catalyst was the powder of pure TiO_2 and co-doped TiO_2, added the powder into secondary water at the level of 1.0g/L, the original level of degrading methyl orange was 200mg/L. The solution was kept away from the light and stirred for 30min to make sure adsorption reaction of reactants reach balance at room temperature.

Results

Uv-Vis Diffuse Reflectance Spectroscopy

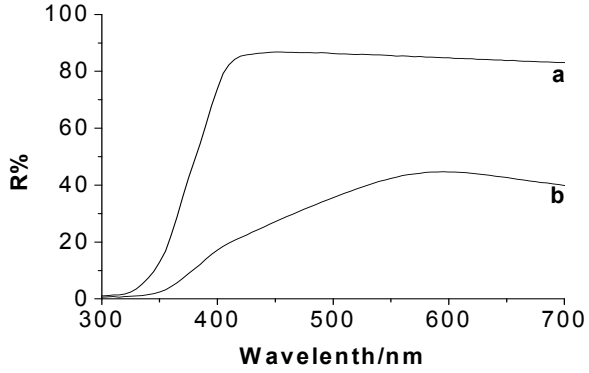

Figure1. Uv-Vis Diffuse Reflectance Spectrum Of (A) Pure Tio_2 And (B) Co-Doped Tio_2

Figure1 shows, compared with pure TiO_2, a red shift was happened in co-doped TiO_2 spectrum from 380nm to 590nm, the corresponding energy dropped from 3.2ev to 2.14ev, the strength of spectrum absorption was greatly improved. The reason might be the nitrogen-atoms incorporated into crystal lattices and replaced oxygen-atoms, and then Cu^{2+} interacted with TiO_2, since nitrogen's electronegativity is lower than oxygen's, electronic hybrid of nitrogen and oxygen leaded to the decrease of band-gap energy. The result indicated the absorption threshold could be broadened after co-doped metallic and nonmetallic elements into TiO_2.

Analysis of Samples Crystal Phase Structure

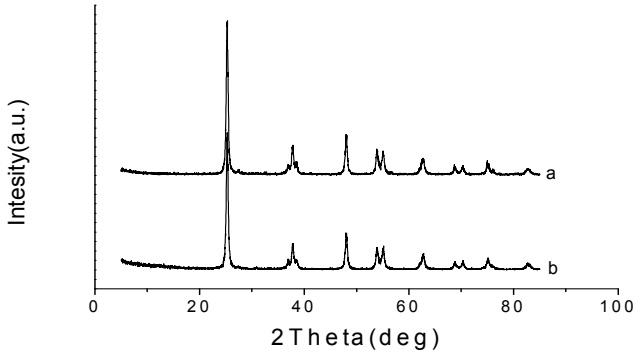

Figure2. Xrd Spectrum Of (A) Pure Tio_2 And (B) Co-Doped Tio_2

Figure2 is XRD spectrum of (a) pure TiO_2 and (b) co-doped TiO_2, the result turned that a and b were anatase types. According to the formula of Scherrer, samples' average size $D=K\lambda/\beta\cos\theta$(β, half band width of the anatase phase; λ,wavelength of X-ray; K, Scherrer constant=0.89). The

average sizes of pure TiO_2 and co-doped TiO_2 are 7.0nm and 4.9nm respectively. The size of co-doped TiO_2 became smaller, the reasons might be the dopant incorporated into TiO_2 lattices and interacted with TiO_2.

Photoreactivitie of Samples

Measured photocatalytic degradation reaction of pure TiO_2 and co-doped TiO_2 with xylenol orange by Uv-Vis spectroscopy. The absorbance of xylenol orange changed at 433nm, according to Beer law, A=KC (K, absorption coefficient; C, level of samples). Degradation rate of xylenol orange is $D=(\Delta C/C_0)\times 100\%=(A_0-A/A_0)\times 100\%$ (D, degradation rate; C_0 , the original concentration of xylenol orange; ΔC, differences between original and final concentration; A_0, the absorbance of original xylenol orange at 433nm; A, the absorbance of final xylenol orange).

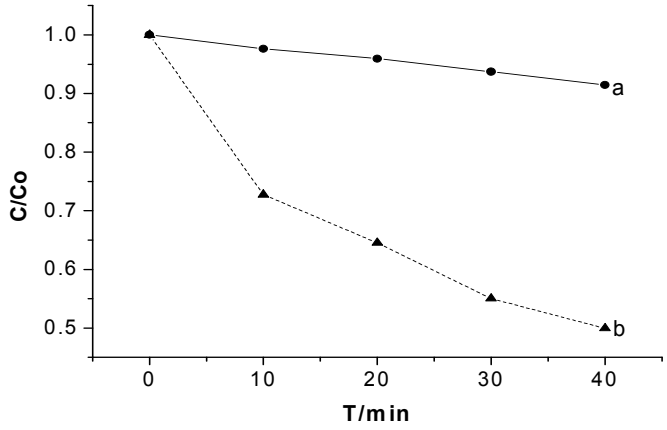

Figure3. Photocatalytic Degradation Reaction Of (A)Pure Tio_2 And (B) Co-Doped Tio_2 With Xylenol Orange

Form Figure 3, we know Photoreactivitie of dopant is higher than pure TiO_2, after 40min catalysts, photocatalytic degradation rate of dopant is 51%, the pure is only about 10%

Conclusion

The absorb threshold of Cu-N co-doped TiO_2 powder prepared by sol-gel method has extend to visible-light. The test of xylenol orange photocatalytic degradation shows Photoreactivitie of dopant is 40% higher than pure TiO_2, Photoreactivitie of catalyst is strengthened obviously.

KeyWords: Kaolin, Flouride, Porous Ceramics, Ghana,Water Contamination, Aluminosilicates

Abstract. Low levels of fluoride in drinking water is healthy for the teeth enamel, however, higher concentrations result in dental fluorosis with prolonged exposures leading to skeletal fluorosis. Fluoride removal capacities of ceramic filters using aluminosilicates (Anfoega clay, Kibi kaolin, Laterite soil and Termitaria earth) samples from Ghana Geological Survey Department have been investigated and analysed for possible application in the Bongo District of Ghana noted forhavinghigh fluoride concentration in its ground water. Batch sorption studies conducted revealed that the amount of fluoride ions removed increased proportionally with increasing filter thickness, temperature and contact time to an optimum value. Using particle size ranges of <355µm and 1cm filter thickness at room temperature, the percentage of fluoride removed by the samples reached an optimum value after 70mins. Increases in filter thickness, contact time or temperatureincreased the amount of fluoride ions removedand the time required to reach the optimum value reduced significantly.

Introduction

Water is a natural resource vital for the healthy growthof mankind. In the rural regions of most developing nations however, there is inadequate access to potable waterand the water sources are contaminated with disease vectors, pathogen, toxins, suspended solids and excessive amount of minerals and organic matter [1, 2].

Ground water is one of the major sources of water for domestic purposes in the rural regions of the world. Due to earth coverings that acts like a filter, ground is considered to be pure and unpolluted by rural indigenes if it is odorless, free from turbidity etc. This perception has however, changed due to proven scientific results showing that water, no matter how colourless, may be polluted by rock bearing minerals rich in As, F- ions[1,3]. Fluoride contaminations in ground water have been observed to occur in two distinct ways: naturally in ground water resources and as toxic waste [4, 5, 6].

Many domestic water purification processes are available and research works have shown that ion exchange techniques, activated carbon, bone char, reverse osmosis and chemical precipitation techniques are capable of removing fluoride ions and other volatile organic compounds (VOCs) very effectively [3, 4, 5]. Due to the complexities and cost involved in these technologies, their applicability in rural regions of sub-Saharan Africa is challenging and often unavailable.

Research reports have also shown thatclays and laterites have high tendencies to effectively remove anions and many other volatile organic compounds from contaminated water bodies by adsorption mechanismbecause they contain minerals such as kaolinite, smectite, amorphous minerals etc that have exchangeable OH groups in the mineral structure [6,7]. Different technological concepts for fluoride adsorption onto Al and Fe based oxides have also been reported [7, 8, 9] and they are well recognized in sub-Saharan Africa [10, 11]. These efforts have helped to effectively reduce turbidity, bacterial and protozoan contamination.The inability of these technologies to substantially

reduce chemical pollutants especially fluoride ions, leaves much to be desired and have been largely attributed to structural changes, influence of pH on adsorption capacity as well as slow kinetics [12].

The Bongo district in the upper east region of Ghana has been associated with high incidence of dental cavities and mottled teeth. In 1993, a dental health survey of 1558 students indicated that 62% had fluorisis and a monitoring programme by then Ghana Water and Sewage Corporation on 93 boreholes and shallow wells indicate 63.5% had fluoride levels in excess of 1.0mg/l. An innovative simple alternative to solve ground water fluoride contamination problems in rural regions is therefore required.

This worktherefore seeks to developcheap, efficient and sustainable porous ceramic bodies (filters) from alumino-silicates (Al oxides) based materials for the potential adsorption of fluoride ions from contaminated water bodies in the Bongo district of Ghana to levels accepted by WHO standards [13,14]. The chemical composition of various aluminosilicate ores will be sampled and analysed. The effect of preheating high temperature processing will also be observed.

Materials &Methods

Raw Materials and Preparation

The porous media (filter) used for this investigation was based on aluminosilicates and includes Anfoega clay deposits in Anfoega- Volta region of Ghana, Kibi Kaolin deposits in Kibi- Eastern region of Ghana. Laterite and Termataria Earth received from Ghana Geological Survey Department (GGSD) sampled from the Bongo region in Ghana was also included in this investigation. Mortar and pestle were used to ground the sample in order to reduce the particle size. We then sized the ground samples using a sieve stack of:500µm, 355µm, 90µm and 63µm.Saw dust was used for the formation of pores in the aluminosilicates materials (Anfoega clay, Kibi Kaolin and Laterite as well as Termataria Earth). The sawdust was obtained from a local sawmill and it was dried in an oven at 80˚C for 1 hour.

Chemical Analysis

The chemical analysis of the aluminosilicate samples used in this investigation was done with SpectroXLab 2000 X-Ray fluorescence spectrometer (AMETEK, USA) at the Ghana Geological Survey Department. The aluminosilicate samples to be analysed were sieved in a 106um sieve after which 4 grams of each was mixed with aucowax powder acting as a binder. We then milled the mixture was for about 3minutes in a Retich milling machine (model MM 301) and the mixture was later pressed in an XRF pellet press. The samples were then loaded into a Spectra Xlab 2000 sample holders for the analysis.

Porous Ceramics Filter Preparation

We prepared batch formulations comprising of the aluminosilicates test samples, sawdust and water. The batch green bodies (unfired clay) were subsequently formed by slip casting using a funnel connected to a suction pump. After the suction pump had taken all the moisture from the slip, the green body was left to dry in the open air for 4 hours before transferring the mass to a drying oven maintained 110˚C to completely dry. The formed bodies were fired to 850˚C using a CSIR manufactured gas furnace. When the desired firing temperature was reached, it was held constant for 2 hours (“Soaking Period”). The firing process burns off the saw dust after which the kiln was left to cool for 24 hours before the fired filters were removed. We observed dimensional stability and modulus of rupture (MOR) test conducted on the filters. The batch formulations experiment was repeated for thicknesses of 0.5cm, 1.0cm, 1.5cm, 2.0cm and 2.5cm.

Batch Sorption Test

Fluoride concentration in Bongo ground water has been reported in excess of 4mg/l to as high as 6mg/l [16]. As a baseline guide a stock solution of NaF containing 6mg/l was prepared to serve as contaminated fluoride water for the fluoride sorption studies. The NaF powder was dried in a drying oven for 1 hour at 100˚C; 6g of the dried NaF was weighed and dissolved in deionized water and it was then diluted to 1000ml in a volumetric flask.

The adsorption capacity of the different ceramic filters at room temperature and at higher temperature up to 100ºC was tested. The flow rate studies of the ceramic filters were conducted by

first soaking the filters completely inside a bowl of the stock solution for 2 hours and the time it takes for 10ml of the stock solution to completely pass through the filters was observed and recorded. The concentration of fluoride in the filtrate was also recorded.

Results and Discussion

Physical Properties Evaluation

Shrinkage after drying and firing was observed. The degree of shrinkage was independent of the pore formers (saw dust) used. As seen in Fig. 1, Anfoega clay which was observed to be more plastic during the test processes exhibited a much higher strength.Observed variation in the strength of the filters as measured by the MOR test and is expected due to differences in mineralogical composition as well as the plastic nature of the alumino-silicate samples used.

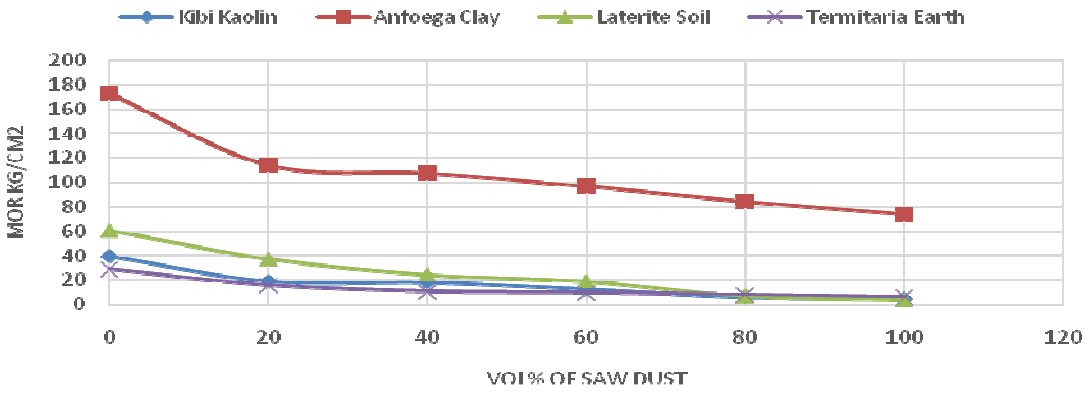

Fig 1 Effect of Pore Formers on MOR

Chemical Composition

Table 1 shows the chemical composition of the alumino-silicate samples used in this investigation. The samples have varying degrees of SiO2, Al2O3 and Fe2O3 because they represent a group of mineral deposits consisting of residual insoluble ferric and aluminum oxides, clay minerals and quartz formed by weathering of rocks [12].

Table 1: Chemical Compositions of Samples (%)

	Afoega Clay	Kaolin, Kibi	Laterite	Termataria, GGSD
Si02	**66.09**	45.81	48.2	57.6
Al2O3	23.15	41.64	22.2	9.8
Fe2O3	2.55	0.95	12.1	7.1
FeO	-	-	0.63	-

Cl-	0.026	<0.01	-	0

Fluoride Removal Capacity

The filter prepared from 850˚C fired Anfoega clay, Kibi kaolin, Laterite soil and Termitaria earth demonstrated different fluoride adsorption capacities at different dose thicknesses as seen in Fig. 2.

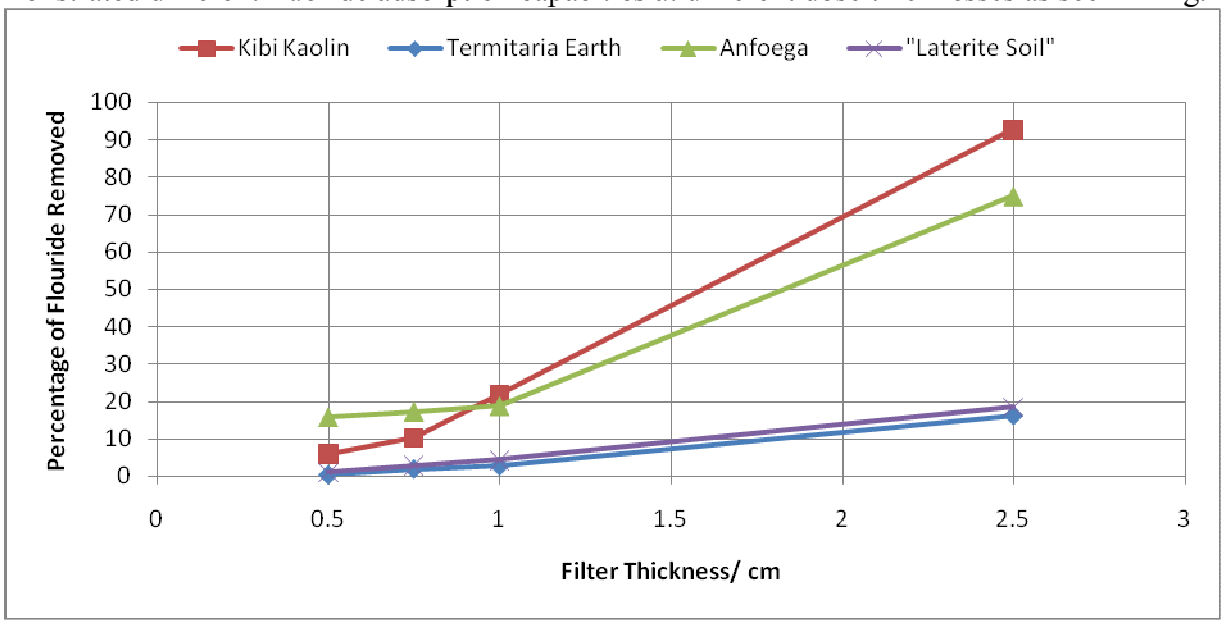

Fig 2 Effect of Filter Thickness on Fluoride Adsorption

At very low thickness below 1cm, Anfoega Clay removed more fluoride ions than the other batch samples. However, when the thickness of the samples was increased Kibi kaolin removed more of the fluoride than the other formulations. This indicates that the Kibi based filters performs better when the filters are thick and the solution contact the material for a longer period. From this observation, it was also calculated that 0.5cm of Anfoega clay and Kibi kaolin filters fired to 850˚C and having a particle size range of <355µm will take away 6mg/l of fluoride in 100ml beaker in less than 20 minutes, while Laterite soil and Termitaria earth will require 2.5cm thickness to achieve the same effect.

Effect of Contact Time on Fluoride Adsorption

Fig. 3, shows the percentage of defluoridation of Anfoega clay, Kibi kaolin, Laterite soil and Termitaria earth with time using a filter thickness 1.0cm. The percentage of fluoride removed increased steadily during the period. Laterite and Termataria earth showed lower degree of fluoride removal strength. This indicates that Anfoega clay particles and Kibi kaolin have more specific surface area for the adsorption of fluoride than Laterite soil and Termitaria earth.

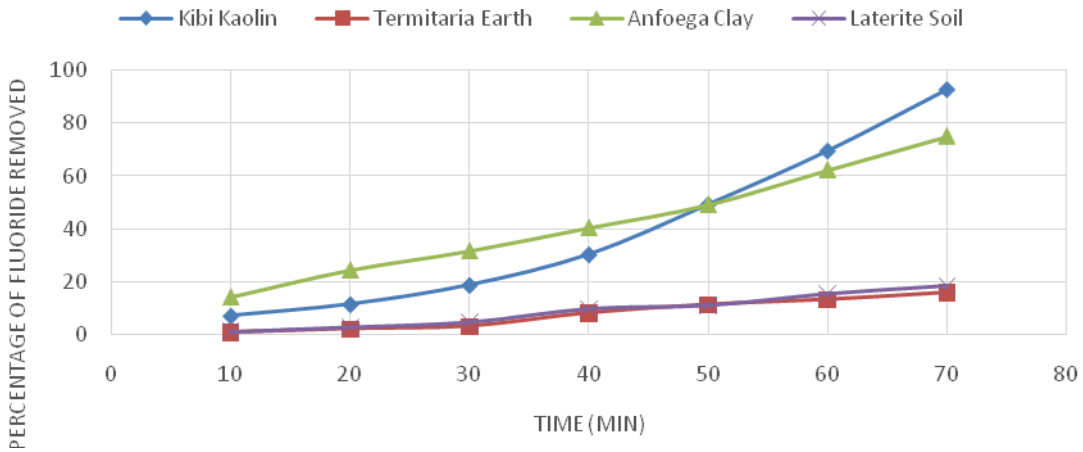

Fig 3 Effect of Contact Time on Fluoride Adsorption

Effect of Flow Rate on Fluoride Sorption

The highest flow rate achieved in the composed ceramic filters showed in Fig. 4 was 0.3ml/s and the lowest flow rate was 0.0029ml/s. Even though a high flow rate was desirable, it decreased the amount of fluoride removed. To compensate this effect the filtration process would have to be repeated to allow more time for the fluoride to be removed. Low flow rate is undesirable even though it results in better fluoride removal.

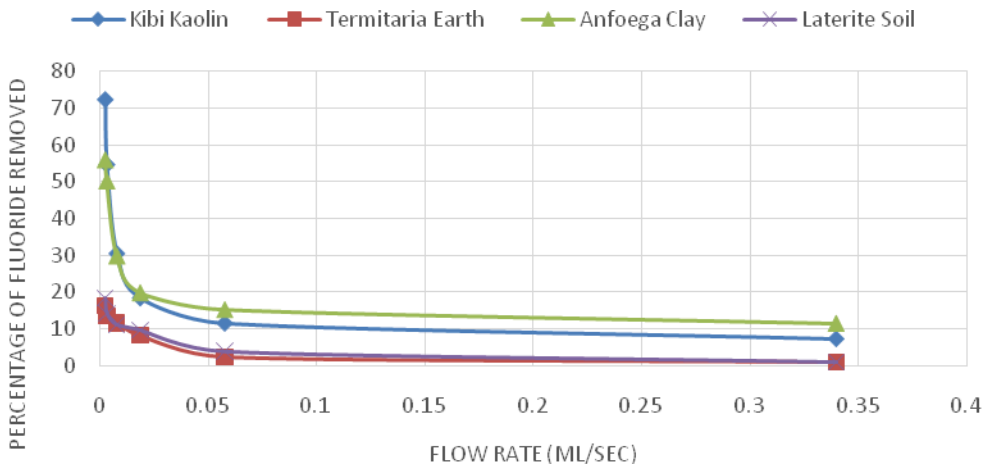

Fig 4 Effect of Flow Rate on Fluoride Adsorption

Effect of Temperature on Fluoride Adsorption

The temperature dependence of fluoride adsorption by Anfoega clay, Kibi kaolin, Laterite soil and Termitaria earth was studied over the range of 24-100˚C. Above 70˚C, it was observed that all the samples removed significant amount of fluoride ion and approached completion as the temperature further increased as seen in Fig. 5. This shows that, if the Bongo ground water is boiled before passing it through any of the formulated filters, fluoride contamination of the water will be reduced significantly. This is attributed to thermodynamics and kinetics of the adsorption reaction which are temperature dependent through $\Delta G = -RT\ln Kc$ [13].

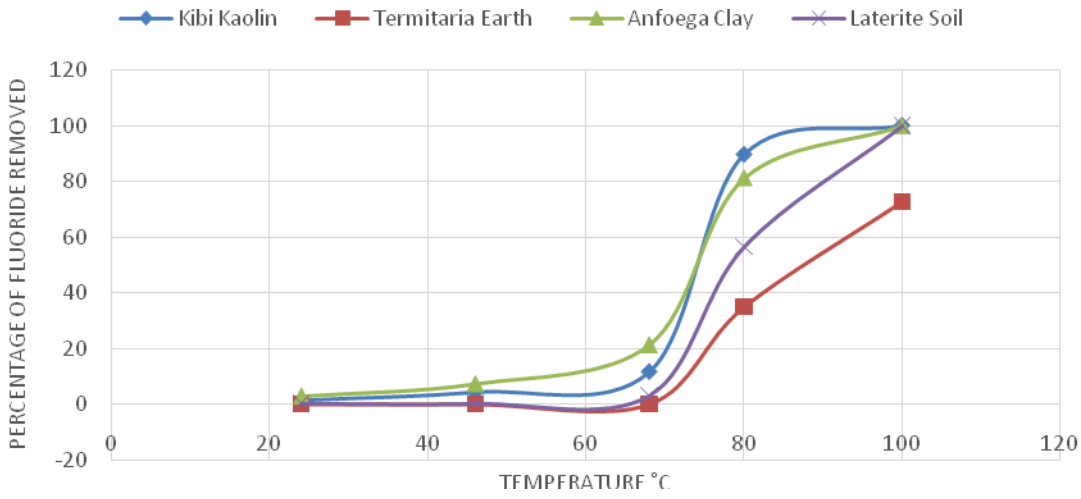

Fig 5 Effect of Temperature on Fluoride Adsorption

Micrograph Results

Fig. 6 shows optical micrographs of the ceramic filters produced. The observed dimensional stability of the porous media in the thickness ranges investigated confirms the feasibility of producing such filters for rural household usage.

Fig 6 Optical Micrograph of Ceramic Filters

Conclusions

Fluoride contamination of water in rural regions of Ghana especially in the Bongo district of the Northern Ghana causes a number of health related problems for the indigenes living in such communities. The possibility of using porous ceramic bodies (filters) as fluoride removal media have been successfully investigated in this work.

The results showed that excess fluoride ions in ground water can be removed to different levels using aluminosilicate based mineral deposits and that preheating to temperatures above 70˚C improved the adsorption characteristics of the filters.

Keywords: Magnetic chitosan resin, biosorbents, adsorption, nickel (II).

Abstract: The purpose of this work is to prepare a low-cost biosorbent, Magnetic chitosan resin (MCR), and determine the ability of this biosorbent to removing Ni (II) ion from aqueous medium. Both kinetics and thermodynamic parameters of the adsorption process were also estimated. The thermodynamic parameters indicated an exothermic spontaneous process and the kinetics followed the second-order adsorption process.

Introduction

Heavy metals are potentially hazardous to human beings and environment. Various industrial processes result in the production of considerable residual water contaminated with heavy metals [1]. Metallic nickel and nickel compounds have many industrial and commercial applications including use in stainless steels and other nickel alloys, catalysts, batteries, pigments, and ceramics [2, 3]. Nickel and nickel compounds generally cause a variety of pathologic effects like skin allergy, lung fibrosis and human carcinogen. Therefore, Nickel removal from aqueous waste streams is currently of great concern for public health and environmental conservation. Several treatment methods have been developed to remove nickel from aqueous waste streams, such as adsorption [4], ion exchange [5], microfiltration and chemical precipitation [6]. Adsorption is considered an effective and economical method among the treatment. Recently utilize low-cost adsorbents has become a new focus point mainly using biopolymers, which obtained from renewable sources and adsorbed metallic ions selectively and effectively. As available biopolymers in nature, chitosan attracted much consideration because of its excellent features, such as biocompatibility, biodegradability, and anti-bacterial properties [7]. Further physical and chemical modification of chitosan has been developed to improve mechanical strength, selectivity and capacity for the adsorption of metals. Magnetic chitosan resin (MCR) is a typical modification method which keeps the properties of chitosan for the adsorption of metal ions, and moreover, techniques employing magnetism are imparted to resins facilitating their trapping from the medium using a magnetic field compared to the centrifugal methods. So it has been widely used in various applications such as enzyme purification, cell separation, and waste treatment [8]. In our present work, we aim to prepare a Magnetic chitosan resin（(MCR) adsorbent and determine the ability of this biosorbent to removing Ni(II) ion from aqueous medium.

EXPERIMENTAL

Preparation of Magnetic chitosan resins (MCR) adsorbent

Chitosan powder (1.0g) was dissolved in 2.0% aqueous acetic acid (200 ml) and 5 g magnetite was added and stirred at room temperature for 2h until the mixture dispersed sufficiently. Next, the magnetic chitosan precipitation was obtained after the addition of ethanol. After dried at 80 ℃, it was placed in ethanol solution in contact with 5% of glutaraldehyde for 2 h, according to the chemical crosslinking with glutaraldehyde occurs by Schiff's reaction. Next the magnetic chitosan resins were collected by magnetic separation and further washed with distilled water and ethanol in order to

remove the unreacted glutaraldehyde. At last, it was dried at 80 ℃ and the magnetic chitosan resin (MCR) was finally prepared. The characteristic of magnetism provides an easy and efficient way to separate the MCR from aqueous solutions. It can be seen that the magnetic chitosan resins with adsorbed Ni could be easily separated by a magnetic field, resulting in clean water (Fig. 1).

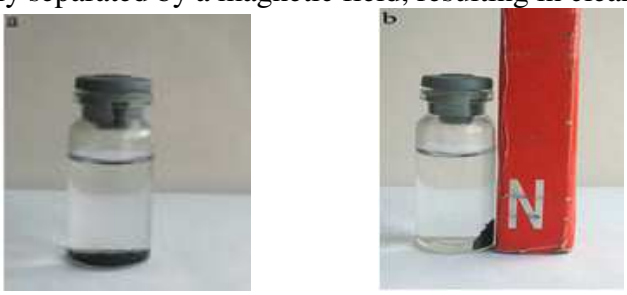

Fig.1 MCR gathered in solution (a) and separated with magnet (b)

Adsorption experiments

The sorption experiments were studied by batch technique. 0.2g MCR were equilibrated with 50 mL of aqueous $Ni(NO_3)_2$ solution with 50mg·L^{-1} in a 100 mL glass stoppered Erlenmeyer flask at 30±2 ℃ in a shaking bath. The initial pH was adjusted with HNO_3 (0.1M) or NaOH (0.1M) before adding the adsorbent. After shaking for 150 min to ensure full equilibration, the MCR were collected and the concentration of nickel (Ⅱ) ions in the supernatant was estimated by monitoring with atomic absorption spectrophotometer. The adsorption capacity was calculated from the following expression:

$$Q = \frac{(C_i - C_t)V}{m} \tag{1}$$

where, Q is the adsorption capacity of the adsorbent (mg/g), C_i and C_t (mg/L) are the initial and terminal concentrations of Ni(Ⅱ) respectively, m (g) is the mass of adsorbent, and V is volume of solution liters.

RESULTS AND DISCUSSION

Kinetics Of Adsorption

The experimental results of Ni (II) adsorption on MCR versus time are shown in Fig.2 The extent of adsorption increases with time and attained equilibrium near 150 minutes. After this equilibrium period, the amount of metal adsorbed did not change remarkably with time. Many researchers have found that if the reaction rate is chemically controlled, the pseudo-second-order model [9] will be the most appropriate model to describe the reaction [10] The experimental data were tested by the pseudo-second-order model whose expression is given as follows：

$$\frac{dq_t}{dt} = k(q_e - q_t) \tag{2}$$

For boundary conditions t=0 for Q_t =0 and t=t for $Q_t = Q_t$, integrating Eq (2) gives below:

$$\frac{t}{q_t} = \frac{1}{kq_e^2} + \frac{t}{q_e} \tag{3}$$

where q_t (mg/g) and q_e (mg/g) are the absorbances at time t and at equilibrium respectively. The slope and intercept of plot of t/Q_t vs. t were used to calculate the pseudo-second-order rate constant k and q_e.

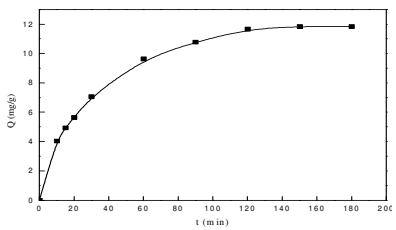

Fig. 2 Effect of adsorption time on adsorption capacity of Ni (II)

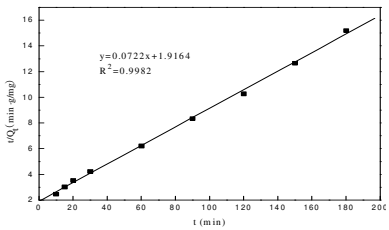

Fig. 3 Pseudo-second-order equation for the adsorption of Ni (II) on MCR

As illustrated in Fig.3, the pseudo-second-order model fitted well with the kinetic experimental data and the correlation coefficients were greater than 0.99. Therefore, the Ni (II) adsorption process is controlled by the chemical process.

Equilibrium isotherm of adsorption

Analysis of the equilibrium data is the most significant to accurately represent the adsorption isotherm. Langmuir and Freundlich adsorption isotherms were often used to fit the experimental data [11]. The Langmuir isotherms assume monolayer coverage of adsorption of each molecule onto the surface has equal sorption activation energy and no interaction between sorbed species. It has traditionally been used to quantify and contrast the performance of different biosorbents. In mathematical form, it is written as:

$$\frac{C_e}{Q_e} = \frac{Ce}{Q_m} + \frac{1}{(Q_m b)} \tag{4}$$

where C_e is the equilibrium concentration of metal ions ((mg·L^{-1}), Q_e is the amount of metal ions adsorbed ((mg·g^{-1}), Q_m is the maximum adsorption capacity of metal ions (mg·g^{-1}), and b is the Langmuir adsorption equilibrium constant (L·mg^{-1}). Therefore, the polt of C_e/Q_e against C_e gives a straight line with a slope of $1/Q_m$ and an intercept of $1/(Q_m b)$ (Fig 4 and Table 1). Table 1 indicates that Langmuir model has perfectly application for nickel (II) sorption with a regression coefficient. The maximum sorption capacity revealed MCR can remove Ni (II) with a higher affinity compared to chitosan in its natural form and most of the modified forms reported in the literature [12].

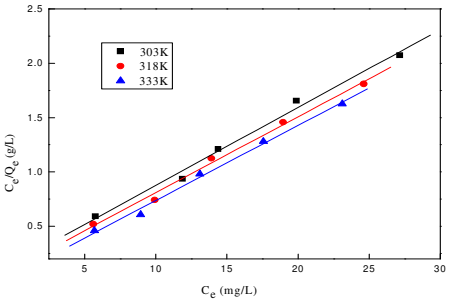

Fig.4 Langmuir isotherms for the adsorption of nickel (II) on MCR

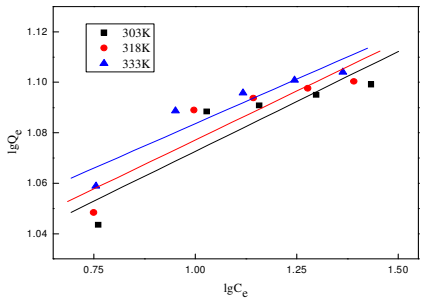

Fig.5 Freundlich isotherms for the adsorption of nickel (II) on MCR

Table 1 Langmuir and Freundlich constants for Ni (II) biosorption on MCR

Temperature	Langmuir constants			Freundlich constants		
(K)	Q_m (mg/g)	b (L/mg)	R^2	K_f	n	R^2
303	13.93	0.4503	0.9908	9.861	12.66	0.8134
318	14.29	0.6393	0.9936	9.992	12.91	0.8270
333	14.47	1.509	0.9942	10.31	14.18	0.8712

The equilibrium adsorption data were applied to the Freundlich isotherm equation for multilayer adsorption isotherm on heterogeneous surfaces. The Freundlich isotherm is an empirical equation based on an exponential distribution of sorption sites and energies. In mathematical form, it is represented as:

$$Q_e = K_f C_e^{1/n} \tag{5}$$

$$\lg Q_e = \lg K_f + \frac{1}{n} \lg C_e \tag{6}$$

In the equations, C_e and Q_e are equilibrium Ni (II) ion concentration (mg/L) and equilibrium adsorption capacity (mg/g), respectively. Freundlich constants, K_f and n can be determined from a liner plot of $\lg Q_e$ versus $\lg C_e$, which affect the adsorption process such as adsorption capacity and intensity of adsorption, respectively. Fig. 5 depicts the plots obtained by the Freundlich isotherm for the adsorbents along with their R^2 values. The Freundlich constants for the adsorption were also

presented in Table 1. As can be seen, the experimental data did not fit well in the Freundlich isotherm equation with low correlation coefficients from 0.81 to 0.87.

Thermodynamic parameters of adsorption

In order to explain the effect of temperature on the adsorption thermodynamic parameters, the adsorption behavior of Ni (II) on the adsorbent at different temperatures were also investigated (Fig. 6). The results showed that as the temperature increased, the value of Q increased, which implied that the adsorption process was endothermic.

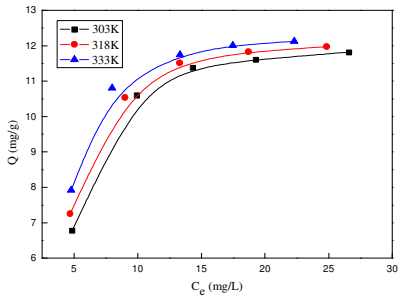

Fig. 6 Equilibrium isotherms for the adsorption of nickel (II) on MCR at different temperature

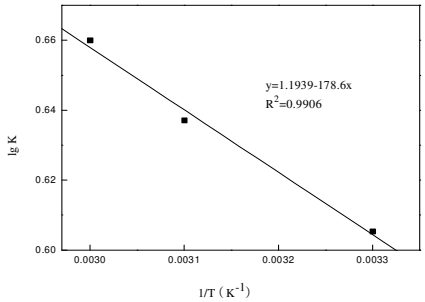

Fig. 7 Van't Hoff plot for the adsorption of nickel (II) on MCR

The thermodynamic equilibrium constant (K) for each system was obtained by calculating the apparent equilibrium constant K'_c at different initial concentration of Ni (II) and extrapolating the same to zero.

$$K_c^{'} = \frac{C_a}{C_e} \tag{7}$$

where C_a is the concentration of Ni(II) on the adsorbent at equilibrium in mg/L and C_e is the equilibrium concentration of Ni(II) in solution in $mg \cdot L^{-1}$. The adsorption parameters thermodynamic standard enthalpy (ΔH^{θ}), standard entropy (ΔS^{θ}), and standard Gibbs free energy (ΔG^{θ}) can be calculated by the thermodynamic equation [13] :

$$\lg K = \frac{\Delta S^{\theta}}{2.303R} - \frac{\Delta H^{\theta}}{2.303RT} \tag{8}$$

$$\Delta G^{\theta} = \Delta H^{\theta} - T\Delta S^{\theta} \tag{9}$$

In the Eq (8), R is the gas constant, 8.314×10^{-3} (kJ/mol·K), T is absolute temperature, K is equilibrium constant at the temperature T, respectively. When lgK is plotted against 1/T, a straight line with slope $\Delta H/2.303RT$, and intercept $\Delta S/2.303R$ were obtained (Fig. 7). The values of ΔH^{θ} and ΔS^{θ} were also obtained from the slope and intercept of the Van't Hoff plots of lnK versus 1/T (Fig.7). The thermodynamic parameters for the adsorption process are given in Table 2. It can be observed that the positive value of ΔH^{θ} indicates the adsorption is endothermic and higher temperature makes the adsorption easier. In addition, this also indicates that adsorption of Ni (II) on MCR is rather chemical process. If it was only physisorption process, the enthalpy of the system would be exothermic [14]. The positive value of ΔS^{θ} indicates that there is an increase in the randomness at the solid/solution interface during the adsorption process [15]. The negative value of ΔG^{θ} decreases with the increase of temperature indicating that the spontaneous nature of adsorption of Ni (II) are inversely proportional to the temperature, and the adsorption is more favorable at high temperatures.

TABLE 2 THERMODYNAMIC PARAMETERS FOR FOR NI (II) BIOSORPTION ON MCR

Temperature (K)	$\triangle G^{\theta}$ (kJ • mol $^{-1}$)	$\triangle H^{\theta}$ (kJ • mol $^{-1}$)	$\triangle S$ (J • mol $^{-1}$ • K $^{-1}$)
303	-3.506		
318	-3.848	3.421	22.86
333	-4.191		

CONCLUSIONS

In this study, a low-cost biosorbent, Magnetic chitosan resin (MCR) was prepared by cheap and environmentally friendly chitosan and iron salts. The biosorbent could remove nickel (II) ions from aqueous solution efficiently via the chemical adsorption process which can be described by pseudo-second rate model. The Langmuir adsorption model and Freundlich equation were used for the mathematical description of the adsorption, and the results showed that the Langmuir isotherm was better compared with the Freundlich isotherm. And the adsorption thermodynamic parameters demonstrated the adsorption process was endothermic.

Keywords: adsorption; Eriochrome black T; mesoporous alumina sphere

Abstract. The present study presents the adsorption behavior of mesoporous alumina sphere for Eriochrome black T (EBT) azo dyes. The batch adsorption experiments were carried out to optimize various experimental parameters such as contact time and dye concentration. The maximum adsorption of EBT was achieved 312.5mg/g. The kinetic studies revealed that the adsorption process followed the pseudo-second-order kinetic model. The adsorption behavior was analyzed by Langmuir and Freundlich isotherms. The values of correlation coefficients (R) showed that the Langmuir isotherm model found to be best fit. Results of study showed that Mesoporous alumina sphere proved to be highly effective for the removal of selected azo dyes.

Introduction

Dyes and pigments as additive materials have been widely used in many industries such as textiles, rubber, paper, and plastics. Recently, over 7×10^5 tons of dyes and pigments are produced annually, of which more than 10% of them persist in the waste effluents of these industries [1]. As the disposal of these effluents into the receiving water body may cause severe damage to aquatic biota and humans due to mutagenic and carcinogenic effects [2], it is of great importance to provide waste-treatment facilities for minimizing these substances in the effluents before discharge.

Hence, the removal of color from waste effluents has significant importance to the environment [3,4]. Various techniques have been employed for the removal of dyes from wastewaters. Due to the low biodegradability of dyes, a conventional biological treatment process is not very effective. Dye laden wastewaters are usually treated by physical or chemical processes. The conventional methods for treating dyes containing wastewaters are coagulation and flocculation [5], oxidation or ozonation [6-7], membrane separation [8,9] and adsorption [10-12]. Among them, adsorption has been found to be a proficient and economic method, and a successful and widely in use for wastewater treatment [13,14]. Conventional porous adsorbent such as activated carbon, peat, chitin, silica, fly ash and clay with nonuniform pore size and discontinuous pore structure, normally showed lower absorption capacity and adsorption efficiency. Therefore, to enhance the sorption performance new sorbents are still under investigation [15].

Mesoporous materials, whose pore sizes range from 2 to 50 nm, are of interest because of their potential use in various fields such as heterogeneous catalysis, energy, biotechnology and nanodevices [16-17]. Owing to their large pore sizes and high surface areas, mesoporous materials are also promising adsorbents for various pollutants in water. From a viewpoint of practical use, the adsorbents themselves should readily be prepared and they should not be toxic. Recently, mesoporous alumina with high surface area, uniform pore-size distribution, a spongelike interlinked

pore system [18,19], large pore size and easy of regeneration can be an alternative for organic pollutants removal. However, the research of dye adsorption on mesoporous alumina was seldom reported.

The main objective of the present research is to investigate the azo dye pollutants removal capacity of mesoporous alumina from aqueous solutions as a possible adsorbent. Here EBT was selected as typical organic pollutants in wastewater. The kinetics and isotherm of EBT adsorption onto mesoporous alumina were also investigated in view of understanding the nature of adsorption.

Experimental

Synthesis and Characterization of Adsorbent.

Mesoporous alumina powders were synthesized using the procedure, which was similar to that reported by Wang et al.[20]. In a typical synthesis, 1.0 g of P123 was dissolved in 25.0 mL of anhydrous ethanol and stirred for 3 h at 40℃. 20 mmol of aluminum nitrate (or aluminum chloride) was then dissolved in a mixed solvent composed of 3.0 mL of 37 wt.% hydrochloric acid and 12 mL of anhydrous ethanol. Once dissolved, two solutions were mixed and vigorous stirred at 40℃. Then the homogeneous sol was transferred to a flat-bottomed flask with plug and aging for 4 d at 40℃. After that, the aged sol evaporation was performed at 70℃ for 48 h in a drying oven without stirring. The resulting solid was calcined at 400℃ for 4 h in muffle furnace at a heating rate of 1.0 ℃ min^{-1}. At last, white alumina powders were obtained. The final powdery sample was labeled as N-MA (aluminum nitrate) and Cl-MA (aluminum chloride).

The synthesized mesoporous alumina was thoroughly characterized using powder X-ray diffraction (XRD), Transmission electron microscopy (TEM) and BET surface area analysis. The Powder X-ray diffraction (XRD) patterns were recorded with a (Rigaku D/max-βB) diffract meter using a Cu Kα radiation at 40 KV and 50 mA. Transmission electron microscopy (TEM) images were obtained on a (JEOL 2000 EX) electron microscope operating at an accelerating voltage of 200 KV. Nitrogen adsorption–desorption isotherm measurements were performed on a Micrometitics ASAP 2020 volumetric adsorption analyzer at 77 K. Before adsorption–desorption isotherm measurements, the samples were out gassed at 150 ℃ for 4 h in the degas port of the analyzer. The Brunauer-Emmett-Teller (BET) method was utilized to calculate the specific surface area of each sample and the pore-size distribution was derived from the adsorption branch of the corresponding isotherm using the Barrett-Joyner-Halenda (BJH) method. The total pore volume was estimated from the amount adsorbed at a relative pressure of $P/P_0 = 0.99$.

Batch adsorption studies.

Adsorption of EBT on mesoporous alumina was studied by batch experiments. A stock solution (1.0 g L^{-1}) of EBT was prepared from analytical-reagent product. The stock solution was then diluted to give a series of standard solutions in different concentrations. Batch adsorption experiments were carried out using a model SHA-C thermo stated shaker (Changzhou Boyuan Experimental Analysis Instrument Manufacture, China) at 100 rpm. Typically, adsorption volume of solution was 40ml and 10 mg mesoporous alumina were used in each adsorption at giving time intervals, the suspension containing adsorbents was extracted and adsorbents were collected using 0.25 μm Millipore filtration. EBT concentration in supernate after separation was monitored by UV-vis 722 spectrophotometer (Shanghai precision Instrument CO., Ltd) at λ_{max} =540 nm. The adsorption capacity (q_t: mg g^{-1}) and percent adsorption (r) were calculated from the change of EBT concentration according to the following equation (1) and (2), respectively:

$$q_t = \frac{(C_0 - C_t) \times V}{m} = \frac{C_0 - C_t}{m_c} \quad (1) \qquad r = \frac{C_0 - C_t}{C_0} \times 100 \quad (2)$$

Where C_0 is initial EBT concentration (mg L^{-1}); C_t is the instantaneous EBT concentrations (mg L^{-1}); m_c is the weight of the adsorbent (g) and V is the volume of the solution (L).

Regeneration experiments.

Mesoporous alumina (50 mg) were suspended in 400 mL of EBT solution (100 mg L^{-1}) and the adsorption was conducted with constant shaking for 24 h at a pH of 6.8 ± 0.05. Then the solution was filtered and the adsorbent was calcinated at 350 ℃ for 2 h in the air to remove the adsorbed EBT after which the morphology and structure of adsorbent were characterized by TEM and infrared spectrum.

Results and discussion

Characterization of mesoporous alumina.

Powder X-ray diffraction (XRD) patterns of the calcined mesoporous alumina samples designated as N-MA and Cl-MA are shown in Fig. 1. Both N-MA and Cl-MA exhibited only single XRD peak at 2θ values around 0.8, which indicates a mesoporous structure without a long range order, but having a fairly uniform pore size. It is worth mentioning that the single low angle XRD peak in mesoporous alumina does not necessarily prove well-ordered mesoporous material with uniform pores [21]. Low angle peak remained intact after calcinations at 400℃, which implies the structural stability of the materials during and after the removal of surfactant. As shown by the wide angle XRD patterns of samples (inset of the Fig. 1) no discernable diffraction peak were observed which indicated that the structure character of mesoporous alumina powders was amorphous (the pore wall is not crystalline) [22]. Fig. 2 shows TEM images of mesoporous alumina samples used in this work. Both N-MA and Cl-MA show a typical sphere structure with different diameter from tens to hundreds nano-meter and wormhole-like morphology mesoporous structure were observed. The interconnected pore system of mesoporous alumina can reduce transport limitations, enhance accessibility to the active sites [23-24], and contribute to the adsorption uptake elevation [25]. The textural property of the samples was determined by N_2 adsorption–desorption. As can be seen from Fig.3, nitrogen adsorption–desorption isotherms of mesoporous alumina sphere were typically IV type with large hysteresis loops, which suggested the existence of mesoporous framework. A BJH analysis (inset in Fig.3) of the desorption branch of the isotherm indicates that N-MA and Cl-MA with mesoporous structure possess a mean pore size of 10.0 nm and 14.6 nm with pore volume bearing 0.33 $cm^2 g^{-1}$ and 0.35 $cm^2 g^{-1}$ respectively. The mesoporous sphere exhibited relatively high specific surface area and the BET surface area is 127.1 $m^2 g^{-1}$ and 95.68 $m^2 g^{-1}$ respectively. We deduce that the increase of the specific surface area among the as-synthesized mesoporous structure can be ascribed to the interactions between anionic and surfactant. The higher surface area and interlink pore system structure will facilitate more active sites exposed and enhance the adsorption property of mesoporous materials. According to Yuan [26] that NO_3^- does not strongly influence the self-assembly process because of its weak complexation ability, however, chloride ion can strongly coordinate with aluminum ions, and disturb the assembly process, leading to long-range disordered mesostructures.

Effect of contact time.

The effect of contact time on the adsorption of EBT was studied to determine the time taken by N-MA and Cl-MA to remove 100.0 mg L^{-1} EBT solution. The results are shown in Fig. 4. Sorption equilibrium was reached after 15 hours with two samples. The adsorption capacity of N-MA and Cl-MA were 312.5 and 135 mg g^{-1}respectively, which means the adsorption capacity of N-MA was about one time higher than that of Cl-MA. These preliminary results led us to deduce that the higher surface area, narrower pore size distribution and interlinked pore system of N-MA results in a better acid dye sorption capacity. This investigation is only devoted to the N-MA, which is more efficient than Cl-MA in the acid dye removal process. In the following discussion N-MA, as its superior adsorption capacity was selected as the adsorbent for EBT removal.

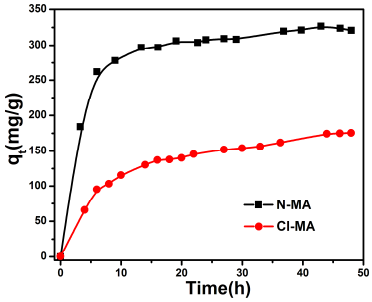

Fig. 4 Effect of contact time on EBT adsorption rate for different mesoporous alumina.

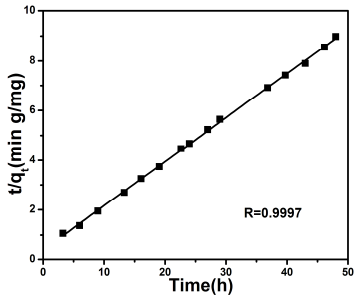

Fig. 5 The pseudo-second-order kinetic plots for the adsorption of EBT onto N-MA at various time intervals.

TABLE 1. KINETIC PARAMETERS FOR THE ADSORPTION OF EBT ONTO AL$(NO_3)_3$-MA AT VARIOUS TIME INTERVALS

sorbent	qexp (mg/g)	k1 (min-1)	|r1|	qe1 (mg/g)	k2 (g/mg·min)	|r2|	qe2 (mg/g)
Al(NO3)3-MA	307.75	3.22*10-2	0.938	177.95	2.29*10-5	0.9997	333.33

Adsorption kinetic models.

Adsorption kinetics, demonstrating the uptake rate of pollutants, is one of the most important characteristics representing the adsorption efficiency of mesoporous alumina. The Lagergren's first order kinetic model [27-28] and the Ho's pseudo second order model [29-30] are the most frequently used in the literature to describe the sorption process. The Lagergren's first order model is expressed by the equation:

$$\lg(q_{e1} - q_t) = \lg q_{e1} - k_1 t / 2.303 \quad (3)$$

Where q_t and q_{e1} (mg g^{-1}) are the amounts of dye adsorbed per unit mass of the adsorbent at time t and at equilibrium, respectively and k_1 (min^{-1}) is the first order rate constant of adsorption. Eq. (3) shows a linear relationship between $\lg(q_{e1} - q_t)$ and t. Linear regression calculations allow to obtain the values of the rate constant k_1 and the equilibrium removal capacity q_{e1}. These parameters (k_1, q_e) were calculated for the sorption of EBT on N-MA and were reported in Table 1. The calculated values from the first order kinetic model show that the experimental results fit this model with determination coefficient values of 0.938. Moreover, large differences between experimental and calculated values of the equilibrium sorption capacities are observed (Table 1). We conclude that the first order kinetic model is not adequate to describe the sorption process. Due to its good correlation with the experimental results, pseudo second order model has been extensively used by several researchers in the same field. This model is expressed by equation:

$$\frac{t}{q_t} = \frac{1}{k_2 q_{e2}^2} + \frac{1}{q_{e2}} t \quad (4)$$

Where k_2 is the second order rate constant (g mg^{-1} min^{-1}). The plots of t/qt versus t should give straight lines where slopes and intercepts are respectively $1/q_{e2}$ and $1/(k_2 q^2_{e2})$ (Fig.5). The values of the rate constant k_2 and of the equilibrium sorption capacity q_{e2} are calculated from these parameters. The calculated k_2 and q_{e2} values and the corresponding linear regression determination coefficient R values for 100 mg L^{-1} (EBT) initial concentrations are also reported in Table 1. Good correlation is observed between experimental data and the pseudo second order kinetic model with determination coefficient values higher than 0.9997. These results implied that the pseudo-second-order kinetics model fitted better with kinetic data than pseudo-first-order kinetic model.

Effect of EBT initial concentration.

The experiments studying the effect of EBT initial concentration were carried out using 10 mg of N-MA for 24 h at room temperature. The results of the experiments with varying EBT initial concentrations were shown in Fig. 6. With an increasing of the EBT initial concentration, from 15 to 180 mg L^{-1}, the adsorption capacity at equilibrium rose significantly and then the increasing trend became smaller. The percentage of EBT removal reached 100 % when the initial concentration was

as low as 28.01 mg L^{-1} or lower, and the color of the EBT solution changed from purple to clarification.

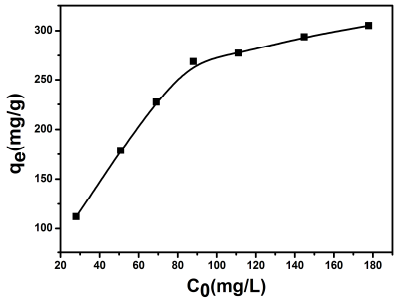

Fig. 6 Effect of initial concentration of EBT on the adsorption of EBT onto N-MA.

TABLE 2. THE ADSORPTION ISOTHERM CONSTANTS FOR THE ADSORPTION OF EBT ONTO AL$(NO_3)_3$-MA AT VARIOUS INITIAL CONCENTRATIONS OF EBT.

Sorbent	Langmuir				Freundlich		
	q_{max}	k_L	r_L	R_L	n	k_F	r_F
Al$(NO_3)_3$-MA	312.5	0.215	0.995	0.0255	5.679	141.55	0.942

Equilibrium isotherms.

Equilibrium studies were carried out in order to determine the optimum conditions for maximum EBT removal by N-MA. Two general-purpose equilibrium models and a modified combined model were used in an attempt to fit the experimental data: (i) the Langmuir model (Eq. (5)), and (ii) the Freundlich model (Eq. (6)).

$$\frac{1}{q_e} = \frac{1}{q_{\max}} + \left(\frac{1}{k_L q_{\max}} \right) \frac{1}{C_e} \tag{5}$$

$$\lg q_e = \lg k_F + \frac{1}{n} \lg C_e \tag{6}$$

Where q_{max} and K_L are constants related to the loading capacity and the free energy of adsorption; K_F and n are the Freundlich temperature-dependent constants; Ce is the equilibrium concentration (mg L^{-1}) and q_e is the amount adsorbed at equilibrium (mg L^{-1}). The Langmuir and Freundlich parameters for the adsorption of EBT are list in Table 2. The results shows that the Langmuir isotherm model gives a better fit to the experimental isotherm than Freundlich isotherms based on regression coefficients (R_L=0.995, R_F=0.942). The best-fit Langmuir parameters are q_{max}= 312.5 mg g^{-1}, K_L=0.215 L mg^{-1}.

The effect of isotherm shape has been discussed [31] with a view to predict whether an adsorption system is favorable or unfavorable. The essential feature of the Langmuir isotherm can be expressed by means of 'R_L', a dimensionless constant referred to as separation factor or equilibrium parameter. R_L is calculated using the following equation:

$$R_L = 1/(1+K_L C_0) \tag{7}$$

Where C_0 is the highest initial dye concentration (mg L^{-1}). As the R_L values lie between 0 and 1, the adsorption process is favorable [31]. The R_L value for the adsorption of EBT is 0.0255 indicating that the adsorption is favorable.

Regeneration Studies

Desorption studies help to elucidate the nature of adsorption and recycling of the spent adsorbent and the EBT. After adsorption, the adsorbent was calcined at 350 ℃ for 2 h to remove the adsorbed organic matter. Then, the obtained sample was used to repeat adsorption experiment for about several times and the adsorption capacity of adsorbent were calculated. The results showed that the adsorption capacity of N-MA could be maintained to 237.74 mg g^{-1} after three times of regeneration experiment, which indicated that the adsorbent has excellent regeneration capacity.

Conclusion

In summary, regular mesoporous alumina spheres were prepared by a simple evaporation induced self assembly procedure. The high surface area and interconnected pore system of mesoporous alumina can reduce transport limitations and enhance accessibility to the active sites that highly increase the adsorption property of mesoporous alumina. The adsorption experiment of EBT solution showed that the as-synthesized mesoporous alumina sphere can effectively remove EBT from aqueous solutions and the adsorption capacity was 312.5 mg L^{-1}. The percentage of EBT removal by mesoporous alumina sphere reached 100 % when the initial concentration of adsorbate is or below 28.01 mg L^{-1}. The kinetic and sorption data fitted well with the second order kinetic model and the Langmuir model respectively. Regeneration experiment showed that the adsorption capacity was still 237.74 mg g^{-1} after three times of simple calcined desorption treatment. Hence, it is suggested that these mesoporous alumina sphere have higher potential to be employed as a highly efficient alternative adsorbent for azo dye wastewater.

Keywords: chlorpyrifos; molecular imprinted film; sensor;water

Abstract. Molecularly imprinted microspheres for recognition of chlorpyrifos were prepared by thermal initiation and precipitation polymerization, and were characterized using scanning electron microscope and infrared spectroscopy. Binding characteristics of the microspheres were also investigated. Sensitive film electrode of chlorpyrifos was prepared using the microspheres above on the surface of gold electrode by spin coating. Electrochemical sensor was constructed with the electrode prepared above as recognition element, and the response characteristics of the sensor to chlorpyrifos in water were investigated based on constant-current potentiometry. It was shown that a reasonable linear response curve between potential and concentration was obtained from 1.0×10^{-12} mol/L to 2.0×10^{-8} mol/L, with a detection limit of 1.0×10^{-13}mol/L. The suitable pH was 2.2～3.4， and response time was 10 min. The imprinted electrode showed relatively high selectivity to chlorpyrifos and was applied to the analysis of chlorpyrifos in the simulated river samples with recovery rates ranging from 89% to 105%.

Introduction

Chlorpyrifos (CPF) is widely-used as a pesticides as well as a herbicide given its low toxicity and high efficiency [1]. Due to its low degradation speed, frequent existence in the surface water and crops, and the potential carcinogenic effects to human body, it is quite necessary to detect CPF residues in both environment and food [2,3]. At present, the national standard detection methods for CPF are mostly based on the liquid-liquid extraction-gas chromatography, which require complex operation, long time, and large amount of organic reagents[4,5]. Therefore, it is significantly important to develop a new efficient, low-cost, and simple method for CPF determination.

Molecular imprinting technique (MIT) is a hot applied technology by synthesizing molecular imprinted polymers (MIPs) with peculiar selectivity for special molecules. In recent decades, MIT has been widely developed for solid extraction[6,7,8],chromatographic separation[9,10], chiral resolution[11,12]. For the outstanding advantages like strong tolerability, low cost, good stability, MIPs have also been used as the recognition elements in sensors research [13-17]. Recently, molecularly imprinted sensor technology has been applied to analyze pesticides. For example, Zhao Jun et al [15] prepared an aminophenol isoproturon imprinted film sensor on gold electrode by electric polymerization. With the use of K3Fe(CN)6 as the probe between imprinted electrode and base solution, a detection method of isoproturon was developed . Peini Zhao et al [18] prepared a chemiluminescence molecularly imprinting sensor for the determination of glyphosate in the food. However, MIT used for analyzing CPF is seldom reported. Furthermore, such sensors still have some problems including relatively high test concentration range. In this study, an imprinted sensitive film electrode of CPF was prepared on the surface of gold electrode by spin coating method, and then a highly sensitive film electrode sensor was constructed. A reasonable result was achieved rapidly when the sensor was preliminary applied to the actual water samples.

Experimental

Apparatuses and Reagents

Potentiostat/Galvanostat Model 273 electrochemical workstation(PE Company, USA); three-electrode system(the MIPs sensor developed in this study was used as working electrode, with a saturated calomel electrode (SCE) and a Pt filament electrode being respectively used as reference electrode and counter electrode); portable acidity meter pH B-5(Hangzhou Ray Magnetic Analysis Instrument Factory, China); the XL-30FEG scanning electron microscope (Philips Company, Holland); Nicolet MAGNA-IR 560 infrared spectrometer (Thermoelectric Co., USA).

CPF(95% of the technical grade of pesticide, Shenyang Dongda Dick Bio-pharmaceutical Co. Ltd., China) were purified by recrystallization in our laboratory; 2-2' azoisobutyronitrile(AIBN) (chemical grade, Tianjin Bodi Chemical Co., Ltd., China); Methacrylic acid(MAA) (analytical grade, Tianjin Regent Chemicals Co. Ltd, China); Ethylene glycol dimethacrylate (EGDMA) (98%, Shanghai crystal pure reagent Co. Ltd, China); Polyvinyl chloride powder (PVC) (National Key Laboratory of Sichuan University Materials Engineering). all the reagents were all of the analytical grade and were purchased from Bodi Chemical Co.Ltd. Mill-Q ultra-pure water was used.

Construction of Molecular Imprinted Electrochemical Sensor

1)Preparation of molecular imprinted microspheres

The molecularly imprinted polymers (MIPs) for CPF were synthesized according to literature[19] and part of the preparation steps were modified. 175 mg of CPF (0.5 mmol) and 0.17 mL of MAA (2mmol) were dissolved in 40 mL acetonitrile. After shaking for 60min at room temperature, the solution was placed into the refrigerator for overnight to complete the reaction. 1.7 mL of EDMA (10mmol) and 10mg of AIBN (0.06mmol) were then added. After nitrogen gas sparged into the mixture for 10min, the solution system was sealed and kept in a constant temperature water-bath at 60°C for 24 h. Then the polymerization products were taken out, cooled to room temperature, and centrifuged to obtain the polymer microspheres.

The microspheres were washed with a mixture of methanol-acetic acid((9:1, v/v) until the template molecule of CPF was no longer detected in the elution, and then rinsed with methanol to wash off acetic acid to ensure the neutralization of hydrogen ion. The microspheres were dried to constant weight in vacuum, resulting in the desired imprinted microspheres (MIPs). For comparison, the non-imprinted polymers were also prepared using the same steps without the addition of CPF

2) Pretreatment of gold electrode

The gold electrode was polished carefully with sand paper of 3000#, polishing paper (either withα-Al2O3 polishing powder of 30 nm~50 nm) and chamois successively, and then sonicated in ultra-pure water for 5 min. The procedure was repeated for three times.

3) Preparation of molecularly imprinted film electrode

5 mg of PVC powder and 15 mg of imprinted microspheres(MIPs) were dissolved in 20mL of tetrahydrofuran and then sonicated for 30 min. 20 μL of the above solution was coated on the surface of the gold electrode using the self-made spin coating device. After complete evaporation of the tetrahydrofuran, the MIPs microspheres were deposited uniformly. The above spin coating operation was repeated for 4 times, thus shaping the film electrode. The prepared film electrode was placed at 4℃ in the refrigerator overnight for use.

Test Method

A three-electrode system was adopted in our experiment. The working electrode was the prepared sensitive film electrode, the reference electrode was the Ag/AgCl electrode and the counter electrode was the Pt filament. The constant current potentionmetric method was used for

testing and the response time was 10min. Before the test, the film electrode was placed in the blank solution for activation for 5 min. The blank and test solution both contained 0.03 mol/L of HCl and 0.02 mol/L of KCl.

Results and Discussion

Scanning Electron Microscopic Observation and Infrared Spectrum Analysis of MIPs

Bulk polymerization was the regular preparation method of MIP. However, its preparation required grinding and screening, which caused serious damage to the hole, irregular particle and poor uniformity. In this study, CPF molecularly imprinted microspheres was prepared by thermal initiation and settlement polymerization in the presence of acetonitrile solvent. Then, SEM was used for morphology analysis of the polymer microspheres (see Fig.1). As Fig. 1 showed the products were spherical, uniform particles, of which the diameter ranged from100 nm to 200 nm.

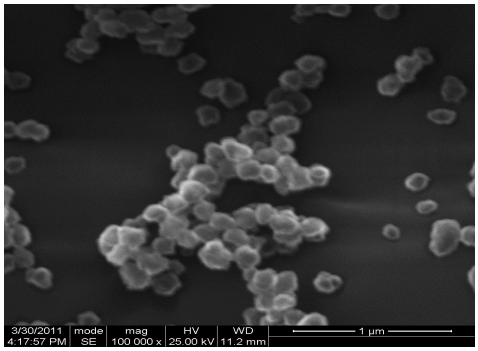

Fig.1 Scanning Electron Micrograph of CPF

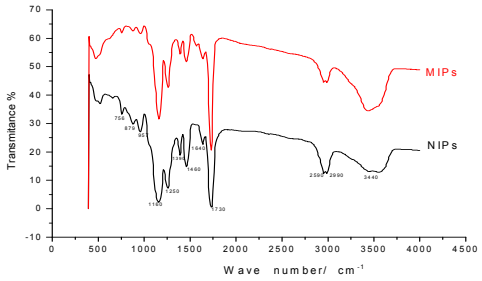

Fig.2 IR Spectra of MIPs and NIPs Molecularly Imprinted Polymer MIP_S: Imprinted Microspheres; NIP_S: Non-imprinted Microspheres.

Infrared spectrometer was used for the analysis of the functional group of the polymer.(see Fig. 2) As Fig. 2 showed - stretching vibration absorption of -C=C double bond near 1640 cm^{-1} was very small, which illustrated that the cross-linking agent and functional monomer polymerized mostly, and the template molecules could be crosslinked to the polymers. The infrared spectra of MIPs and NIPs were nearly consistent in peak shape and peak position, indicating that CPF template molecules in the MIPs were completely eluted [20]. Meanwhile, the absorption peak near 3400 cm^{-1} was the -OH characteristic absorption peak of -COOH functional group in MAA. The peak strength of MIPs near 3400 cm^{-1} was higher than NIPs obviously, indicating that the holes formed in MIPs made -OH active groups increase significantly, which can produce more hydrogen bonds function to help the combination and adsorption of the template molecules.

Adsorption Capacity of MIPs

The adsorption isotherm of CPF onto imprinted microspheres and non-imprinted microspheres were drawed at CPF 10^{-5} mol/L~10^{-7} mol/L with static adsorption method (see Fig. 3).With the increase of concentration of CPF, the adsorbance of the imprinted microspheres increased significantly and then reached a saturation value. However, the adsorbance of CPF onto non-imprinted microspheres was few and it did not change significantly along with the concentration of CPF. It showed that the adsorption of imprinted microspheres to CPF was due to the specific combination on the selective binding sites. The experiment results were analyzed with Scatchard method (see Fig.4).The figure was comprised of two straight lines with good linear relationships, which indicated that in the studied concentration range, it existed two non-equivalent binding sites between CPF and imprinted microspheres at the molecular level, that caused a significant adsorption behavior, and provided the necessary conditions for the sensor study.

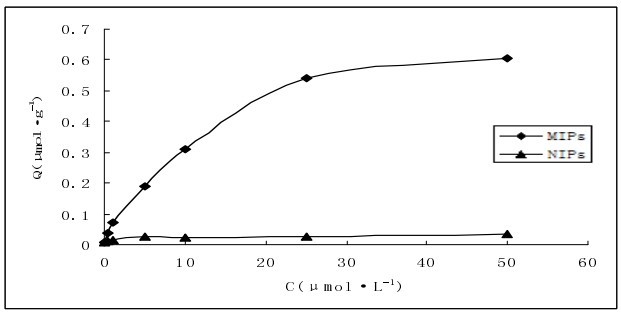

Fig.3 Binding isotherm of MIPs-CPF and NIPs-CPF (20℃) MIP_S: imprinted microspheres; NIP_S: non-imprinted microspheres.

Optimization of Imprinted Film Electrode Preparation

Film-forming material is one of the basic materials for film electrode preparation. Materials such as PVC SG-2, PVC SG-3, PSH-10, and PSH-30 were compared in the study. According to the operation of Ⅱ,B,3), PVC SG -2 showed better hardness, toughness and adhesion onto the electrode than other materials.

The effect of THF solvent volume and the times of spin-coating on the film quality and sensor property were also investigated. It indicated that the film showed good uniformity and the film electrode showed good repeatability with appropriate response time when 20mL THF and 4 times of spin-coating were adopted.

Effect of pH Value on the Film Electrode Test

For 1.0×10^{-10} mol/L of CPF solution, the potential under different pH values was recorded using the film electrode.It was shown in the E-pH curve (see Fig.5) that when the pH ranged from 2.2 to 3.4, the potential value was basically stable; when the pH was greater than 3.4, the potential value obviously declined. In order to reduce the effect of pH value on the accuracy of results, 2.2 to 3.4 of pH range was selected for testing.

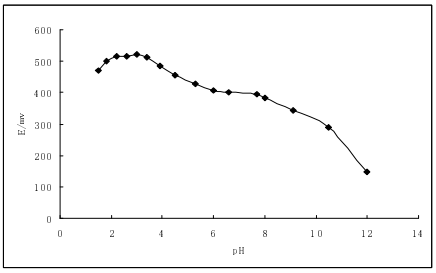

Fig.5 The effect of pH value

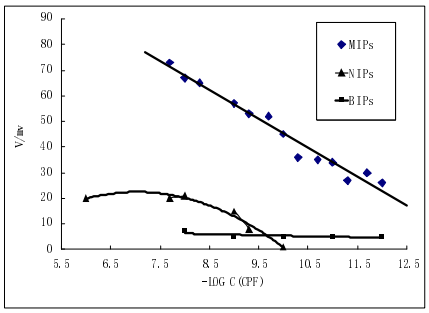

Fig.6 Analysis of Molecular Imprinting Effect
mip_S: Imprinted Film Electrode; Nip_S: Non-imprinted Film Electrode;
Bip_S: Bare Gold Electrode.

Analysis of Molecularly Imprinting Effect

Response of bare gold electrode, non-imprinted film electrode and imprinted film electrode to different concentrations of CPF were tested in this study,(see Fig. 6). The results showed that the bare gold electrode had no apparent responses to different concentrations of CPF solution; the non-imprinted film electrode showed a certain responses when CPF concentration varied from 1.0×10^{-10} mol/L to 2.0×10^{-6} mol/L without a linear relationship, which quickly approached an equilibrium in 3 min; for CPF concentration ranging from 1.0×10^{-12} mol/L~2.0×10^{-8} mol/L, there existed a good negative linear relationship between potential and CPF concentrations.. It can be concluded that recognition site formed in the imprinting polymer film played an important role.

Electrochemical Response of Imprinted Film Electrode

Using constant current-potential, the response of film electrode to CPF was detected. A good linear relationship was achieved when the concentration of CPF ranged from 1.0×10^{-12} mol/L to 2.0×10^{-8} mol/L. With the minus logarithm of test concentration(m) as abscissa and potential difference (V) between test solution and blank solution as ordinate, the linear equation was V=11.26m +157.9 (R2 = 0.9897). The detection limit was 1.0×10^{-13} mol/L, which was significantly lower than previous research [14, 17]. Hereby, samples with low content of CPF can be determined directly without preconcentration which is time-consuming and complex.

Investigation of the Sensor Selectivity

The selectivity of film electrode to dimethoate, malathion, phorate and atrazine were investigated. The results showed that the sensor exhibited a weak response to dimethoate, malathion, phorate and atrazine, with the reduction of potential significantly less than that for CPF under the same concentration of solution. The response to phorate was more obvious, but the response potential was instable with great fluctuation of the potential value. Possible reasons were that the molecular structure of dimethoate, malathion and atrazine was quite different from CPF, and did not match the electrode surface holes, so could not close to the holes. But non-specific adsorption could still cause a weak response which did not interfere with the determination of CPF. However, phorate which was small molecule could enter the hole freely, closed part of the hole to some extent, and objectively impeded the diffusion of ions in the solution. However, this random combination was not firm, showing an instable response value [21]. As a whole, the sensor showed a relatively good selectivity to CPF.

Sample Analysis

Three samples of river water were adjusted to pH 2.8 for recovery test carried out with the calibration curve method. Three samples of river water were adjusted to pH 2.8 for recovery test carried out with the calibration curve method. 1.0×10^{-9} mol/L, 5.0×10^{-9} mol/L, and 1.0×10^{-8} mol/L CPF were added into three river water samples respectively. As shown in Table1, the average recovery rate ranged from 88% to 105%, and RSD(n=3) ranged from 5.8% to 8.6%. It showed that this method had good accuracy and precision.

TABLE 1 RECOVERY OF CPF WITH CALIBRATION METHOD

Sample	Addcd (mol/L)	Meaured (mol/L)（n=3）	Recovery rate (%) (n=3)	RSD (%) (n=3)
1	1.0×10^{-9}	1.05×10^{-9}	105	8.6
2	5.0×10^{-9}	4.4×10^{-9}	88	6.4
3	1.0×10^{-8}	0.90×10^{-8}	90	5.8

Conclusions

It was reported in this paper a method of molecularly imprinted film sensor on determination of CPF in water. Compared with sensors for determining other pesticides, this sensor has relatively higher sensitivity with lower detection limit and wider linear concentration range. A good result was achieved when this method was applied to the actual water samples with only a simple adjustment of pH. There are many advantages of this method, including easy and time-saving operation, low cost, and low toxicity because toxic organic solvents were generally avoided. And so it was a good alternative for some of costly instrumental methods such as gas chromatography. A follow-up study will focus on optimizing the procedure of film-coating and improving sensor’s reused times.

Keywords: NNO; Imidacloprid; Adsorption; Dispersant

Abstract: Some factors such as imidacloprid dose, contact time, initial NNO concentration, stirring speed and temperature affecting the dispersant NNO (formaldehyde condensate sodium salt of naphthalene sulfonic acid) adsorption on imidacloprid particle was investigated in this paper. It demonstrated that NNO adsorption amount decreased with the increasing imidacloprid dose and temperature, but increased with the increasing contact time, initial NNO concentration and stirring speed. The results implied that the dispersant NNO was adsorbed on imidacloprid particle physically and exothermically.

Introduction

For the successful utilization of imidacloprid aqueous suspension concentrate (SC) in commercial products, a high imidacloprid concentration is desired, and it is necessary for imidacloprid SC to display good fluidity and stability for its handling in preparation, storage and transport processes. The proper type and dosage of dispersants are crucial to obtain commercially suitable imidacloprid SC, these dispersants adsorb on imidacloprid particle surface, and modifying properties of particle surface[1]. The main objective of this paper is to investigate some factors, including imidacloprid dose, contact time, initial NNO concentration, stirring speed and temperature, affect the dispersant NNO adsorption, and the results provide useful data for manufacturing commercially suitable imidacloprid SC.

Experimental Section

Imidacloprid (purity 97 %) was obtained from Sigma-Aldrich. The chemical structure of imidacloprid and dispersant NNO were presented in Fig.1. The NNO solution (1000 $mg \cdot L^{-1}$) was prepared by dissolving weighted proper NNO powders in distilled water, which was diluted with appropriate volumes of distilled water into dispersant NNO solutions at different concentrations.

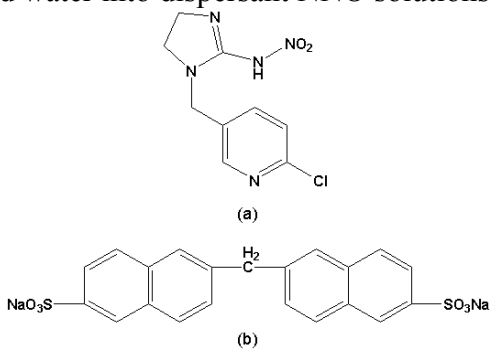

Fig. 1 Chemical structure of imidacloprid (a) and NNO (b)

Batch adsorption studies were conducted at different imidacloprid doses (0.5-2.0 g·L^{-1}), contact times (0-30 min), initial NNO concentrations (250-1000 mg·L^{-1}), stirring speeds (50-250 rpm) and temperatures (298-328 K) with 50 mL of NNO solution in a water bath to optimize the adsorption conditions. At last, dispersant NNO and imidacloprid particles were separated by centrifugation (Hettich universal 320R) at 5000 rpm for 20 min, and NNO concentration in solution was determined using a UV-visible spectrophotometer (Shimazu UV-1800) by monitoring the absorbance changes at 225 nm. Moreover, the amounts of NNO at time t (min) and equilibrium were calculated by Eq. 1 and 2, respectively:

$$q_t = (c_0 - c_t)V/M \quad (1)$$

$$q_e = (c_0 - c_e)V/M \quad (2)$$

Results and Discussion

The plot of NNO adsorption amount versus imidacloprid doses (0.5-2.0 g·L^{-1}) was shown in Fig. 2. It was found that NNO adsorption amount decreased with the increasing imidacloprid dose. This is due to aggregation or overlapping of adsorption sites on imidacloprid particle surface. That is, the diffusion path length increase and available total imidacloprid surface area decrease with the increasing imidacloprid dose[2].

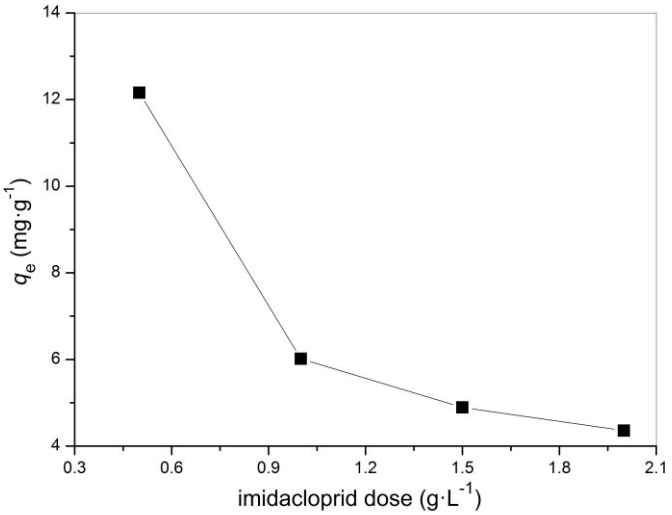

Fig. 2 Effect of imidacloprid dose on the adsorption of NNO. (c_0 = 500 mg·L^{-1}; stirring speed 200 rpm; T = 298 K; t = 30 min)

The plot of NNO adsorption amount versus contact time at initial NNO concentration of 250-1000 mg·L^{-1} was shown in Fig. 3. NNO adsorption amount increased rapidly with elapsed contact time at the beginning stage of adsorption, then the adsorption rate decreased gradually. At last, NNO adsorption amount did not change significantly after 15 min when there was a dynamic equilibrium between desorption and adsorption.

In addition, Fig. 3 indicated that NNO adsorption amount was increased with an increase in the initial NNO concentration. It is attributed to that initial NNO concentration provides a principal driving force to overcome mass transfer resistances of all molecules between the aqueous (dispersant NNO solution) and solid phases (imidacloprid particle)[3].

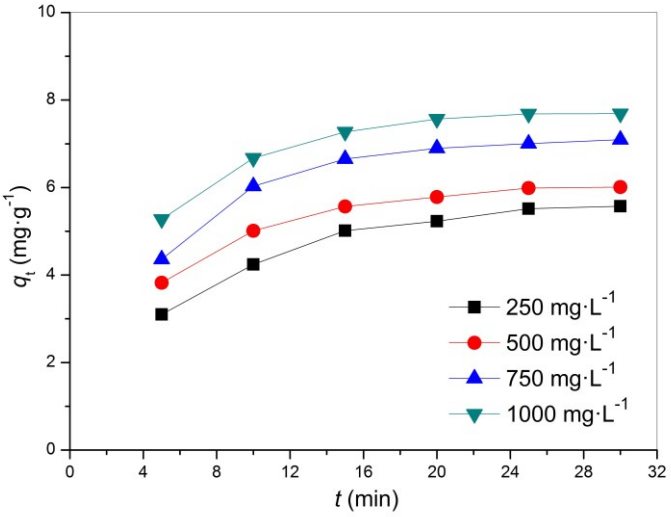

Fig. 3 Effect of contact time and initial NNO concentration on the adsorption of NNO. (imidacloprid dose 1.0 g·L^{-1}; stirring speed 200 rpm; T = 298 K)

The effects of stirring speed on NNO adsorption amount were analyzed at 50-250 rpm (Fig. 4). NNO adsorption amount was significantly augmented as the stirring speed increased from 50 rpm to 200 rpm, which is attributed to the increase in turbulence and the decrease in boundary layer thickness around imidacloprid particles as a result of increase in the degree of mixing[4]. However, NNO adsorption amount remained approximately constant when the stirring speed reached over 200 rpm.

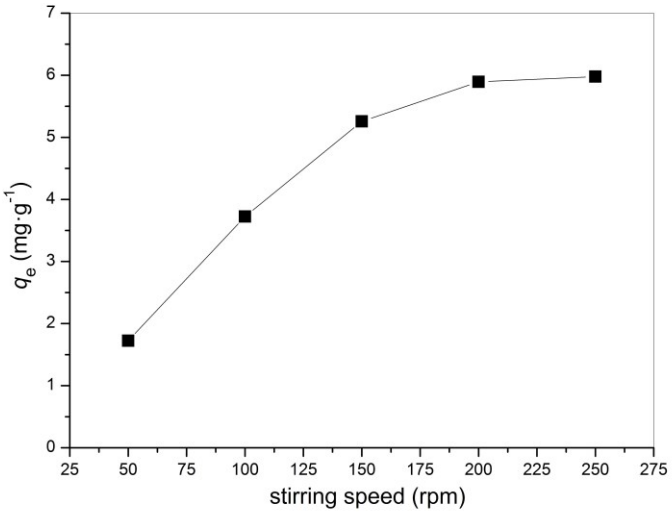

Fig. 4 Effect of stirring speed on the adsorption of NNO. (c_0 = 500 mg·L^{-1}; imidacloprid dose 1.0 g·L^{-1}; T = 298 K; t = 30 min)

The effects of temperature on that adsorption were investigated at 298-328 K (Fig. 5). NNO adsorption amount slightly decreased with increasing temperature, which implied that dispersant NNO was mainly adsorbed physically rather than chemically as an exothermic process on imidacloprid particle surface.

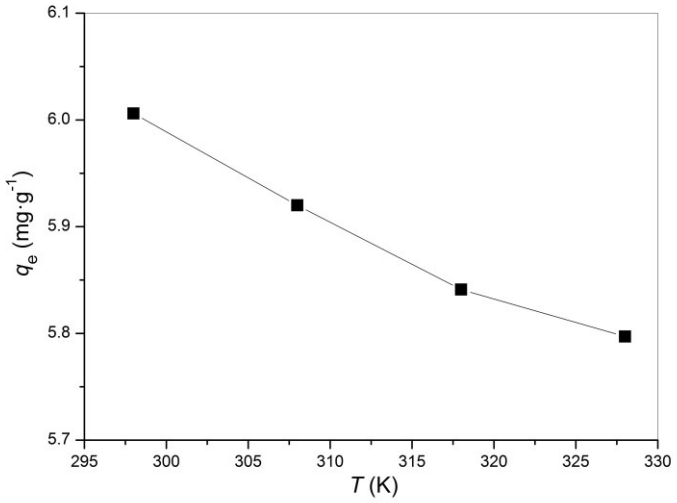

Fig. 5 Effect of temperature on the adsorption of NNO. (c_0 = 500 mg·L^{-1}; imidacloprid dose 1.0 g·L^{-1}; stirring speed 200 rpm; t = 30 min)

Nomenclature

c_0 — initial NNO concentration, mg·L^{-1}
c_e — equilibrium NNO concentration in the solution, mg·L^{-1}
c_t — NNO concentration at any time t, mg·L^{-1}
M — mass of imidacloprid, g
q_e — amount of NNO adsorbed at equilibrium, mg·g^{-1}
q_t — amount of NNO adsorbed at any time t, mg·g^{-1}
T — temperature, K
t — contact time, min
V — volume of dispersant NNO solution, mL

Keywords: Adsorption; Imidacloprid; Methacrylic acid-styrene-acrylic polyether copolymer; Kinetic; Thermodynamics

Abstract: The adsorption of methacrylic acid-styrene-acrylic polyethers (MAA-St-APEG) copolymer on the insecticide imidacloprid particles was studied to calculate the kinetic, isotherm and thermodynamic parameters. The kinetic data followed the pseudo-second order kinetic model, and the equilibrium data were well fitted by the Langmuir isotherm model with the maximum adsorption amount of 7.610 $mg \cdot g^{-1}$ at 298 K. The calculated thermodynamic parameters including ΔG, ΔH and ΔS, demonstrated that this adsorption was a spontaneous and exothermic process in nature. Therefore, MAA-St-APEG copolymer are eligible for the dispersion of imidacloprid particles in aqueous solution as a effective dispersant.

Introduction

The poly-carboxylic acid copolymer hyper-dispersant has attracted much attention, and it is actively researched and developed because of its characteristics of keeping the dispersion of particles and the stability of dispersion system. Methacrylic acid-styrene-acrylic polyethers (MAA-St-APEG) copolymer were used to be a dispersant on pesticide aqueous suspension concentrate (SC) in recent years. However, a proper dispersant is vitally important to improve the stability of SC[1]. The adsorption kinetic, isotherm and thermodynamic of MAA-St-APEG copolymer on imidacloprid particles was studied in this paper, which provide experimental data for using MAA-St-APEG copolymer in imidacloprid SC as a dispersant.

Experimental section

Analytical-grade NaOH and HCl were obtain from Sinopharm Chemical Reagent Co., Ltd. Imidacloprid (purity 97 %) was purchased from Sigma-Aldrich, the chemical structure was showed in Fig.1. The chemical structure of MAA-St-APEG copolymer was presented in Fig.2. The MAA-St-APEG copolymer solution (2000 $mg \cdot L^{-1}$) was prepared by dissolving weighted appropriate copolymer particles in distilled water, which was diluted with appropriate volumes of distilled water into experimental solutions at different concentrations.

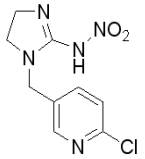

Fig. 1 Chemical structure of imidacloprid

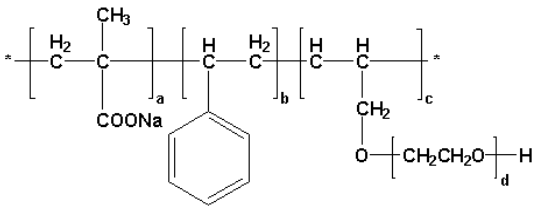

Fig. 2 Chemical structure of MAA-St-APEG copolymer

The weight average molecular weight, number average molecular weight and polydispersity of MAA-St-APEG copolymer were obtained by gel permeation chromatography (GPC), the carboxyl group content of MAA-St-APEG copolymer were determined by conductometric titration using 0.1 mol·L^{-1} NaOH and HCl solution, and these results are summarized in Table 1.

Table 1 Molecular weight and carboxyl content of MAA-St-APEG copolymer

M_w / Da	M_n / Da	Polydispersity	Carboxy content / mmol·g^{-1}
13886	7690	1.806	1.328

2.0 g of imidacloprid particles were mixed with 50 mL of MAA-St-APEG copolymer solution and shaken at 200 rpm in a 250 mL conical flask, and duplicate samples were obtained at different time intervals at 298, 308, 318 and 328 K.

At the end of adsorption, imidacloprid particles and MAA-St-APEG copolymer were separated by centrifugation (Hettich universal 320R, Germany) at 5000 rpm for 10 min, then MAA-St-APEG copolymer concentration was determined by monitoring the absorbance changes at 191 nm using a UV-visible spectrophotometer (Shimazu UV-1800, Japan).

The amount of MAA-St-APEG copolymer at equilibrium was obtained from the mass balance equation:

$$q_e = (c_0 - c_e)V/M \tag{1}$$

Standard deviation (SD) and chi-square test (χ^2) combined with correlation coefficient (R^2) are commonly used to quantitatively compare the applicabilities of different kinetic and isotherm models, respectively. Higher R^2, lower SD and χ^2 values represent a better fitting of the model, and the SD and χ^2 values can be calculated by eq. 2 and 3, respectively[2].

$$SD = \{\Sigma[(q_{t,exp} - q_{t,cal}) / q_{t,exp}]^2 / (p - 1)\}^{0.5} \tag{2}$$

$$\chi^2 = \Sigma[(q_{e,exp} - q_{e,cal})^2 / q_{e,exp}] \tag{3}$$

Results and discussion

It is most important to predict the adsorption rate in adsorption system design with the adsorbate contact time and the reactor dimensions controlled by the kinetics[3]. In this study, the pseudo-first order and pseudo-second order models were used to test the experimental data[4-5]. All of calculated kinetic parameters were showed in Table 2.

Table 2 Kinetic parameters for the adsorption at 298 K.

c_0 / mg·L^{-1}	$q_{e,exp}$ / mg·g^{-1}	Pseudo-first-order kinetic model			
		$\ln(q_e - q_t) = \ln q_e - k_1 t$			
		$q_{e,cal}$ / mg·g^{-1}	k_1 / min^{-1}	R^2	SD
400	4.720	8.532	0.211	0.905	0.401
800	6.948	8.361	0.202	0.880	0.122
1200	7.397	7.477	0.189	0.863	0.113

c_0 / mg·L^{-1}	$q_{e,exp}$ / mg·g^{-1}	Pseudo-second-order kinetic model			
		$t/q_t = 1/k_2q_e^2 + (1/q_e)t$			
		$q_{e,cal}$ / mg·g^{-1}	$k_2 \times 10^{-2}$ / g·mg^{-1}·min^{-1}	R^2	SD
400	4.720	5.450	3.569	0.996	0.097
800	6.948	7.524	3.387	0.992	0.060
1200	7.397	7.663	3.181	0.994	0.085

As seen in Table 2, it was found that the adsorption process of MAA-St-APEG copolymer on imidacloprid particles were well represented by the pseudo-second order kinetic model due to high R^2 and low SD values.

To optimize the adsorption process of MAA-St-APEG copolymer on imidacloprid particles, it is essential to establish a most appropriate adsorption isotherm using equilibrium data. Two well-known models including the Langmuir and Freundlich isotherm models were used to fit the equilibrium data, and the results were summarized in Table 3[6-7].

Considering the R^2 and χ^2 values in Table 3, the adsorption of MAA-St-APEG copolymer on imidacloprid particles followed the Langmuir isotherms due to high R^2 and low χ^2 values.

Table 3 Isotherms parameters for the adsorption at different temperatures

Temperature / K	Langmuir isotherm			
	$c_e/q_e = 1/bq_m + c_e/q_m$			
	q_m / mg·g^{-1}	$K_L \times 10^{-2}$ / g·mL^{-1}	R^2	χ^2
298	7.610	13.663	0.998	0.460
308	7.450	11.364	0.997	0.283
318	7.348	10.995	0.995	0.227
328	7.243	10.823	0.999	0.168
Temperature / K	Freundlich isotherm			
	$\ln q_e = (1/n_f)\ln c_e + \ln K_f$			
	n_f	K_f / mg·g^{-1}·(L·mg^{-1})$^{1/n}$	R^2	χ^2
298	5.784	2.710	0.847	0.814
308	5.459	2.510	0.815	0.966
318	5.414	2.461	0.808	0.979
328	5.316	2.378	0.785	1.062

To reveal the thermodynamic behavior of MAA-St-APEG copolymer adsorption, thermodynamic parameters, such as Gibbs free energy change (ΔG), entropy change (ΔS) and enthalpy change (ΔH) were calculated (eq. 4-6):[8]

$$K_D = q_e/(c_e \cdot 10^{-3}) \quad (4)$$

$$\ln K_D = (\Delta S/R) - (\Delta H/RT) \quad (5)$$

$$\Delta G = \Delta H - T \cdot \Delta S \quad (6)$$

Table 4 Thermodynamic parameters for the adsorption

c_0 / mg·L^{-1}	ΔS / J·mol^{-1}·K^{-1}	ΔH / kJ·mol^{-1}	ΔG / kJ·mol^{-1}			
			298 K	308 K	318 K	328 K
400	12.004	−10.236	−13.815	−13.935	−14.055	−14.175
800	22.337	−5.223	−11.883	−12.106	−12.330	−12.553
1200	21.640	−3.402	−9.854	−10.070	−10.287	−10.503

The calculated values of ΔG, ΔH, and ΔS for the adsorption of MAA-St-APEG copolymer on imidacloprid particles are listed in Table 4. The negative values of ΔG reflected that this adsorption process was spontaneous[9]. The negative value of ΔH (absolute values < 20 kJ·mol^{-1}) indicated that the adsorption of MAA-St-APEG copolymer on imidacloprid particles was exothermic in nature, and

involved a physisorption process mainly[10]. The positive value of ΔS indicated the increased randomness at the solid-solution interface in this sorption process. Thus, it was feasible for the adsorption of MAA-St-APEG copolymer on imidacloprid particles.

Nomenclature

c_0 — initial MAA-St-APEG copolymer concentration, $mg \cdot L^{-1}$

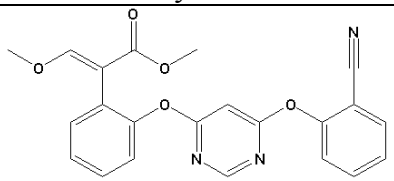
Keywords: Azoxystrobin; Methacrylic acid-styrene copolymer; Kinetic; Thermodynamics; Adsorption

Abstract: In order to investigate the feasibility of using methacrylic acid (MAA)-styrene (St) copolymer as dispersants to disperse azoxystrobin particles in aqueous suspension, the adsorption kinetics, isotherm and thermodynamics of MAA-St copolymer onto azoxystrobin particle surfaces were studied by batch equilibrium experiments. The results showed that the adsorption process followed the pseudo-second-order kinetic model with the entire adsorption, adsorption rate decreased with the initial concentration of MAA-St copolymer increasing. The equilibrium data were fitted with Langmuir isotherm equation better. The thermodynamic parameters were calculated, which indicated that the adsorption was a spontaneous and exothermic process in nature, and higher temperature is not beneficial to that adsorption process.



Introduction

Aqueous suspension concentrate (SC) is a very important environment friendly modern agrochemical formulation, and has a bright developing foreground for less dust pollution problem and favorable bioactivity. Choosing a proper dispersant is a key point in improving the stability of SC[1]. In this paper, the adsorption characteristics of MAA-St copolymer on azoxystrobin particles surface was studied, which provide a theoretical basis for choosing the optimal quantity of MAA-St copolymer as dispersant, developing stable and environmental friendly pesticide SC.

Experimental Section

Analytical-grade HCl and NaOH were purchased from Sinopharm Chemical Reagent Co., Ltd. azoxystrobin with the purity of 99 % was purchased from Sigma-Aldrich, the chemical structure and physical properties are shown in Table 1. Methacrylic acid (MAA)-styrene (St) copolymer were purchased from Beijing Grand AgroChem., Ltd, and the chemical structure is shown in Fig. 1. The stock MAA-St copolymer solution (2000 $mg \cdot L^{-1}$) was prepared by dissolving accurately weighted MAA-St copolymer particles in distilled water, which was diluted with appropriate volumes of distilled water into experimental copolymer solutions at various concentrations.

log K_{ow}	2.64

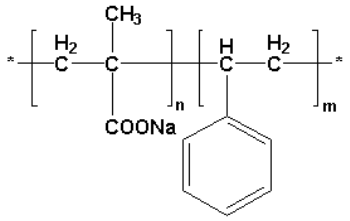

Fig. 1 Chemical Structure of MAA-St Copolymer

The weight average molecular weight (M_w), number average molecular weight (M_n) and polydispersity of MAA-St copolymer were determined by gel permeation chromatography, the carboxyl group content of MAA-St copolymer were obtained by conductometric titration using 0.1 mol·L^{-1} HCl and NaOH solution. Finally, the results obtained are summarized in Table 2.

TABLE 2 MOLECULAR WEIGHT AND CARBOXYL CONTENT OF MAA-ST COPOLYMER

M_w / Da	M_n / Da	Polydispersity	Carboxy content / mmol·g^{-1}
9442	5976	1.580	2.784

Azoxystrobin particles (2.0 g) were mixed with 50 mL of MAA-St copolymer solution and shaken at 220 rpm in a 250 mL conical flask. Duplicate samples were obtained at various time intervals at 288, 298, 308, and 318 K.

At the end of adsorption experiments, all samples were separated from the adsorbent by centrifugation (Hettich universal 320R, Germany) at 3500 rpm for 15 min, and then the MAA-St copolymer concentration was evaluated using a UV-visible spectrophotometer (Shimazu UV-1800, Japan) by monitoring the absorbance changes at 191 nm.

The amount of MAA-St copolymer adsorbed into azoxystrobin at equilibrium was calculated from the mass balance equation:

$$Q_e = (c_i - c_e)V/M \quad (1)$$

Results and Discussion

Two well-known kinetic models including the pseudo-first order and pseudo-second order equation were employed in investigating the mechanism of the MAA-St copolymer adsorption on azoxystrobin particles[2-3]. The results of kinetic parameters and the correlation coefficients were calculated and listed in Table 3.

TABLE 3 FITTED VALUES OF TWO KINETIC EQUATION FOR THE ADSORPTION AT 298 K.

c_i / mg·L^{-1}	$Q_{e,exp}$ / mg·g^{-1}	Pseudo-first order Kinetic model		
		$\ln(Q_e-Q_t)=\ln Q_e-k_1t$		
		$Q_{e,cal}$ / mg·g^{-1}	k_1 / min^{-1}	R^2
400	4.105	4.954	0.209	0.878
800	5.115	4.818	0.183	0.819
1200	5.324	4.253	0.164	0.809
c_i / mg·L^{-1}	$Q_{e,exp}$ / mg·g^{-1}	Pseudo-second order Kinetic model		
		$t/Q_t=1/k_2Q_e^2+(1/Q_e)t$		
		$Q_{e,cal}$ / mg·g^{-1}	k_2 / ×10^{-2} g·mg^{-1}·min^{-1}	R^2
400	4.105	4.690	4.783	0.989
800	5.115	5.522	4.201	0.981
1200	5.324	5.679	4.093	0.987

The results presented in Table 3 indicate that the adsorption of MAA-St copolymer on azoxystrobin particles were well represented by the pseudo-second order kinetic model due to high R^2 values. In addition, the rate constant of adsorption decreased with increasing MAA-St copolymer concentration due to more intensive competition for adsorption sites on azoxystrobin particles surface.

To optimize the design of an adsorption system, it is crucial to establish the most appropriate correlation for the equilibrium curves. The Langmuir and Freundlich models were used to fit the equilibrium data, and the results were showed in Table 4[4-5].

TABLE 4 FITTED VALUES OF TWO ISOTHERMS FOR THE ADSORPTION AT DIFFERENT TEMPERATURES

Temperature / K	Langmuir Isotherm		
	$c_e/Q_e=1/bQ_m+c_e/Q_m$		
	$b\times10^{-2}$ / g·mL^{-1}	Q_m / mg·g^{-1}	R^2
288	4.492	5.612	0.996
298	4.275	5.482	0.998
308	3.957	5.325	0.997
318	3.562	5.128	0.996
Temperature / K	Freundlich Isotherm		
	$\ln Q_e=(1/n_f)\ln c_e+\ln K_f$		
	n_f	K_f / mg·g^{-1}·(L·mg^{-1})$^{1/n}$	R^2
288	5.005	1.548	0.876
298	4.854	1.446	0.828
308	4.817	1.382	0.777
318	4.647	1.275	0.787

All of calculated isotherm parameters were summarized in Table 4. It was found that the adsorption of MAA-St on azoxystrobin particles was fitted better by the Langmuir model than the Freundlich model due to high R^2 values. Moreover, The maximum adsorption amount of MAA-St copolymer slightly decreased with increasing temperature, suggesting that the adsorption was mainly physical rather than chemical as an exothermic process.

Theoretically, thermodynamic parameters imply the feasibility of adsorption process. In this paper, thermodynamic parameters were calculated by using the following equations:[6]

$$K_D = Q_e/(c_e\cdot10^{-3}) \quad (2)$$

$$\ln K_D = (\Delta S^0/R)-(\Delta H^0/RT) \quad (3)$$

$$\Delta G^0 = \Delta H^0 - T\cdot\Delta S^0 \quad (4)$$

The plot of $\ln K_D$ versus $1/T$ gave straight lines with the intercept of $(\Delta S^0/R)$ and the slope of $(-\Delta H^0/R)$, and the thermodynamic parameters are listed in Table 5. As seen in Table 5, the negative values of ΔG^0 and ΔH^0 implied that the adsorption process was spontaneous and exothermic in nature. The positive value of ΔS^0 suggested that randomness at the solid-solution interface increased during the adsorption of MAA-St copolymer on azoxystrobin particles. The ΔG^0 values for physisorption range between −20 and 0 kJ·mol^{-1}, but those for chemisorption range from −80 to −400 kJ·mol^{-1}[7].As evidenced by the calculated ΔG^0 values, physisorption was the dominant mechanism.

TABLE 5 DETERMINATION RESULT OF THERMODYNAMICS

c_i / mg·L^{-1}	ΔS^0 / J·mol^{-1}·K^{-1}	ΔH^0 / kJ·mol^{-1}	ΔG^0 / kJ·mol^{-1}			
			288 K	298 K	308 K	318 K
400	15.134	−5.440	−9.801	−9.952	−10.104	−10.255
800	7.817	−4.094	−6.346	−6.425	−6.503	−6.581
1200	4.391	−3.318	−4.583	−4.627	−4.671	−4.715

Keywords: Silica gel; 5-sulfosalicylic acid; enrichment; Lead

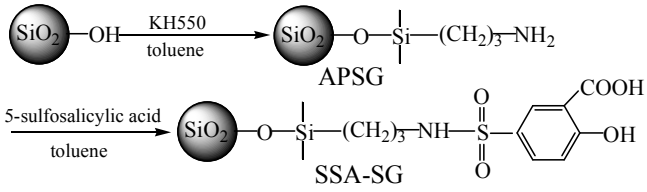
Abstract：A new sorbent (SSA-SG) with 5-sulfosalicylic acid as functional group has been prepared and characterized with FTIR and then used as micro-column packing for enrichment of Pb(II). Enrichment conditions of lead were optimized. The enrichment factor reaches 200 and the dynamic sorption capacity was 15.46 mg•g^{-1} for Pb(II). The proposed column enrichment procedure was applied for the preconcentration/separation and atomic absorption spectrometry (AAS) determination of Pb (II) in water samples successfully.

Introduction

Lead is one of the toxic elements and can enter the organism by food, drinking water and air and accumulate in human body, which carry high risk to human health. Lead pollution has been paid more attention and the analysis of lead is an important research field. Atomic absorption spectrometry and mass spectrometry are the most used methods for the analysis of lead. Considering the low lead concentration and interferences in environmental samples, enrichment techniques are often necessary. Solid-phase extraction (SPE) is one of the most interesting enrichment procedures. Chelating sorbents, such as silica gel[1], chelating resin [2], activated carbon [3] are often used extraction materials.

In the present work, 5-sulfosalicylic acid modified silica gel was prepared and its performance of adsorption for lead was investigated. It was used as the micro-column packing for enrichment of Pb (II) in water samples successfully.

Experimental



Apparatus and Reagents

Atomic absorption spectrometer (TAS-990AFG) of Beijing Purkinje General Instrument Co., Ltd. (China) was employed. Peristaltic pump (BT01S-YZ1515) of Yi Kang Xin Da Technology Co., Ltd (China) and a self made micro-column (7 cm × 0.5mm i.d.) were used. PTFE tubing (0.8mm i.d.) was used for connections.

Silica gel (Qingdao Shuoyuan Chemical Co. Ltd., China) was 60–100 meshes, and its surface area was 300-600 m^2•g^{-1}. γ-Aminopropyltriethoxysilane (Beijing Shenda Fine Chemical Co. Ltd., China) was purified by distillation at 123℃ under 10 mm Hg. All of the other reagents were analytical reagent grade. Distilled water was used throughout. Stock solution of Pb(II) (1000 mg• L^{-1}) was prepared by dissolving appropriate amounts of analytical pure $Pb(NO_3)_2$ in pH=2 HNO_3 solution. Standard solutions of Pb(II) were prepared by dilution of the stock solution just before use.

Preparation of SSA-SG

APSG and SSA-SG was prepared according to reference [4] and [5]. 5.0g 5-sulfosalicylic acid was added to a 250mL flask and dissolved with 20ml dimethyl sulfoxide. 20.0g APSG and 80ml toluene were added to the flask and the mixture was stirred for 8h at 80℃. The resulting solid product was filtered off and washed in order with dimethyl sulfoxide, toluene and ethanol respectively for 3 times. Then the solid product was dried at 70℃ for 7h. The synthesis routine to SSA-SG is shown schematically in Scheme 1.

Scheme 1 The Synthetic Route for SSA-SG

Enrichment Procedures

One end of the micro-column was packed with polypropylene fiber, SSA-SG was packed in micro-column, then the other end was packed with polypropylene fiber, two ends were connected with suitable silicone tubing. In Step 1, the blank solution (its pH is the same as Pb (II) standard solution) was pumped through micro-column with flow rate of 1.2 mL•min^{-1}. In Step 2, the Pb(II) solution was pumped through micro-column with flow rate of 1.2 mL•min^{-1}. In Step 3, the blank solution was pumped through micro-column with the same flow rate. In Step 4, the eluent solution was introduced through micro-column in the reverse direction with flow rate of 2.4 ml•min^{-1}. Then the eluent solution was determined with flame atomic absorption spectrometry (FAAS).

Sample Pretreatment

2500ml water sample was acidified with 5 mL of HNO_3 and kept in refrigerator for 3 days and then filtered. 95 ml filtrate was adjusted to pH 5, transferred to 100 ml flask and then its volume was adjusted to 100 ml pH=5 HCl solution. Then Pb(II) in the solution was preconcentrated and determined with FAAS.

Results and Discussion

Characterization of Sorbent

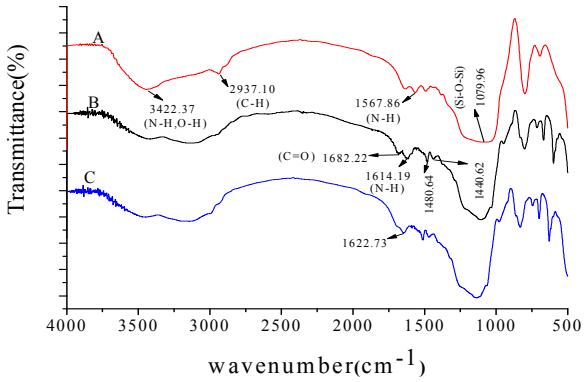


Fig.1 Infrared Spectra

A:APSG B:SSA-SG C: SSA-SG (Pb(II) was absorbed)

Fig.1 are the Fourier transmission infra-red (FTIR) spectra of APSG, SSA-SG and SSA-SG after Pb(II) was absorbed. In FTIR spectra of A, B and C, the absorption of 1079.96 cm^{-1}and 798.39cm^{-1} cm^{-1} are characteristic of Si-O-Si skeleton, and the absorption at 3422.37cm^{-1} is characteristic of

-OH and $-NH_2$ groups. In the FTIR spectra of B and C, the absorption at 1682.22 cm^{-1} is characteristic of carboxyl groups. The changes of FTIR spectra suggested 5-sulfosalicylic acid was successfully introduced to the surface of silica-gel.

Effect of pH

In the range from 2 to 10, adsorption rate of Pb(II) reached more than 95% when pH is in the range of 5-6. The solution of pH=5 was selected as the sample medium.

Effect of Eluent Concentration

In the range of 0.05~4 .0 mol•L^{-1}, when the concentration of HCl was more than 1.0 mol•L^{-1}, elution recovery of Pb(II) could reach more than 95%, but high concentration of HCl would effect adsorption rate of next sample loading. So 1.0 mol•L^{-1} HCl was selected as eluent.

Effect of Flow Rate

In the range of 0.6–6.0 ml•min^{-1}, when sample solution flow rate was not more than 1.2 ml•min^{-1}, adsorption rate of Pb(II) reached more than 95%. So 1.2 ml•min^{-1} was used as the sample solution flow rate. When the eluting flow rate was 2.4 ml•min^{-1}, elution recovery could reach more than 98%. So 2.4 ml•min^{-1} was used as eluting flow rate.

Effect of Sample and Eluent Solution Volume

Under the above selected conditions, different volume (5.0-50.0 ml) sample solution of 5.0 μg•mL^{-1} Pb(II) was used respectively for sample loading. When sample solution volume was not more than 10.0 ml, adsorption rate of Pb(II) were more than 98%. So sample solution volume was 10.0 ml. Different volume (5.0-25.0 ml) HCl solution (1.0 mol•L^{-1})was used as eluent, and elution recovery of Pb(II) could reach more than 95%. So 5.0 ml eluent was used in the further experiments.

Interference of Co-exiting Ions

The effects of anions and co-existing metal ions were tested when 10 ml sample solution with 5.0 μg•ml^{-1} Pb(II) was determined. More than 25 μg•ml^{-1} of co-existing metal ions (Na^+, K^+, Ca^{2+}, Mg^{2+}, Zn^{2+}, Al^{3+}, Mn^{2+}, Cu^{2+}, Cr^{3+}, Co^{2+}, Cd^{2+}, Ni^{2+}, NH_4^+) and 1000 μg•$ml^{-1}$of anions (PO_3^{4-}, SO_4^{2-}, NO_3^-, CH_3COO^-, Cl^-) (added as sodium salts) did not interfere with the enrichment and determination.

Saturated Adsorption Capacity

5.0 μg•mL^{-1} Pb(II) solution (pH=5.0) passed through micro-column with flow rate of 1.2 ml•min^{-1} to obtain the break-through curve. The saturated adsorption capacity of SSA-SG for Pb(II) was 15.46 mg•g^{-1}. Pseudo-first kinetic model and quasi-two kinetic model fitting results showed that quasi-two kinetic model was suitable for describing the adsorption of Pb(II) on SSA-SG.

Low concentration Enrichment

Different volume solutions with 50 μg Pb(II) were respectively preconcentrated according to the enrichment procedure, and then Pb (II) was eluted with 5.0 ml eluent and determined. When solution volume reached 1000 ml (larger volume solution was not tested), Pb(II) could be quantitatively preconcentrated on SSA-SG. The enrichment factor was 200.

Water Sample Analysis

In order to test the applicability of sorbent, SSA-SG was applied for the enrichment of Pb (II) in water samples. The analysis results listed in Table1 demonstrated that SSA-SG is suitable for quantitative preconcentration of Pb (II) from water samples.

TABLE 1 DETERMINATION OF PB(II) IN WATER SAMPLES AND ADDITION–RECOVERY TESTS

Sample	Added ($\mu g\ ml^{-1}$)	Found ($\mu g\ ml^{-1}$)	RSD (%)	Recovery (%)
Tap water	0	unfound	---	---
	1.0	1.02	2.1	102
	3.0	3.29	5.0	109.8
Lijiang River water	0	1.78	1.4	---
	1.0	2.78	0.8	100
	3.0	4.88	3.3	103.3

Summary

SSA-SG sorbent with 5-sulfosalicylic acid as functional group has been synthesized and characterized with FTIR, then enrichment conditions for Pb(II) was investigated. After being used for no less than 200 times of enrichment cycle, the performance of SSA-SG has not changed yet. SSA-SG showed good characteristics, such as simplicity, fast extraction, stability, selectivity for Pb(II). It was used as the microcolumn packing for enrichment coupled with FAAS determination of Pb(II) in water samples successfully.

Keywords: Alligator weed; Mesoporous activated carbon; Chemical activation; Optimum condition; Phosphoric acid

Abstract: Alligator weed, containing ash of 8.56 wt.% (dry basis), is a low-cost and renewable material for preparing activated carbon (AC) by chemical activation. Yield and iodine number results of orthogonal experiments showed H_3PO_4 was the optimal activator comparing with NaOH and $(NH_4)_2HPO_4$. And optimal condition was at impregnation ratio of 4 to 1 with the impregnation time of 6h, carbonization temperature of 873K and carbonization time of 1h. According to calculation of Brunauer-Emmett-Teller (BET), the surface area of P1 (AC prepared by H_3PO_4 under optimum condition) attained the value of 1100.720 m^2/g. Calculated by Barrett-Joyner-Halenda (BJH), the total pore volume and average pore size of P1 were 0.610 cm^3/g and 2.216nm. The rate of mesoporous range, as high as 72.00%, revealed P1 was mesoporous AC. FT-IR spectrum suggested P1 contained carboxyl, phenol, ether and other functional groups. XRD showed a graphitization degree of 65.12% indicating its high stability in application.

Introduction

Alligator weed (*Alternanthera philoxeroides* (Mart.) Grisebach) is a famous invasive weedy species originated in South America [1]. Since it has been introduced into China in the 1930s, alligator weed has rapidly expanded in 18 of 31 provinces bringing direct economic loss of 10 billion yuan per year [2]. To control its expansion, every year billions of tons of alligator weed have been weeded or salvaged as agricultural wastes [3]. Discarding arbitrarily and setting on fire are traditional methods of deposing these wastes, while the former is useless since the broken stems from the parental plants can rapidly grow root systems, and soon anchor on soil and develop into complete plants and the latter can cause serious air pollution [1, 4]. The utilization of large quantity of alligator weed debris yielded as agriculture wastes every year in China has not been well understood. Thus, development of methods to re-use these waste materials is greatly desired.

Preparing activated carbon from environmental wastes has attached many researchers attention which is motivated by strong market position and growing need for activated carbon and also helpful for solving environmental problems. Philip and Girgis[5] succeeded in preparing microporous activated carbon from apricot stone shells by phosphoric acid with a BET surface area of 1000 m^2/g. Tseng [6] published that mesoporous activated carbon was prepared from corncob by NaOH with high surface area in narrow range from 2318 to 2474 m^2/g. Shi et al. [7] proved that cattail could also be prepared to activated carbon by H_3PO_4 and activated temperature had the greatest effects on surface area of resulting activated carbon. Gao et al. [8] reported the preparation of activated carbon from rice straw by $(NH_4)_2HPO_4$ with apparent surface area of 1154 m^2/g. Based

on the above results, characteristics and constituents of alligator weed on a dry basis was analyzed. As shown in Table 1, low content of ash, high content of cellulose and renewable characteristic show that alligator weed is potential as precursor to active carbon [9].

Table 1. Characteristics and constituents of alligator weed (dry basis)

Component analysis (wt.%)	Moisture	Cellulose	Lignin	Ash
	2.76	23.5	9.9	8.56
Ultimate analysis (wt.%)	C	H	O*	N
	39.31	5.23	53.15	2.45
* Calculated by difference.				

The purposes of the present work were to prepare activated carbon from alligator weed by chemical activation and achieve the optimal activator and condition. The characteristics (surface area, pore volume, functional groups and so on) of activated carbon obtained by optimum activator under optimum condition were also detected.

Experimental

Raw material

Alligator weed used in this study was obtained from Xiaoshahe River, a branch of Nansihu basin, Shandong, China. All reagents were analytically graded.

Preparation of Activated Carbon and Orthogonal Experiment

Pre-oxidation experiment: Alligator weed was dried in an oven kept at 378 K for 24 h and then cut into short sections with 2-3cm in length each. The dried short sections were soaked in a solution of NaOH (2 wt. %) for 24h to remove wax, ash and other water-soluble impurities on the surface. After alkaline liquor pretreatment, they were washed with distilled water to neutral pH and then dried in an oven kept at 473 K for 1h.

Orthogonal experiment: Using activator H_3PO_4 (85 wt. %), NaOH (solid) and $(NH_4)_2HPO_4$ (30 wt. %), three series experiments, each series of 9 experiments, were made following $OA_9(3^4)$ matrix. The factors and levels of orthogonal experiment are presented in **Table 2**. The pre-oxidization samples were mixed with a solution of activator with varying ratios (3-5) and times (6-24). Then impregnated samples were loaded on ceramic crucibles and placed inside a muffle furnace heating up for carbonization at heating rate of 10K/min. After cooling to room temperature in muffle furnace, they were washed with hot distilled water to remove the remaining activator and filtered, and finally dried at 373 K for 24 h in a thermostatically controlled oven. The washing and filtration steps were repeated until the filtrate reached neutral pH. All activated carbon products were kept in screw-cap bottles.

Table 2. Factors and levels of the orthogonal experiment

Level	Impregnation ratio(A)	Impregnation time (B)	Carbonization temperature(C)	Carbonization time(D)
1	3	6 h	773 K	1 h
2	4	12 h	873 K	2 h
3	5	24 h	973 K	3 h

Yield and Adsorptive Properties

The yield was based on the following equation:

Yield=weight of prepared activated carbon / weight of sample after alkaline pretreatment

Adsorptive properties were described by the iodine adsorption which gave the information on the quantity of pores larger than 1 nm. The amount of iodine absorbed (in milligrams) by 1 g of

carbon was called the iodine number. The iodine adsorption was measured by the sodium thiosulfate volumetric method.

Characterization of Prepared Activated Carbons

Activated carbon prepared under optimum activator and condition was characterized by N_2 adsorption at 77K, Fourier Transform Infrared Spectrometer (FT-IR), X-ray Powder Diffraction Pattern (XRD) and Scanning Electron Micrograph (SEM).

The adsorption isotherm of N_2 on the prepared activated carbon was measured at 77 K using the constant volume adsorption apparatus (Quanta chrome Autosorb-3B, JAPAN, Inc.). The surface area of the activated carbon was calculated by the Brunauer-Emmett-Teller (BET) method using the adsorption isotherm data of N_2. The micropore volume (V_{micro}) was calculated from the amount of N_2 adsorbed at a relative pressure P/P^0 of 0.1, and the mesopore volume (V_{meso}) was estimated from the amount adsorbed between relative pressures of 0.1 and 0.95. The total pore volume (V_t) was evaluated from the volume adsorbed at the relative pressure of 0.98. FT-IR was determined at Nexus 670 FT-IR spectrometer to characterize the functional groups of activated carbon sample which determined the adsorption of activated carbon. X-ray powder diffraction pattern was determined at D/texultra (Rigaku, Japan) with Cu Kα radiation at a step of 0.01°. XRD results helped to characterize the crystal structure of activated carbon sample. Scanning electron micrographs carried out in secondary electron imaging mode was measured by a Hitachi DSM-4600, after plating the sample with gold.

Results and Discussion

Yield and Iodine Number

The average values of yield of AC prepared by H_3PO_4, NaOH and $(NH_4)_2HPO_4$ are 34.7%, 25.8% and 33.4%. The average values of iodine number of AC prepared by H_3PO_4, NaOH and $(NH_4)_2HPO_4$ are 726 mg/g, 521 mg/g and 396 mg/g. With comprehensive consideration of yield and iodine number, we come to a conclusion that H_3PO_4 is the optimal activator.

The analysis results presented in

Table 3 reveal that yield and iodine number of activated carbon prepared by H_3PO_4 are variously affected by impregnation ratio impregnation time, carbonization temperature and carbonization time. According to the range analysis of yield, with the decrease sequence of range R, the order of factors is C>A>D>B. The range analysis of iodine number is consistent with that of yield.

The result of K (the average of yield and iodine number for each factor at different levels) is K_2(C) >K_2 (A) >K_1 (D) >K_1 (B). Thus, the best combination is $A_2B_1C_2D_1$, which means the optimum condition possibly has an impregnation ratio of 4, impregnation time of 6h, carbonization temperature of 873K and carbonization time of 1h.

Table 3. Range analysis results of yield ratio and adsorption of I_2 of H_3PO_4

	Level	Impregnation ratio(A)	Impregnation time (B)	Carbonization temperature(C)	Carbonization time(D)
Yield	K 1	38.50	35.70	31.87	36.35
	K2	32.17	35.30	38.80	34.22
	K3	33.31	32.98	33.31	33.41
	R	6.33	2.72	6.93	2.94
Iodine number	K1	730.97	731.41	740.60	737.36
	K2	739.19	720.79	729.56	734.23
	K3	708.35	726.32	708.35	706.93
	R	30.84	10.62	32.25	30.43

Additional Verification Experiment

An additional experiment was carried out to verify whether the combination of $A_2B_1C_2D_1$ was optimum condition or not. The results of yield and iodine number in additional experiments were 37.44% and 752.36mg/g, which were both higher than the average of the orthogonal experiments. It proves that optimum condition of preparing activator carbon from alligator weed by H_3PO_4 is exactly $A_2B_1C_2D_1$. The activated carbon prepared under optimum condition was named P1 and characterized by N_2 adsorption, FT-IR, XRD and SEM.

N_2 adsorption at 77 K

According to the classification standard of International Union of Pure and Applied Chemistry (IUPAC), the N_2/77K adsorption/desorption isotherm of P1 is classified as a type IV, as shown in **Fig. 1**. It indicates that P1 has apparent mesoporous structure and the aperture is mainly between 2 to 50 nm. Furthermore, the inconsistency between adsorption and desorption isotherm, with the formation of hysteresis loop of a type H4, shows P1 contains a narrow wedge-shaped hole [10].

The surface area of P1 is calculated by the equation of Brunauer-Emmett-Teller (BET) and pore size distribution is calculated by the Barrett-Joyner-Halenda (BJH) model. The results shows P1 is mesoporous activated carbon, which is coincident with N_2/77K adsorption/desorption isotherm, with surface area of 1100.720 m^2/g, total volume of 0.610 cm^3/g , mesoporous volume of 0.540 cm^3/g and average pore diameter of 2.216nm.

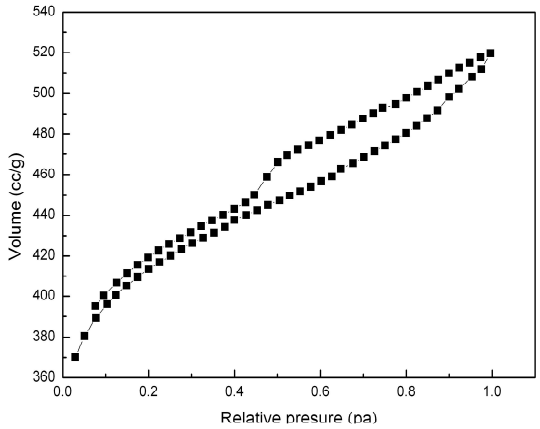

Fig. 1. Adsorption and desorption isotherms of N_2/77K on P1

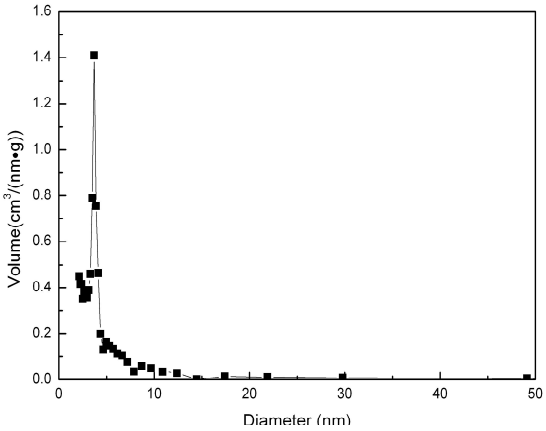

Fig. 2.Mesopore size distributions of P1

The rate of mesoporous range of P1 obtains 72.00% and pore size distribution is mainly concentrated in the 2-5 nm as shown in **Fig. 2**. The study of Wang et al. [11] showed that lignin played a major role in the formation of microporous, while cellulose is important to the formation of mesoporous.

FT-IR

FT-IR is useful to analyze the function groups and chemical structure of P1 qualitatively. **Fig. 3** shows the FT-IR spectrum of P1. A broad band around 3430 cm^{-1} is most likely caused by hydroxyl (OH) or carboxyl (COOH). The weak band around 2922 cm^{-1} can be attributed to the stretching vibration of CH_2 groups, while the relatively strong band located around 1600 cm^{-1} is attributed to C=C, C=O, NHCO or NH_2. The band around 1384 cm^{-1} may be caused by aliphatic or aromatic compounds which means such substances haven't degraded or volatilized completely during the carbonization process. The stretching vibration of ether or alcohol groups may lead to a band located around 1162cm^{-1}. The band in the region of 1003-714cm^{-1} is caused by bending vibration of tertiary amine possibly. The FT-IR spectrum obtained is in agreement with the results reported in the studies of preparing activated carbon from bamboo and rice bran [12-14].

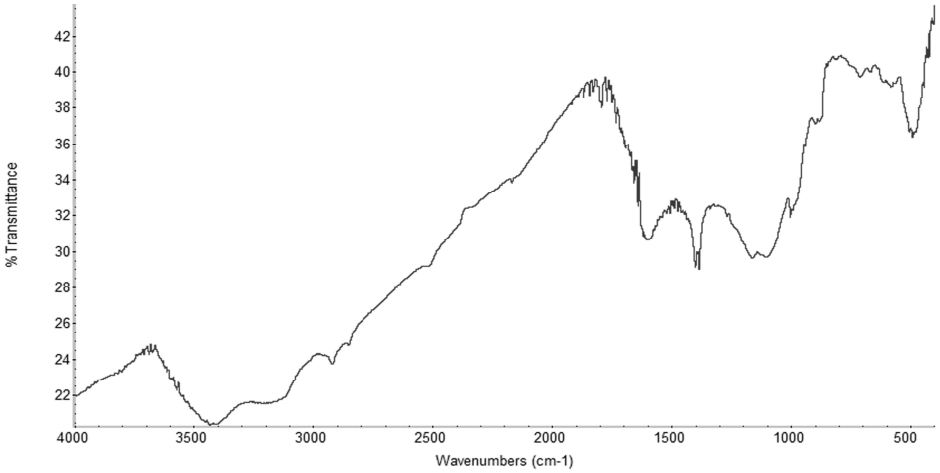

Figure 3. FT-IR spectrum of P1

XRD

XRD pattern of P1 is given in **Fig. 4**. It is clear that when 2<theta> is nearly 26°, there is an obvious diffraction peak. The reason for this phenomenon is that during the carbonization procedure of P1, some carbon atoms formed into relatively stable structure of lamellar graphite. The other amorphous structure leads to the increase of lamellar gap and surface area of P1. In addition, there is a relatively weaker peak at 42° which may be caused by the elimination of distortion or defects in the graphite crystal. It is because that under high temperature, P atoms enter into the microcrystalline layer and makes catalytic oxidation reaction with carbon atoms [15].

From the position of the peak around 26°, an estimate of the interplanar spacing, d_{002}, can be calculated by application of the Bragg's Law [7]. On this basis, we summarize a calculation method from previous studies and calculate that the graphitization degree of P1 is 65.12% [16]. The higher graphitization degree, the better stability of activated carbon in subsequent application it is.

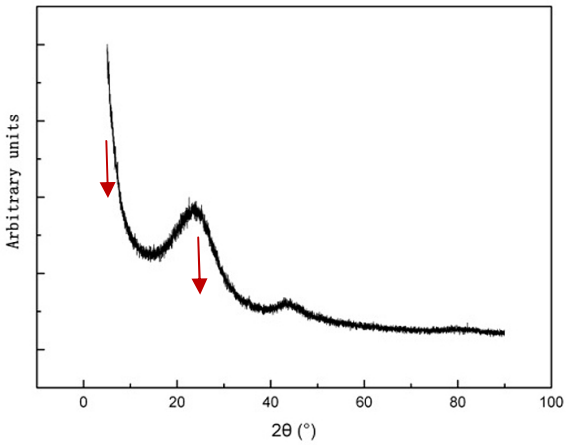

Fig. 4. XRD of activated carbon P1

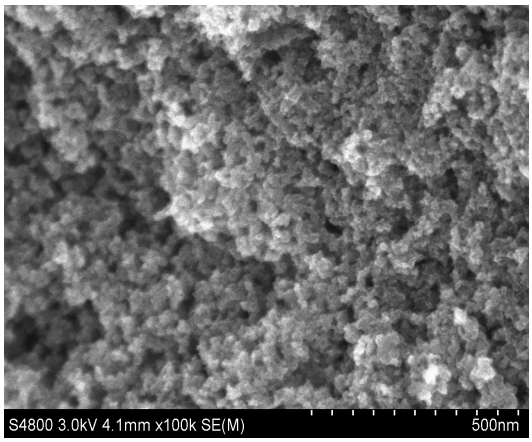

Fig. 5. SEM of P1 enlarged 100K

SEM

The scanning electron micrograph of P1 enlarged 100K is shown in **Fig. 5**. From the shape of pore, it is observed that the surface of activated carbon is the distribution of well developed porous with various shapes. Some of them are oval shape, and others are crack and irregular shape. In addition, surface morphology of P1 is rough, showing an uneven and honeycomb structure. From the size of pore, mesoporous and microporous are the majority with the distribution of few macroporous.

Conclusions

To prepare activated carbon from alligator weed by chemical activation, H_3PO_4 is demonstrated to be an optimal agent as the results of yield and iodine number in orthogonal experiments. The optimal condition appears to be impregnation ratio of 4, impregnation time of 6h, carbonization temperature of 873K, and carbonization time of 1h. High-performance activated carbon has been prepared with surface area, total pore volume and average pore size as high as 1100.720m^2/g, 0.610cm^3/g and 2.216nm, respectively. This work confirms that alligator weed can be employed as a good material in preparing mesoporous activated carbon which has a promising precursor in removing relatively macromolecular pollutants.

Keywords: Silica gel; Adsorption; Dye; Regeneration; Oxidation

Abstract. The removal of cationic Blue X-BL in aqueous solution by adsorption of silica gel was investigated. Effects of pH, initial concentration of dye solution and temperature on the adsorption of Cationic Blue X-BL onto silica gel were studied. When the initial concentration of the blue dye was 100 mg/dm^3, silica gel is 0.6 g at pH 9.3 and at 303 K, adsorption reached equilibrium after 2 h with the final adsorption quantity 16.38 mg/g. Fenton reaction with UV light was applied in the regeneration operation of silica gel which can transmit most of the UV light. The concentration of Fe^{2+} and H_2O_2 was evaluated and when the concentration of Fe^{2+} and H_2O_2 were 0.05 mmol/dm^3 and 0.132 mol/dm^3, the first, second, third and forth regeneration efficiency were 84.68 %, 82.05 %, 65.26% and 50.73 %, respectively. In order to improve the regeneration capacity and silica gel's reuse times, acid washing was introduced in the forth regeneration after Fenton reaction, which can enhance the regeneration efficiency to 92.19%.

Introduction

Many of dyes can cause health problems such as allergic dermatitis, skin irritation, cancer and mutation in human [1]. While adsorption techniques have found many practical applications as it can aggregate dyes to high concentration especially for the non-biodegradable dyes [2]. Among numerous absorbents, silica gel deserves particular attention, considering its high thermal and chemical stability, controlled porosity, swelling resistance, relative rapidity in reaching equilibrium, high surface area and inexpensive cost [1,2]. UV-Fenton reaction has its own unique advantage in the degradation of pollutants as one of advanced oxidation processes (AOPs) [3].

In this work, the influence of pH, initial concentration of dye solution and temperature were evaluated on the adsorption behavior of Cationic Blue X-BL by silica gel to get the most optimizing adsorption condition. UV-Fenton reaction was applied to regenerate silica gel loaded with dyes.

Materials and methods

Materials

Silica gel (Sanpont Co., China), for column chromatography, presenting particle size and average pore size of 100–200 mesh and 60 Å, respectively, was used in the present work. H_2O_2 (30%), $FeSO_4 \cdot 7H_2O$, NaOH and H_2SO_4 were analytical grade. The dye, commercially available as Cationic Blue X-BL were gifts from Runtu Co., China (see to Fig. 1). shows the chemical structure of the dye. Model 2100UV spectrophotometer(Unico Inc., Shanghai, China).

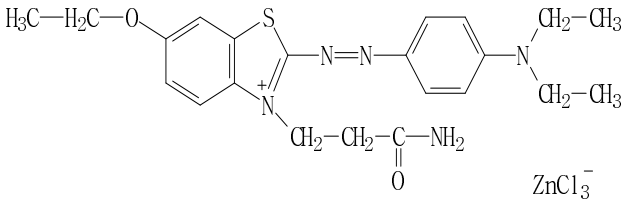

Fig.1. The chemical structure of Cationic Blue X-BL

Preparation of Dye Solution and Concentration Measurements

Stock solution (1 g/dm^3) of the blue dye was prepared in distilled water. The desired concentrations were obtained by dilution. The concentrations of the studied dyes were measured using spectro- photometric method. Calibration curves of the blue dye were prepared by measuring their absorbance against concentration at λ_{max} 622 nm. The amount of the adsorbed dye on the investigated silica was determined using the following mass balance equation: $q=(C_0-C_i)\times V/W$. Where q represents the amount of the dye adsorbed (mg/g), C_0 and C_i the initial and final concentrations (mg/dm^3) of dye, V is the volume (dm^3) of adsorption solution and W is the weight (g) of silica gel.

Adsorption Experiment

A 0.6 g of dry silica gel samples were placed in a series of flasks containing 100 cm^3 of dye stock solution with different initial concentration of the dye. The various pH was adjusted using 0.1 mol/dm^3 H_2SO_4 and 0.1 mol/dm^3 NaOH. The flasks were equilibrated on a digital control thermostat water bath shaker, at 100 r/min and different temperature for 2 h. Get the concentration of the dye solution measured at time interval after shaking, respectively. The residual concentration of the dye was determined at λ_{max} 622 nm by UNIC-2100 spectrophotometer.

Regeneration of Silica Gel

Regeneration of Silica Gel by UV-Fenton Oxidation and Evaluation of the Regenerative Capability of Silica Gel.The regeneration experiments were carried out inside photochemistry reactor XPA-II, Xujiang Electromechanical Plant, Nanjing, China. Fig. 2 shows structural drawings of the photochemistry reactor. A UV lamp (300W) of medium pressure mercury positioned in the center of reactor was used as an irradiation source. The container was stirred magnetically during irradiation. In this process, The contact time was 90 min and solution pH (adjusted by H_2SO_4) was 2.8. After 90min the solution was centrifuged to separate regenerated silica gel from the solution. Then get the silica gel dried treated with or without acid washing (H_2SO_4 1 mol/dm^3, 100 cm^3), waiting for the adsorption process to evaluate the regenerative capacity. Regeneration efficiency was calculated according to the following equation: $R= q_i/q_e$. Where R represents the regeneration efficiency (%), q_i the equilibrium adsorption (mg/g) of regenerated silica gel and q_e is 16.38 mg/g.

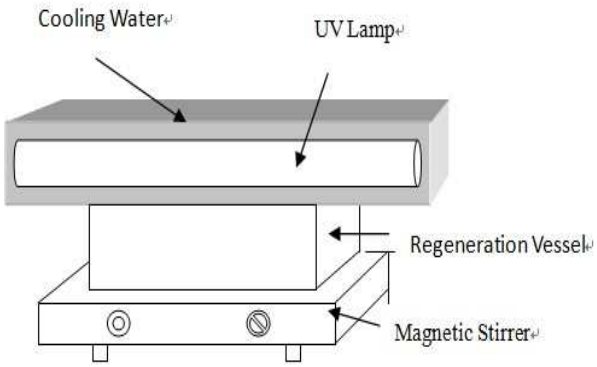

Fig. 2. Structure chart of photochemistry reactor

Results and discussion

Effect of pH on the adsorption of the investigated dye

The role of pH playing on the adsorption of the blue dye onto silica gel is shown in Fig. 3. It shows that pH has a powerful impact on the adsorption and the maximum adsorption rate occurs at pH 10.96. Adsorption performs well when pH is above 4. As the pH value of the solution of the investigated dye is 9.3, pH at 9.3 is used in the latter adsorption.

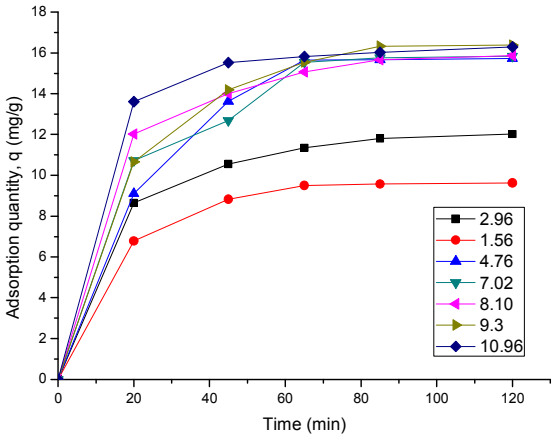

Fig.3. Effect of pH on the adsorption of the investigated dye with initial concentration of 100mg/dm^3 in 2 h and at 303K

Effect of Initial Dye Concentration

The effect of initial concentration of the investigated dye solution on the adsorption onto silica is displayed in Fig. 4. All of the adsorption with different initial dye concentrations occur mainly in the first 80 minutes and get finished after processed 100 minutes. With the consideration of industries wastewater with low concentration, the initial concentration of 100 mg/dm^3, which can contribute to both high adsorption rate and large adsorption quantity, is introduced into latter test.

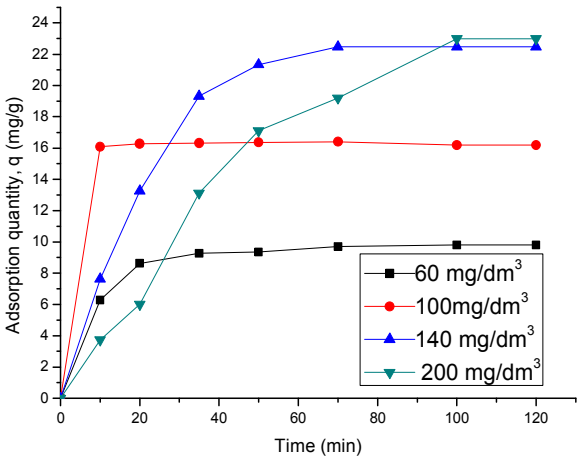

Fig. 4. Effect of initial concentration on the adsorption of the dye at 303 K and in 2 h.

Effect of Temperature

Fig. 5 displays that adsorption rate increases as the adsorption temperature goes up. After 80 minutes, all of the adsorption under different temperature reached equilibrium and when temperature higher than 303K equilibrium adsorption can be easily got just in 20 minutes. This may be attributed to high temperature providing a large diffuse rate. Considering both adsorption rate and final adsorption efficiency, 303 K is accepted.

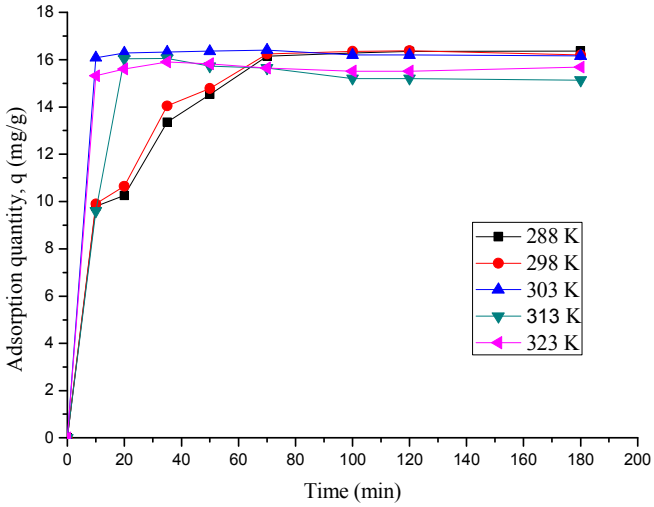

Fig. 5. Effect of temperature on the adsorption of the investigated Dye with initial concentration of 100 mg/dm^3 in 2 h.

The Regeneration of Dye-loaded Silica Gel

Fig. 6 shows that silica gel has very low absorptivity in the range of UV-VIS part, especially from wavelength 380 nm to 780 nm lower than 10 %. This indicates that silica gel has a good performance in transmitting UV-VIS light. The influence of the concentration of H_2O_2 on the regeneration operation of silica gel is presented in fig. 7. Too high or too low concentration of H_2O_2 both resulted poor regeneration capacity. Table1 provides the role of Fe^{2+} playing on the regeneration effect of silica gel. Regenerations with concentration of Fe^{2+} in the range of 0.05 to 0.10 did not have much different in regeneration capacity. So the proper regeneration process are regeneration with concentration of H_2O_2 0.132 mol/dm^3, concentration of Fe^{2+} 0.05 mmol/dm^3, contact time 90 min

and at pH 2.8. Table 2 provides the regeneration efficiency data. After four times regeneration, adsorption of silica gel decreased to 50.73 %. For overcoming the above problem, acid washing was applied after the forth regeneration and it enhanced the regeneration efficiency to 92.19 %.

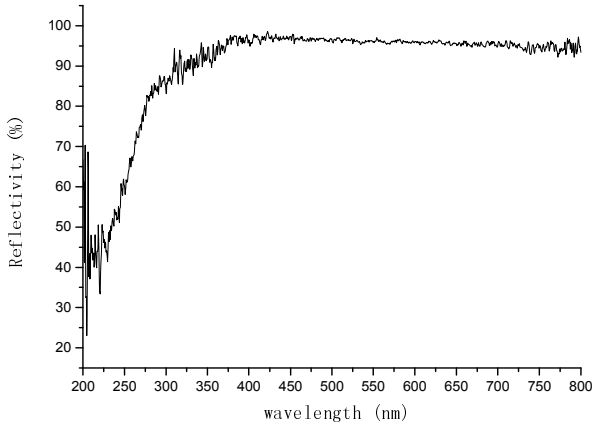

Figure 6.The Diffuse Reflection Spectrum Of Silica Gel

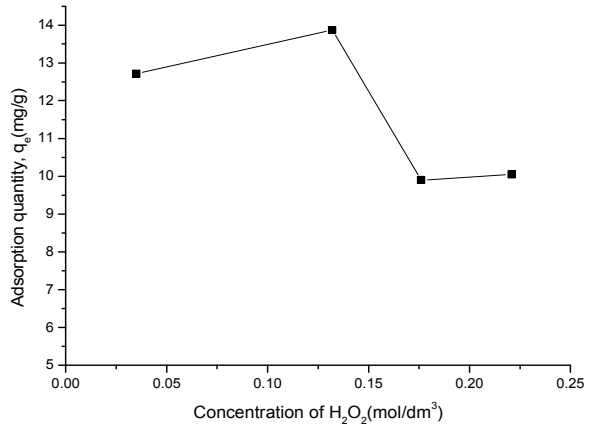

Figure 7. Effect of the concentration of H_2O_2 on the regenerative capacity of silica gel at pH 2.8 and the concentration of Fe^{2+} is 0.075mmol/dm^3.

TABLE1 EFFECT OF FE^{2+} ON THE REGENERATION CAPACITY OF SILICA GEL

C_{Fe}^{2+}(m mol/dm^3)	0.05	0.075	0.10
q_e(mg/g)	13.2	13.14	13.16

TABLE 2 REGENERATION CYCLES AND REGENERATION EFFICIENCY

Number of recycling processes	1	2	3	4
Regeneration Efficiency (%)	84.68	82.5	65.26	50.73

Summary

In this work, the satisfying adsorption quantity 16.38 mg/g was obtained when the initial concentration of the blue dye was 100 mg/dm^3 with 0.6 g silica gel at pH 9.3 and 303 K after 2 h. As Fenton reaction is environmentally benign, fast, cheap and relatively easy to obtain and handle, and silica gel have the ability to penetrate most of the UV light, Heterogeneous Fenton reaction with aid of UV light was adopted in the regeneration of silica gel. When the concentration of Fe^{2+} 0.05 mmol/dm^3 and H_2O_2 0.132 mol/dm^3, the first, second, third and forth regeneration efficiency were 84.68%, 82.05%, 65.26% and 50.73 %, respectively. An acid washing after the forth regeneration can enhance the regeneration efficiency to 92.19%.

Keywords: activated carbon; oxidation desulfurization; SO_4^{2-}/ ZrO_2; catalyst

Abstract: This paper studied how DBT oxidation was influenced by different preparation conditions of diesel desulfurization catalyst. Fuel oil oxidation and desulfurization technology has been studied by using solid superacid prepared by activated carbon loaded SO_4^{2-}/ ZrO_2 as catalyst instead of the traditional liquid acid, hydrogen peroxide as oxidant, in mild conditions. Impacting factors on removal sulfur have been investigated such as soaking time, burning temperature, burning time, active ingredient content and concentration of sulfuric acid, etc. The results show that soaking time is 6h, burning temperature is 500 ℃, burning time is 2.5h, the mass ratio of the active ingredient is 3:100 ZrO_2 and activated carbon, sulfuric acid concentration is 0.5mol/L. The desulfurization rate is over 93% and raffinate oil recovery can reach more than 86% under this optimum condition.

Introduction

Organic sulfur in diesel generates SO_x during combustion and pollutes the environment and endangers human health. Faced with increasingly stringent diesel sulfur content standards and huge market demand for low-sulfur clean diesel, the world's countries have committed to developing a variety of diesel desulfurization technologies[1-3].

Currently, diesel desulfurization consists of two ways, hydrodesulfurization (HDS) and non-hydrodesulfurization. Due to the harsh conditions of hydrodesulfurization reaction and a large requirement for investment in equipment, non-hydrodesulfurization becomes a hot topic. Methods for non-hydrodesulfurization include oxidative desulfurization, adsorption desulfurization, extraction desulfurization, membrane desulfurization and complex biological desulfurization[4-9]. Among them, oxidative desulfurization (ODS) as an alternative process to the traditional processes has received much attention for deep desulfurization of fuels for a number of reasons. This is because the ODS process has two main advantages compared to the HDS process. First, the most refractory sulfur-containing compounds to the HDS process, (e.g., DBT and its derivatives) show high reactivity toward the oxidation by this method. Second, the ODS process can be carried out in the liquid phase and under very mild operating conditions[4].

Oxidative desulfurization technology is a method for deep desulfurization at room temperature, atmospheric pressure and the presence of catalyst, the organic sulfur compounds being converted into polar substances and separated by extraction[10-12]. The choice of catalyst is the core factor affecting the desulfurization effect. Taking into account the requirements of clean production, hydrogen peroxide is frequently used as the oxidant in a variety of oxidative desulfurization methods having been reported, and usually organic acid is used as a catalyst[13-14]. While the oxidative desulfurization system of hydrogen peroxide/organic acids can achieve high desulfurization rate, the organic acids may partially dissolve in the fuel oil, which would affect the quality of fuel oil, and organic acid can corrode the equipment easily, causing high recovery costs. There are many researches and reports about solid superacid catalyzed hydrogen peroxide desulfurization systems home and abroad in recent years[15-16]. Solid superacid catalyst for oxidative desulfurization can simplify the catalyst regeneration cycle links. Separation and recovery of the catalyst is easy and it does not affect the fuel oil quality. Raw materials are fully utilized.

For the above reasons, the present study uses hydrogen peroxide as the oxidant, solid super-acid,instead of liquid acid, as the catalyst to find cheap catalyst, so as to achieve the purpose of the production of ultra low sulfur diesel.

Experimental

Materials, Reagents and Equipment. Materials: model diesel (dibenzothiophene and dodecane mixture, the total sulfur content 400ug/g). Reagents: dodecane(AR); dibenzothiophene(AR); hydrogen peroxide, with a purity of 30%(AR); ammonia purity of 25%-28%; N,N-dimethyl-formamide (DMF, AR); $Zr(NO_3)_4 \cdot 5H_2O$(AR); activated carbon(20-40mesh). Instrument: KQ3200DB CNC ultrasonic cleaner, Kunshan Ultrasonic Instrument Co., Ltd.; SZCL-3A-type digital temperature magnetic stirrer functions, Gongyi Branch Equipment Co., Ltd.; centrifuges, Shanghai Anting Scientific Instrument Manufacturing; tube furnace, Anhui BEQ Equipment Technology Co., Ltd.; fluorescence sulfur analyzer TEA-6000, Taizhou Suntoc Precision Instrument Co., Ltd..

Experimental Process. Catalyst preparation. A certain amount of activated carbon (20-40 mesh) was added to Zr $(NO_3)_4 \cdot 5H_2O$ dispersed by ultrasonic cleaner and immersed in aqueous solution at room temperature for 10h, aqueous ammonia with a mass fraction of 25% -28% was added to adjust the PH to 9-10 to precipitate. Aged at room temperature for 12h, the activated carbon was washed with ultrapure water and dried for 12h at 110 ℃. Then, impregnated the activated carbon with H_2SO_4. Filtered, dried and then roasted in a tubular furnace filled with nitrogen. That was activated carbon loaded SO_4^{2-}/ZrO_2 catalyst (denoted as SO_4^{2-}/ZrO^{2-}AC).

Catalytic Oxidative Desulfurization. Catalytic oxidative desulfurization process is divided into two parts: the catalytic oxidation and solvent extraction. Oxidation: a certain amount of diesel model was put into the reactor vessel and the right amount of self-made catalyst and hydrogen peroxide were added. The reaction vessel was placed in a water bath at a set temperature(60℃). After reacting for a certain period in a reflux condenser with magnetic stirring, the reaction system was then cooled. After cooling to room temperature, the catalyst was recovered by centrifugal separation, the reaction solution was desulfurized. Solvent Extraction: The desulfurization reaction solution was poured into a separatory funnel, adding a certain amount of DMF, the solution was extracted at room temperature after being thoroughly shaken. The oil phase and the extract phase were collected , recovery and sulfur content of the collected oil phase were determined.

Determination of Sulfur Content. Determination of total sulfur content: sulfur content of model diesel and diesel fuel after desulfurization were analyzed by fluorescence sulfur analyzer. Fluorescence sulfur analyzer trace of liquid injection, the temperature is set to 1000 ℃, pyrolysis oxygen flow 400ml/min, import oxygen flow rate 80ml/min, an argon flow of 160ml/min. Desulfurization rate is calculated based on the measured total sulfur content. It is calculated as follows:

$$\eta = \frac{C_0 - C_x}{C_0} \times 100\%$$

of which:

η——the desulfurization rate,%;

C_0 —— the sulfur content of diesel models, ug/g;

C_x —— the sulfur content of diese model after desulfurization, ug / g.

Results and Discussion

Effect of Sulfuric Acid Soaking Time on the Desulfurization Rate. Experimental conditions for the desulfurization was that the mass ratio of the active ingredient was 3:100 ZrO_2 and activated carbon, sulfuric acid concentration of 0.5mol/ L, calcined at 500 ℃ for 3h, soaking time was 2h, 4h, 6h, 8h and 10h. Performance of the catalyst prepared was shown in Fig.1.

As can be seen from Fig.1 that with the increase of soaking time below 6h, the removal sulfur increased. When the soaking time was above 6h, desulfurization rate was decreased, this may be because the soaking time was too short, the loaded active centers on the catalyst surface could not be sufficient, resulting in the reduction of desulfurization rate. The soaking time was too long, the effect would be a salt of sulfuric acid, it could also affect the performance of the catalyst, so the optimum soaking time was 6h.

Effect of Burning Temperature on the Desulfurization Rate. Experimental conditions for the desulfurization was that the mass ratio of the active ingredient was 3:100 ZrO_2 and activated carbon, sulfuric acid concentration of 0.5mol/L, soaking time was 6h, calcined at 400℃, 450℃, 500℃, 550℃ and 600℃ for 3h respectively. Performance of the catalyst prepared was shown in Fig.2.

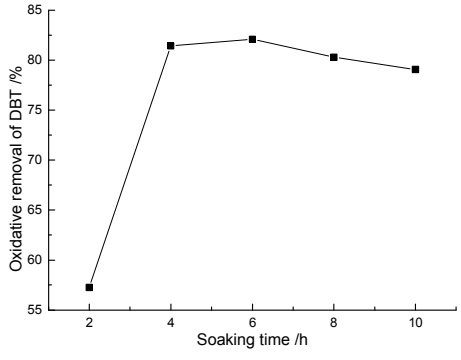

Fig.1. The connection between the soaking time and removal of DBT

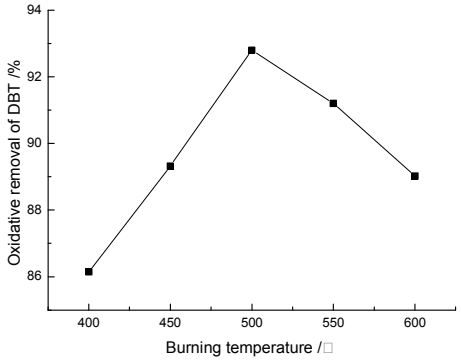

Fig.2. The connection between the burning temperature and removal of DBT

Calcination temperature significantly affected the performance of catalytic desulfurization, different calcination temperatures can form SO_4^{2-}/M_nO_m-AC superacid catalysts with different acid strength and acid distribution. As can be seen from Fig.2 that the calcination temperature was

500 ℃, the desulfurization rate was highest; with the increase of calcination temperature below 500℃, the removal sulfur rised. When the soaking time was above 6h, the desulfurization rate decreased. This may be because the calcination temperature was too low, it can not form a sufficient number of acid centers; the calcination temperature was too high, the acid center of superacid would decompose, reducing the number of catalytically active centers due to the loss of sulfate, and the surface area decreased.Strong acid center of SO_4^{2-}/M_xO_y-AC solid superacid can be formed to appropriate temperature in the Process for preparing the solid acid, which is because ion type S-O bond in high temperature can be converted into the covalent S = O bond, the covalent bond has the capacity of inducing effect to make metal ion has a strong electron withdrawing ability to be acidic. There is also a suitable calcining temperature range determined by type of crystalline metal oxide of catalyst surface and the sulfur content.

Effect of Burning Time on the Desulfurization Rate. Experimental conditions for desulfurization was set as follows: the mass ratio of the active ingredient was 3:100 ZrO_2 and activated carbon, sulfuric acid concentration of 0.5mol/L, soaking time was 6h, calcined at 500℃ for 1.5h, 2h, 2.5h, 3h, 3.5h and 4h respectively. Performance of the catalyst prepared was shown in Fig.3.

As can be seen from Fig.3 that when the burning time is 2.5h, the desulfurization activation was highest. The burning time was too short, it can not form sufficient acid centers; burning time was more than 2.5h, the formation of acid sites may be decomposed, reaction reactivity was decreased. That the burning time was too long would reduce specific surface area of the solid acid, and a large number of square phase ZrO_2 was converted into monoclinic phase ZrO_2, sulfur species were not firmly bonded to the surface, reducing the number of acid sites , the catalytic activity was not high.

Effect of Active Ingredient Content on the Desulfurization Rate. Experimental conditions:the mass ratio of the active ingredient was n:100 (n=1, 2, 3, 4, 5, 6) ZrO_2 and activated carbon, sulfuric acid concentration of 0.5mol/L, soaking time was 6h, calcined at 500℃ for 2.5h. Performance of the catalyst prepared was shown in Fig.4.

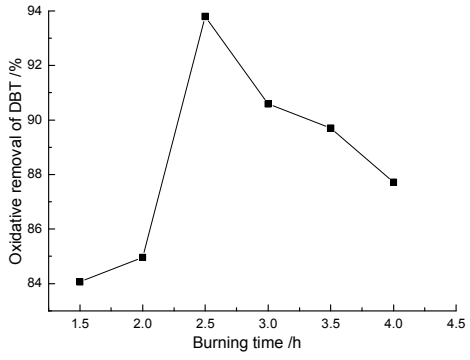

Fig.3. The connection between the burning time and removal of DBT

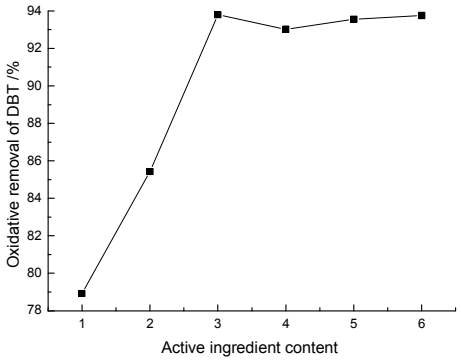

Fig.4. The connection between the active ingredient content and removal of DBT

H_2O_2 under acidic conditions produce hydroxyl radicals with a very strong oxidation strength, even oxidize thiophenic sulfur to sulfate sulfur. Small amount of catalyst can speed the oxidation rate, and increase the desulfurization rate. As can be seen from Fig.4 that with the increase of the active ingredient content, the number of active centers was larger, the oxidation effect was more significant. When the mass ratio of the active ingredient is 3:100 ZrO_2 and activated carbon, desulfurization rate is 93.80%. And then the desulfurization little change with increasing active

ingredient content, this may be because when mass ratio is 3:100, providing sufficient catalytic activity center. Then the content of the active ingredient increased, no increase in catalytic activity.

Effect of the Concentration of Sulfuric Acid on the Desulfurization Rate. Experimental conditions:the mass ratio of the active ingredient was 3:100 ZrO_2 and activated carbon, soaking time was 6h, calcined at 500℃ for 2.5h, sulfuric acid concentration of 0.25mol/L, 0.5mol/L, 0.75mol/L, 1.0mol/L and 1.25mol/L. Performance of the catalyst prepared was shown below.

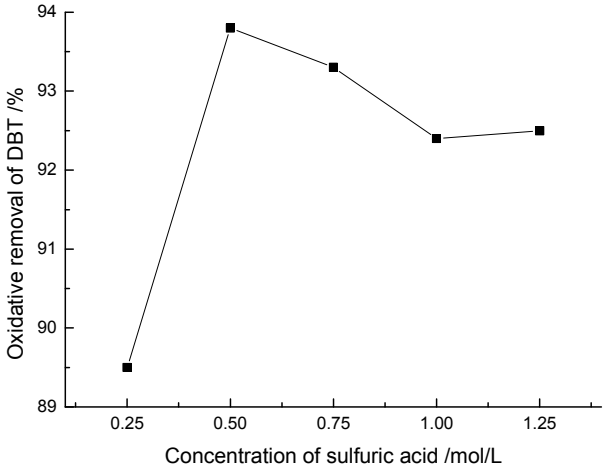

Fig.5. The connection between the concentration of sulfuric acid and removal of DBT

As can be seen from Fig.5 that SO_4^{2-} concentration was too low, the acidity of solid acid wasn't enough, insufficient amount of acid and unevenly distributed. SO_4^{2-}concentration was too high, the sulfate would block pores of catalyst, reducing the specific surface area, reducing the amount of acid, or sulfuric acid could cause side reactions with the metal oxide to form sulfate. For the reasons above, the optimum concentration of sulfuric acid was 0.5mol/L.

Conclusion

In this study, activated carbon loaded ZrO_2 solid acid catalyst for the desulfurization was investigated, the optimal preparation conditions of oxidative desulfurization catalyst: the mass ratio of the active ingredient is 3:100 ZrO_2 and activated carbon, 0.5 mol/L sulfuric acid soaked for 6h, resulting catalyst calcined at 500 ℃ for 2.5h, activated carbon loaded solid super acid catalyst desulfurization rate can reach over 93%, raffinate oil recovery can reach more than 86% under this optimum condition.

Keywords: quicklime treatment;sludge semi-dry;dewatered sludge;mechanical design parameters.

Abstract: The fundamentals of lime treatment for dewatered sludge and main factors which affect the treatment process are introduced in this study. According to the results, higher effective calcium oxide content in lime contributes to faster heating rate of the semi-dry system and better effects of semi-dry process. Sludge at the moisture content of 45%-55% after the semi-dry process can be well balled while that at the moisture content of 35% can easily get collapsed and has hard surface. Mechanical design parameters are determined by experiments. The optimum stirring time is 5-10mins when well stirred and the stirring rate should be slow. Heat preservation jacket is needed for the machine and the water vapor, which is produced by heating, should be exhausted in time.

Introduction

Lime treatment for dewatered sludge is the oldest one of the methods to be applied. Through adding Calcium oxide, this method can increase the PH and temperature to achieve the sludge solidification. Besides, the nature of the sludge may be effectively changed by choosing appropriate mixing conditions and equipment in the process. Treated sludge become particles [1] that have good fluidity and lower moisture content, thus storage and transportation could be much easier. In addition to meet the hygiene index, it is mainly used as pretreatment method of sanitary landfill or building materials using. This paper studies on the technical parameters of lime Semi-dry System and puts forward reasonable mechanical design parameters.

Theory of the Increased Calcium Material Semi-dry System

The Fundamentals of Lime Treatment for Dewatered Sludge

Mixing the sludge with calcium oxide, calcium oxide and water contained in the sludge will produce exothermic reaction and generate calcium hydroxide or calcium hydrate [3] . Quicklime can produce following reaction (Eq. 1 and Eq. 2) per kilogram:

$$1kgCaO+0.32kgH_2O \rightarrow 1.32kgCa(OH)_2+1177KJ \quad (1)$$

$$H_2O\ (l)+2258KJ/kg \rightarrow H_2O\ (g) \quad (2)$$

According to this reaction(Eq. 1 and Eq. 2), 1kg calcium oxide is combined with 0.32 kg water to become calcium hydroxide, the reaction heat generated is equivalent to about 0.5 kg water evaporation heat required. Thus, the method, using calcium oxide to generate heat and absorb water to make sludge achieved semi-dry state, is theoretically feasible.To the drying, chemical reaction heat released of calcium oxide have bigger contribution than the chemical reaction itself.

The Main Factors that Affect the Treatment Process

Determination of Industrial Lime Effective Calcium Oxide Content

During the reaction process of lime and sludge, the heating rate and the temperature height are subject to the restrictions of calcium oxide content. So, it need to determine the content of effective calcium oxide before making semi-dry, The test methods are according to JTG - E51-2009 " Highway Engineering inorganic binder stabilized material testing procedures“ T0811-1994. The effectively calcium oxide content is calculated according to the following formula(Eq. 3).

$$X = \frac{V_5 \times M \times 0.028}{m_1} \times 100 \quad (3)$$

The formula:X—The effectively calcium oxide content(%);

V_5—The volume of consumption of hydrochloric acid standard solution while titration(mL)

0.028—Calcium oxide mg equivalent

m_1—The quality of the sample(g)

M—The molar concentration of hydrochloric acid standard solution (mol/L)

Laboratory determine 4 kinds of samples according to the method, effective calcium oxide content were 98%, 68%, 60%, 55%.The common effective calcium oxide content of industrial lime is between 60% ~ 70%.

Analysis of Industrial Lime Reaction Rate

While using quick lime to semi-dry sludge, the heating rate is determined by the effective calcium oxide content. Figure 1 is the internal heating rate figure that lime whose effective calcium oxide content are 98%, 68%, 60%, 55% 30% outer doped (ratio with sludge mass) sludge with 80.5% moisture content. The test method is puting semi-drying sludge into heat preservation box, to determinate the effect of sludge internal heating.

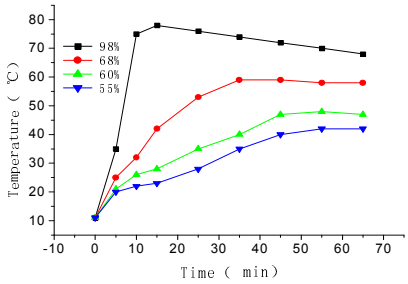

Fig.1 Internal heating curve of sluge- different quality lime(outer doped 30%)

As shown in figure 2, higher effective calcium oxide content in lime contributes to faster heating rate and reaction rate of the semi-dry system outer doped with 30% lime. Lime that have 98% effective calcium oxide content make the internal temperature of mixture system up to 78 ℃ in 15 min,produce large amounts of water vapo. Lime that have 98% effective calcium oxide content raise up to the highest temperature(53℃) in 35min, and the temperature maintained well. The temperature of lime that have 60% and 55% effective calcium oxide content heat up slowly, it still raise slowly after 70min. In such mixture system, the reaction rate is lower and temperature hysteresis is serious.

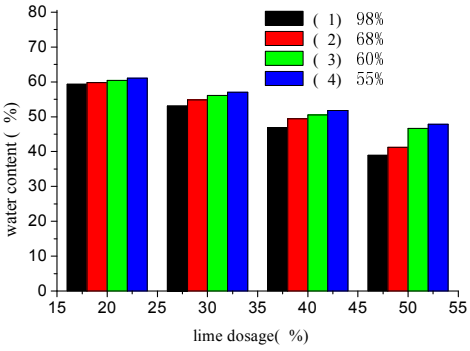

Fig.2 The relation figure of lime dosage- moisture content

Analysis of Effects About Semi-dry Process

The quality of the effect of semi-dry is determined by the sludge moisture content. Moisture content testing method according to the CJ/T221-2005 "test method of urban sludge treatment plant sludge", section 2, the determination of city sludge moisture content (gravimetric method).

We studied the semi-dry effect of different dosage of lime according to the content of calcium oxide, the results shown in fig.2. Fig.2 is the effect figure of semi-dry sludge about the lime with calcium oxide content of 98%, 68%, 60%, 55%. As, we can see, higher effective calcium oxide content in lime and higher dosage of lime contributes to better effects of semi-dry process. Dewatered sludge moisture content of 80.5%, mixed 20% different quick lime has little distinction that the moisture content reduced to（60±1）%, the surface of sludge is wet and easy to be reunited. When the dosage is changed up to 50%, the moisture content of No.1 is 38.9%, No.4 is 48.8%, both moisture content difference of nearly 10%. Adding 30% lime, the moisture content of sludge is (55 + 1) %, after semi-drying the industrial quick lime, sludge can be well balled.

60% 55% 45% 35%

Fig.3 Moisture content figure

The condition of semi-dried sludge is shown in Fig.3. Fig.3 is the condition of mixed lime and sludge which was stirred 2min slowly and layed up 30min in net cement slurry mixer. The lower moisture content of sludge has whiter color and harder surface. The process of semi-drying sludge with strong ammonia smell increases with the increase of dosage of lime. the sludge will have a sticky surface and easy to be reunited when the moisture content figure is 60%. The white particles in the figure are calcium hydroxide produced by the reaction of calcium oxide and water. Sludge at the moisture content of 45%-55% after the semi-dry process can be well balled while that at the moisture content of 35% can easily get collapsed and has hard surface.

The Determination of Lime Semi-drying Machine Designed Parameters

The Mechanical Stirring Time and Stirring Speed

The semi-drying mechanical stirring time and stirring speed is Directly determines the production of dry sludge, it is also directly related to mechanical efficiency.Fig.4 is the diagram of stirring time and moisture content. After adding 30% quick lime, along with the increase of mixing time, moisture content is not significantly reduced. The reaction rate of lime and water is quickly completed within 5 min. the moisture evaporation rate is low without heat preservation measures.

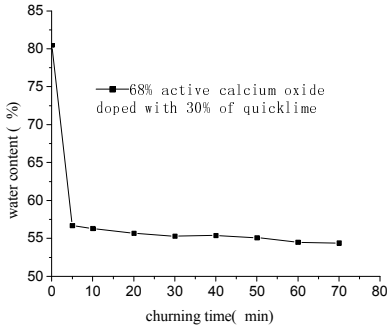

Fig.4 The diagram of stirring time and moisture content

stirring 2min *stirring 5min* *stirring 10min*

stirring 20min *stirring 2min, laying up30min* *stirring 30min*

Fig.5 Stirring time and the condition of sludge

Fig.5 is the condition of sludge with different stirring time. As the extension of stirring time, the sludge get wetter on the surface, the viscosity increased gradually.Along with the increasing of stirring time , the internal capillary bound water and combined water of the sludge are destroyed and appear on the surface. And the faster the stirring speed, the greater the shearing action of sludge is, the easier to release the moisture inside package. Thus, stirring speed is not the sooner the better, time also is not as long as possible. Contrast the sludge that is stirred 2min and layed up 30min to the one that is stirred slowly all the time, difference of the two sludge surface state is very big, the former sludge can be cut into pieces, can into the ball; The latter is wet, sticky.the former sludge can be cutted into pieces, can be balled; The latter is wet, sticky. According to fig.4, the optimum stirring time is 5-10mins when well stirred and the stirring rate should be slow.

Mechanical External Thermal Insulation Jacket Design.

The process of semi-drying can release a large amount of heat, moisture in the sludge can be evaporated. The amount of evaporation is related to the temperature inside the sludge,Fig.6 is internal temperature curve with heat preservation measures or not.Fig.7 is Natural moisture evaporation rate with heat preservation measures or not. The heat preservation measures is puting sludge into foam insulation box. No heat preservation measures is placing dry sludge in indoor and the temperature is 20 ℃. Botth of them need to exhaust air slowly.

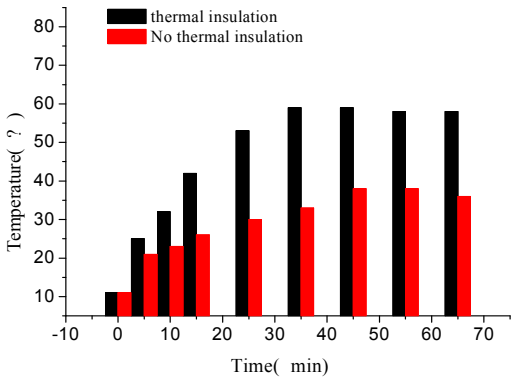

Fig.6 Temperature curve with 30% lime.

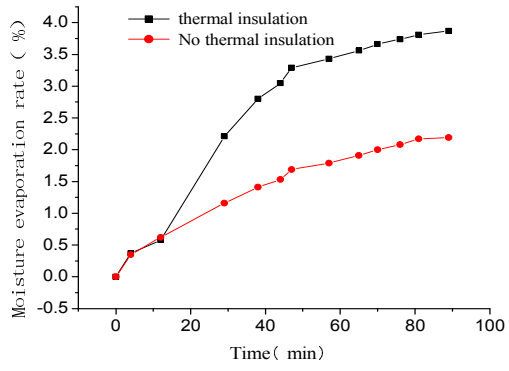

Fig.7 The moisture evaporation rate diagram with 30% lime.

From figure 6 can be seen that the maximum temperature difference is 20 ℃. Figure 7 shows the biggest difference of moisture evaporation rate reached 1.7% within 90 min, and the difference showed a trend of gradual increase. That both shows the The importance of the heat preservation measure. Thus, heat preservation jacket is needed for the machine and the water vapor, which is produced by heating, should be exhausted in time that to improve the rate of evaporation as far as possible for making semi-dry mechanical effectively.

Summary

The method of using increased calcium material to semi-dry sludge is economic and reasonable, convenient and easy.

(1) Higher effective calcium oxide content in lime contributes to faster heating rate of the semi-dry system and better effects of semi-dry process

(2) Sludge basic has no smell after semi-drying.Sludge at the moisture content of 45%-55% after the semi-dry process can be well balled while that at the moisture content of 35% can easily get collapsed and has hard surface. Storage and transportation could be much easier.

(3) The optimum stirring time is 5-10mins when well stirred and the stirring rate should be slow.

(4) Heat preservation jacket is needed for the machine and the water vapor, which is produced by heating, should be exhausted in time to improve the rate of evaporation as far as possible for making semi-dry mechanical effectively.

Simultaneous Reduction and Immobilization of $Cr_2O_7^{2-}$ in Metakaolinite-based Geopolymer Complexed Reductant

Jieyu Chen[1, 2,a *], Xinrong Lei[1,2], Sun Tao[1]

[1] Faculty of Material Science and Chemistry, China University of Geosciences, Wuhan 430074, PR China

Keywords: geopolymer; chromium; Geopolymerization; immobilization

Abstract: Reduction and immobilization of Cr(VI) as $Cr_2O_7^{2-}$ is investigated by using metakaolinite-based geopolymer complexed reductant. Without reductants, the leached Cr concentration from metakaolinite-based geopolymer containing Cr(VI) is very high. Adding reductants as $FeCl_2 \cdot 4H_2O$, $FeSO_4 \cdot 7H_2O$, and $Na_2S \cdot 9H_2O$ respectively during geopolymerization, the leached Cr concentration is below 5 mg L^{-1} with high Cr immobilization rate above 99 %. By comparison with the immobilization of Cr (III), the added reductants reduced Cr (VI) to Cr (III) which can be locked successfully in the amorphous structure of geopolymer. Meanwhile, Cr (VI) initial concentration is lower than 0.7 wt. % in metakaolinite-based geopolymer, the above reductants can all meet the requirements. While for Cr (VI) initial concentration larger than 0.7 wt. %, $Na_2S \cdot 9H_2O$ is more appropriate. Such a simultaneous reduction and immoboilization process enables the feasibility of using metakaolinite-based geopolymer complexed reductant to implement a one-step procedure for chromite ore processing residue cleanup.

Introduction

Chromite ore processing residue (COPR) from the high-lime chromium extraction industry has already been recognized as one of the most hazardous industrial waste. The inherent chromium ions, with the total amount up to 5 wt. % in COPR samples, appear mainly as hexavalent-Cr(VI) and trivalent-Cr(III) oxidation states. However, the Cr(VI) species is severely toxic at moderate doses and has been classified as a respiratory carcinogen to human health [1]. Although the high-lime process has been abandoned in US and UK at later 1960s, however, it is still adopted in developing countries such as China and India [2]. Each year, Chinese chromium industry generates 600,000 tons of COPR and over the years accumulated about 3 million tons in heaps [3]. In fact, millions of tons of COPR have been dumped at urban areas throughout the world waiting for cleanup [4-5]. Unfortunately, due to its highly water-soluble nature, Cr(VI) species can be easily leached out from COPR upon natural exposure and then enter into the vicinal groundwater, streams, soil and atmosphere, leading to severe harmful pollution towards health of living beings.

Several detoxication technologies aiming to reduce Cr(VI) to low-toxic Cr(III) species, including the high-temperature detoxication method [6-9], wet-process, reduction and immobilization of Cr(VI) using nanoscale zero-valent iron [10] and microwave process[11, 12], have been developed. However in the above technologies, the stabilization/immobilization of the reduced product Cr (Ⅲ) is seldom considered and apparently they are not applicable for large-scale processing of COPR. Another potential risk is the fact that Cr (III) ions in the post-processed COPR

may be reoxidized to Cr(VI) upon exposure in air. Consequently, besides Cr (VI) detoxication, the successive immobilization of Cr (III) is another key procedure for the cleanup of COPR. Recently, a low-cost and easily-operated method, named the stabilization/solidification (S/S) technique, which utilizes reductant (such as $FeSO_4$) for Cr(VI) and Portland cement as stabilizer for Cr(III), might be a potential possible solution to meet the industrial desires [13-15]. However, due to the limited lifespan and low acidic resistivity of cement, the immobilized Cr species has to encounter the potential threaten of being leached out again to environment.

In comparison, geopolymer with amorphous network structure, mainly constructed by aluminosilicates, hosts much better acidic resistivity, durability in nature, low permeability and high compressive strength compared with cement [16, 17]. So it attracts more attention in immobilizing heavy metals and has been widely applied to immobilize Zn^{2+}, Co^{2+}, Pb^{2+}, Cu^{2+}, Cr^{3+} and Cd^{2+} [18-22], but fails to deal with Cr(VI) as $Cr_2O_7^{2-}$ [23, 24]. This motivates us to envision the adaptability and feasibility of the geopolymer method coupling with reductant for reduction and immobilization of Cr(VI) in contaminated solid waste, especially COPR.

In the present work, we report a new method of simultaneous reduction and immobilization of Cr(VI) by selecting Fe^{2+}, SO_3^{2-} and S^{2-} as reductant for reducing Cr(VI) to Cr(III) and employing the metakaolinite-based geopolymer to shed light on the immobilization of Cr(III). Using this method, reduction and immobilization of chromium can be realized by one-step procedure of geopolymerization, in which reduced Cr^{3+} is locked in the amorphous structure of geopolymer instead of being re-oxidized. The method is low-cost and simple with high efficient for Cr(VI) cleanup. Thus it provides a highly applicable alternative technique for large-scale cleanup for COPR or other Cr (VI)-contaminated solid waste.

Material And Methods

Materials

Coal-series kaolinite with 86% particles size below 2 μm was obtained from Datong, Shanxi province, China. The chemical composition of the kaolinite sample shown in Table 1 was determined by the X-ray fluorescence (XRF). Before geopolymerization, kaolinite was calcined at 600 ºC for 4 h to harvest metakaolinite product with high pozzolanic activity.

TABLE 1 CHEMICAL COMPOSITION OF KAOLINITE AS OXIDES

Composition	SiO_2	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	Na_2O	K_2O	P_2O_5	LOI [a]
wt. %	45.36	38.49	0.32	0.44	0.16	0.08	0.088	0.053	0.18	14.33

[a] LOI: Loss on ignition at 1000ºC

Analytical-grade reagents NaOH, $K_2Cr_2O_7$, $CrCl_3 \cdot 6H_2O$, $FeSO_4 \cdot 7H_2O$, $FeCl_2 \cdot 4H_2O$, $Na_2S \cdot 9H_2O$ and Na_2SO_3 were obtained from Sinopharm Chemical Reagent Co., Ltd (China). Sodium silicate solution with the Baume degree of 45% - 47% and the modulus of 2.6-2.8 was purchased from Foshan Zhongfa sodium silicate factory (China).

Geopolymerization of metakaolinite-based geopolymers

The metakaolinite, sodium silicate solution and NaOH with a mass ratio of 6:5:1 were first mixed and stirred for 20 min until the formation of homogeneous colloid. The colloid was then casted into a 20 mm × 20 mm × 20 mm mold and vibrated for 2 min to eliminate air bubbles therein. After that, the mold was put in an oven with a constant temperature of 90 °C and a fixed humidity of 100% for 30 min. Then the sample was demolded. The samples with brick-shape were obtained. Finally, the brick was sealed with polyethylene (PE) film and immersed in a 60 °C water bath for 1 h. The pure metakaolinite-based geopolymer was obtained and denoted as MP. For justifying the immobilization efficiency of MP towards Cr(III) and Cr(VI), $CrCl_3 \cdot 6H_2O$ and $K_2Cr_2O_7$ saturated

solutions with certain Cr weight percentage were introduced into the colloid, respectively. For those colloids with Cr (VI), the reductants ($FeCl_2 \cdot 4H_2O$, $FeSO_4 \cdot 7H_2O$, $Na_2S \cdot 9H_2O$ and Na_2SO_3 saturated solution) were successively added with specific molar ratio to Cr(VI) before casting. The denoted names of the brick samples with the detailed reagent composition are listed in Table 2. Before the subsequent measurements, all bricks were stored under ambient condition with the protection of the PE film.

TABLE 2 EXPERIMENTS OF GEOPOLYMERIZATION

Sample	Cr / wt%	Cr species	Reductant	Reductant: Cr
MP	-	-	-

MP-H-SO	0.025	$K_2Cr_2O_7$	Na_2SO_3	1.5

Test method

The leaching tests of chromium in the samples were conducted according to the No.1311 USEPA TCLP (toxicity characteristic) leaching procedure method [25]. And the leached Cr concentration of the filtrates was determined using atomic absorption spectrometry (AAS, Hitachi180-70). The immobilization performance of MP towards chromium was consequently evaluated by the percentage content of chromium immobilized in MP, which was called *immobilization* rate in the following paper. It was calculated according to the leached Cr versus the chromium added in MP.

Results and discussion

Immobilization of Cr(III)

Since the product of detoxicated Cr(VI) is Cr(III), using MP to immobilize Cr(III), similar to those reported for Zn^{2+}, Co^{2+}, Pb^{2+}, Cu^{2+} and Cd^{2+}, has become the first critical issue to match the fundamental requirement of COPR processing. Fig. 1 depicts the total leached chromium concentration and the immobilization rate of the MP-T-x samples from the TCLP experiments. At low initial introduced Cr(III) concentration (≤ 0.2 wt.%), immobilization rate of > 99.99% can be reached with the leached Cr concentration below 0.1 $mg \cdot L^{-1}$. While with the initial introduced Cr(III) concentration increases to 1.0 wt.%, the leached concentration varies quasi-linearly within a small range of 0.1-0.2 mg L^{-1}, far below the current regulatory limit of 5 mg L^{-1} for nonhazardous wastes proposed by the US EPA. Furthermore, all the samples show very high immobilization rate of beyond 99.0%. The result indicates that the MP matrix is capable of immobilizing the Cr(III) species with high efficiency once Cr(VI) is reduced to Cr(III).

Reduction of Cr(VI) and the successive immobilization

Another critical issue arising is whether the Cr(VI) species, generally appears as $Cr_2O_7^{2-}$, can be reduced and immobilized simultaneously. We then fixed the initial Cr(VI) concentration to be

0.025 wt.% and selected various reductants, including Na_2SO_3, $Na_2S·9H_2O$, $FeCl_2·4H_2O$ and $FeSO_4·7H_2O$ (denoted as MP-H-SO, MP-H-NS, MP-H-FC and MP-H-FS, respectively) as well as a blank benchmark (MP-H), to evaluate the feasibility of the proposed process. The result is shown in Fig. 2 Without reductant, the leached Cr concentration is up to 8.233 mg L^{-1}, with a low immobilization rate of 34.14%. While the Na_2SO_3 additive can moderately decrease the leached Cr concentration to 5.286 mg L^{-1} with the immobilization rate of above 50%. It is found that Fe^{2+} and S^{2-} additives can reduce greatly the leached Cr concentration. MP-H-NS, MP-H-FC and MP-H-FS all show the leached Cr concentration far below 5 mg L^{-1} of the regulatory limit for nonhazardous wastes proposed by the US EPA. And the immobilization rate is enhanced dramastically up to 99.0%. The above data confirm that Cr(VI) species as $Cr_2O_7^{2-}$ cannot be directly stabilized by the pure MP system. However, the appropriate reductive agents introduced can help stabilization of Cr in MP and prevent it from leaching out. Obviously, redox reaction happens in the geopolymerization in which Cr(VI) as $Cr_2O_7^{2-}$ is reduced to Cr(III) species as Cr^{3+} under the reductant action which are oxidized conversely and then Cr(III) is stabilized in MP .

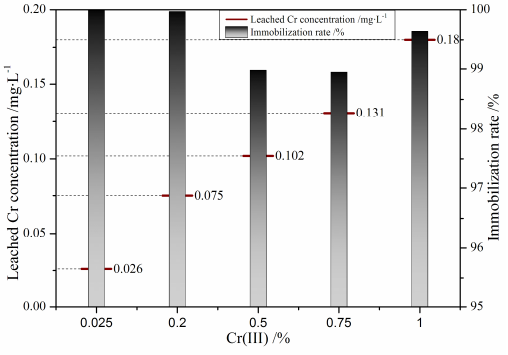

Fig.1.Immobilization performance of Cr (III).

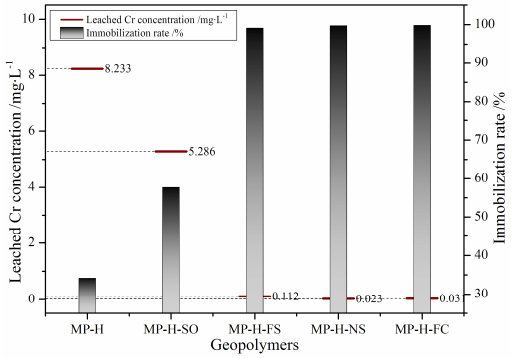

Fig.2. Iobilization rate of performance of Cr (VI

In the above successful experiments, only 0.025% of initial Cr(VI) concentration in MP was studied. But Cr(VI) content is often far higher than this value in Cr(VI)-contaminated solid waste, especially COPR, up to 1%. Five initial Cr(VI) concentrations, ranging from 0.1 wt% to 1.0 wt%, were studied according to the same procedure for the MP-H-FC, MP-H-FS and MP-H-NS systems.The results are summarized in Table 3. It is confirmed that all the MP-H-FC, MP-H-FS and MP-H-NS samples exhibit excellent immobilization rate of above 99.0%, with slight differences on the leached chromium concentration, when the initial Cr(VI) concentrations is from 0.1 wt.% to 0.7 wt.%. However, when the initial Cr(VI) concentration is 1.0 wt.%, MP-H-FC and MP-H-FS bricks could not be prepared because the colloids lose the cementitious activity by adding 1.0 wt.% Cr (VI) and moderate Fe^{2+}. The result further confirms that MP-H-NS bricks can be formed successfully regardless of the initial Cr(VI) concentration. And all the leached concentrations are below the US EPA limitation of 5 mg L^{-1}. If the amount of reductants were set to be appropriate towards the initial Cr(VI) content, Fe^{2+} and S^{2-} both can serve as the additive to the geopolymer matrix to simultaneously realize the reduction and stabilization of Cr(VI) with concentration below 0.7 wt.%. For Cr(VI) concentration larger than 0.7%, S^{2-} can be more appropriate and further study about the mechanism of Cr(VI) reduction and immoboilization is required.

TABLE.3. LEACHED CR CONCENTRATION AND IMMOBILIZATION RATE IN THE BRICKS WITH INCREASED CR (VI) CONTENT

1.0	lose cementitious activity				0.230	99.98

Conclusion

Cr(VI) is a high toxic substance and due to the high water solubility, direct detoxification and immobilization of Cr(VI) within natural environment is technologically difficult. In this paper, simultaneous reduction and immobilization of Cr(VI) as $Cr_2O_7^{2-}$ is investigated by one-step procedure using metakaolinite-based geopolymer added reductant. Cr added as Cr^{3+} can be locked successfully in the amorphous structure in geopolymer and leached Cr concentration is lower 5 mg L^{-1} when initial Cr(Ⅲ) concentration is less than 1 wt.%. Cr(Ⅲ) has slightly influenced on the compressive strength of the sample bricks. On the base of Cr^{3+} immobilized successfully in geopolymer, reductant was introduced to reduce Cr(VI) to Cr(Ⅲ) and the metakaolinite-based geopolymer was applied to immobilize Cr(III). In the absence of reductants, Cr added as $Cr_2O_7^{2-}$ is highly leachable. But addition of $FeCl_2 \cdot 4H_2O$, $FeSO_4 \cdot 7H_2O$ and $Na_2S \cdot 9H_2O$ by certain proportion respectively towards Cr(VI) reduced greatly the leached Cr concentration in metakaolinite-based geopolymer. Under these reductants, Cr(VI) was reduced to Cr(III) and Cr(III) was then locked in geopolymers. When initial Cr(VI) concentration is lower than 0.7% in metakaolinite-based geopolymer, the leached Cr concentration is below 5 mg L^{-1} and Cr immobilization rate above 99%. When initial Cr(VI) concentration is larger than 0.7%, the geopolymer bricks added $FeCl_2 \cdot 4H_2O$ and $FeSO_4 \cdot 7H_2O$ could not be prepared because the colloids lose the cementitious activity. So, $Na_2S \cdot 9H_2O$ may be the best reductant not only to achieve good Cr immobilization effiency. Such a simultaneous reduction/immoboilization process enables the feasibility of using metakaolinite-based geopolymer complexed reductant to implement a one-step procedure for COPR cleanup.

Keywords: hydrothermal synthesis; indium phosphate–phosphite; structure directing agent; fluorescence property.

Abstract. A novel 3D anionic indium phosphate–phosphite, formulated as $|(C_{10}H_{10}N_2)_{1.5}(H_3O)_3|[In_{18}(H_2O)_{12}(HPO_4)_{12}(HPO_3)_{16}(H_2PO_3)_6]$ (1), was hydrothermally prepared by using 4, 4′-bipyridine (4, 4′-bipy) as a structure directing agent (SDA). Single-crystal X-ray diffraction analysis reveals that compound 1 crystallizes in the hexagonal system space group $P6_3/m$ (No. 176) having unit cell parameters a = 13.7843(19) Å, b = 13.7843(19) Å, c = 28.058(6) Å, V = 4617.0(13) Å^3. Compound 1 exhibits a unique pillar-layer open-framework constructed from InO_6 octahedra, HPO_3 pseudo-tetrahedra and HPO_4 tetrahedra, resulting extra-large 16-MRs channels. Synthesis, crystal structure and fluorescence property for compound 1 were reported in this paper.

Introduction

Metal phosphates and phosphites exhibiting open architectures have been recognized for their potential applications in magnetism, nonlinear optics, renewable catalysis, ion exchange and host-guest assembly [1-3]. Numerous metal phosphates have been reported relating to aluminum, gallium and indium metal ions [4-7]. In these years, HPO_3 pseudo-tetrahedral were introduced to explore the design and synthesis of novel open architectures. The replacement of the phosphate group with phosphite forbids self-interpenetration and offers the potential to construct porous solids with extra-large channels[8-12].

Here, We reported the synthesis and structure of a novel 3D indium phosphate–phosphite, $|(C_{10}H_{10}N_2)_{1.5}(H_3O)_3|[In_{18}(H_2O)_{12}(HPO_4)_{12}(HPO_3)_{16}(H_2PO_3)_6]$ (1). Further characterizations for 1 were performed using powder X-ray diffraction (PXRD), infrared spectra (IR), thermal gravimetric analyses, solid fluorescence property, inductively coupled plasma and elemental analyses.

Experiment

Synthesis. Compound 1 was hydrothermally synthesized: 100 mg $In(NO_3)_3 \cdot 4H_2O$, 64 mg $H_2C_2O_4$ and 120 mg H_3PO_3 were dispersed into 6 mL H_2O with stirring. Then, 48mg of 4, 4′-bipy was added. After stirring for 30 min, the mixture was transferred into a sealed Teflon-lined steel autoclave and heated at 160ºC for 3 days. Colorless prism-like crystals of compound 1 were collected and air-dried at room temperature (53% yield based on Indium).

Determination of crystal structure. Suitable single crystal of 1 (0.20 × 0.20 × 0.08 mm^3) was selected for single-crystal X-ray diffraction analyses. The data was collected on a Bruker Smart CCD diffractometer (λ(Mo-Kα) = 0.71073Å). A total of 33564 reflections with 3921 unique reflections (R_{int} = 0.0629) were collected. Data processing was accomplished with the SAINT processing program. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXTL 5.1 software package [13]. First, the In and P atoms were located, followed by location of O, N and C atoms. The hydrogen atoms from framework were located from difference Fourier maps. While the hydrogen atoms from guest molecules were placed geometrically. For the

final refinement, all the non-hydrogen atoms were refined anisotropically. It was noteworthy that P(4) atoms were disordered over two positions with an equal occupancy. Detailed crystallographic data for 1 was presented in Table 1.

Results and discussion

Description of crystal structure for 1. Single-crystal X-ray diffraction analyses reveals that 1 crystallizes in the hexagonal space group $P6_3/m$ (No. 176), formulated as $|(C_{10}H_{10}N_2)_{1.5}(H_3O)_3|[In_{18}(H_2O)_{12}(HPO_4)_{12}\ (HPO_3)_{16}(H_2PO_3)_6]$. As shown in Fig. 1a, each asymmetric unit contains three crystallographically independent In atoms, four crystallographically independent P atoms, eleven oxygen atoms, one guest water molecule and one 4, 4′-bipy molecule. All the three In atoms were octahedrally coordinated. The coordinated environment for In(2) and In(3) atoms were similar, six vertex oxygen atoms were shared with adjacent P atoms. The coordinated environment for In(1) was different, whereby, five vertex oxygen atoms were shared with adjacent P atom. The remaining coordination site was occupied by a coordinated water molecule, as indicated by the In(1)-O(4) bond length of 2.259(12) Å. The coordination fashion for P(1), P(3) and P(4) were pseudo-tetrahedra. The P(2) atom was tetrahedrally coordinated. It was connected to three In atoms via oxygen atoms bearing a terminal –OH group. All bond lengths and angles in the crystal structure of 1 were similar to those reported in the literature.

The novel 3D open-frameworks for compound 1 were constructed from InO_6 octahedra, HPO_3 pseudo-tetrahedra and HPO_4 tetrahedra, featuring intersecting extra-large 16-MRs channels. The guest water molecular and 4, 4′-bipy molecular were deposited in these channels (as shown in Fig. 1b).

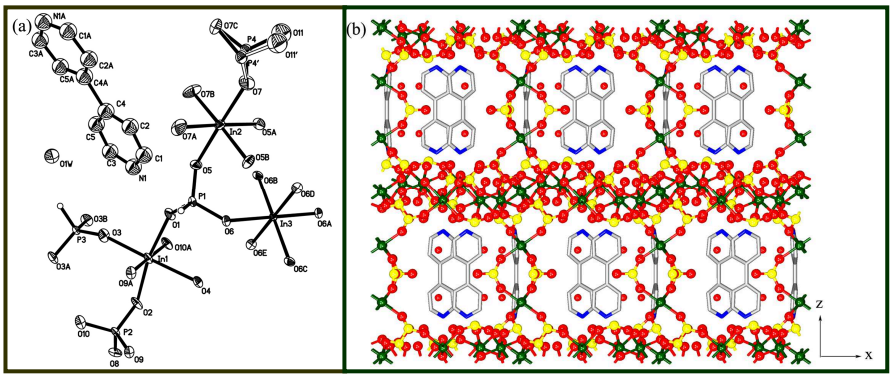

Fig. 1 (a) ORTEP view of the asymmetric unit of compound 1; (b) Ball and stick view of the structure of compound 1 with 4, 4′-bipy deposited in the 16-rings channels.

Characterization for compound 1. The purity of 1 was confirmed by comparison of the experimental PXRD pattern to the calculated ones based on single-crystal structure (as shown in Fig. 2a). The result of elemental analysis for 1 was consistent well with the theoretical values. Analysis found (%): In, 37.56; P, 19.20; C, 3.24; H, 1.50; N 0.66. Calcd. (%): In, 37.61; P, 19.17; C, 3.28; H, 1.61; N 0.76.

IR spectrum for 1 was shown in Fig. 2b, The bands in the range of 3500–3000 cm^{-1} are associated with stretching vibrations of N-H, O-H and C-H groups. The band at 2410 cm^{-1} was ascribed to vibrations of the P-H. The multi-fold bands in the region of 1600-1400cm^{-1} should be attributed to pyridyl rings. The stretching and bending vibration absorption peaks for In-O, P-O and In–O–P were featured in the region of 1200-900cm^{-1} and 600–400 cm^{-1}, respectively.

TG analysis curve for 1 showed two steps of weight loss from 40 to 1000 °C (Fig. 2c). The first step weight loss of 7.87 wt% before 400 °C was attributed to the removal of water molecular and the release of partial 4, 4′-bipy molecules. On further heating, the second step weight loss of 12.50 wt%, which is attributed to the release of residual organic amine. The total observed weight loss 20.37 wt% for the above two steps matches well with the calculated value based on the structure. PXRD studies indicated that the post-residue is a mixture of $InPO_4$ (JCPDS:08-0052) and $In_4(P_2O_7)_3$(JCPDS: 53-1018).

Fluorescence property for compound 1. The guests 4, 4′-bipy molecular acted as SADs to form the large pore structure of 1, which were deposited in the 16-rings channels with the two pyridyl rings twisted at an angle of 59.19°. Compound 1 presented the same solid fluorescence property as the 4, 4′-bipy, attributing to the intraligand π-π* transition in the structure (Fig. 2d).

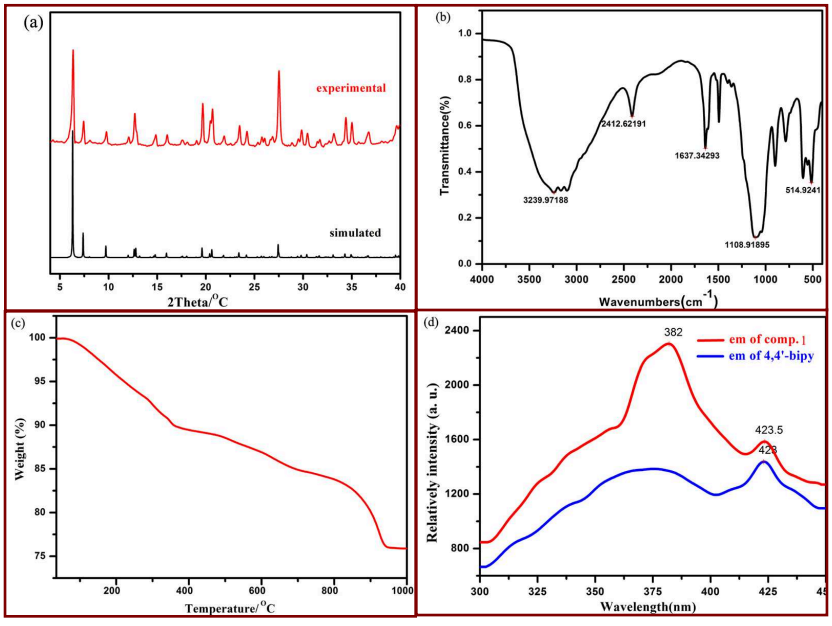

Fig. 2 Structure characterizations for compound 1

Conclusion

In conclusion, a novel indium phosphate–phosphite was synthesized under hydrothermal conditions by using 4, 4′-bipy as a SDA. The construction of InO_6 octahedra, HPO_3 pseudo-tetrahedra and HPO_4 tetrahedra leads to the assembly of 3D open-framework with intersecting extra-large 16-rings channels. The guests 4, 4'-bipy molecular were deposited in the channels. Solid fluorescence property for compound **1** was also studied in this paper. Further investigations on assembly novel indium phosphites and potential applications for these materials are underway.

Keywords: polyvinyl pyrrolidone; polyacrylonitrile; fiber precursor; nickel acetylacetonate

Abstract. The effect of polyvinyl pyrrolidone (K30) and nickel acetylacetonate ($Ni(acac)_2$) on the fabrication of polyacrylonitrile(PAN) fiber was investigated. K30 and $Ni(acac)_2$ were chosen as pore-forming agents to prepare mesoporous carbon fibers.Meanwhile, the concentration of K30 and $Ni(acac)_2$, the mass ratio of pore-forming agent to PAN, the rheological properties of spinning dope, the mechanical properties, thermal performance of fiber precursor were also characterized. Furthermore, the precursor fibers and the carbon fibers were researched by FTIR analysis, TG analysis and static benzene adsorption. Based on the research, when the concentration of K30 and $Ni(acac)_2$ was 5%, the mass ratio of K30/$Ni(acac)_2$ to PAN was 7:3, the fiber precursors had excellent properties. Adding poreforming agent, the pore distribution was controlled.

Introduction

As a type of effective carbonaceous adsorbent, activated carbon fibers (ACF) have attracted considerable interest because of their numerous special features compared to conventional activated carbon[1]. ACF have uniform pore distribution, large specific surface area and performance of heat-resisting, acid-resisting, alkali-resisting, the high electric and thermal conductivity. They generally have narrower pore size distribution and allow greater accessibility of adsorbates to their micropores. These properties have endowed ACF with high adsorption capacity for small-molecular-size pollutants. However, these features might not always be advantageous, especially when ACF are being used as electrodes/capacitor materials or adsorbents for larger-molecular-size pollutants[2]. In microporous carbon materials, adsorption occurs in pores with sizes about 1.7 times larger than the second widest dimension of the adsorbate molecules[3]. As reported previously, the fabrication of mesoporous carbon fibers become a hot research field [4].

At present, the mesoporous ACF was mainly prepared by changing activation process and using additives. Gan Yongjin [5] from Jilin University has researched mesoporous ACF. But he made it mainly from changing activation process to improve the volume of mesopore. Adding additives especially K30 and Ni(acac)2 to prepare mesoporous ACF has not been reported at home and abroad. In this work, the main aim was to select K30 and Ni(acac)2 as pore-forming material. Ni(acac)2 is not only as pore-forming agent, but also it acts as catalyst in activation process. By adding Ni(acac)2, aperture distribution can be controlled [6,7].

To prepare original fiber, dissolve the pore-forming material in the solvent and then mix with PAN slurry to form homogeneous system, finally fulfill the deaeration and wet spinning process. In the whole process, the content of pore-forming material, the ratio of K30 and Ni(acac)2 to PAN and spinning conditions had important influence on the rheological behavior of slurry, the thermodynamics properties and mechanical properties. Furthermore, they would affect the temperature of carbonization and activation.

Experimental

Materials and Agents

PAN copolymers slurry (acrylonitrile: methylacrylate: itaconic acid = 96:3:1), with a viscosity-average molecular weight $M\eta=1.25\times105$g.mol-1 were prepared by our laboratory. DMSO (AR) was purchased from Shanghai Boer Chemical Reagent. K30 and Ni(acac)2 was purchased from Aladdin Chemistry Co., Ltd.

Fabrication Methods

The Fabrication of Spinning Solution

The dried PAN copolymers, K30 and Ni(acac)2 which the mass concentration were 18 wt% and 5 wt% respectively were dissolved in DMSO, then mixed by mechanically stirring to produce a homogeneous viscous solution. Four spinning solution were prepared with different mass ratio of PAN slurry to pore-forming solution of 10:0,9:1,8:2,7:3.The resulting slurry was swollen at 60℃for 24h to make sure that there were no bubbles in the spinning solution.

The Fabrication of PAN Precursor by Wet Spinning

The spinneret was used in this experiment with 6 holes of 0.25mm, which was heated in the oven at 70℃for 24h, then poured into the spinning solution in the charging barrel under 60℃. 40% DMSO at 5℃was used as the coagulation bath. Then heat them up to 100℃.

The wet spinning process in this experiment was depicted as follows:

Preparation before spinning →spinning→coagulation→stretching→boil water stretching

Applying oil →densification →winder

Pre-oxidation, Carbonization and Activation of Fiber Precursor

Put the dried fiber precursor in the furnace and rise temperature to 800 ℃, then keep at this temperature for 2 hours, take out the carbon fibers after pre-oxidation, carbonization and activation.

Characterization

Fourier transformed infrared spectroscopy (FTIR) was recorded between 4,000cm-1 and 400cm-1 on USA Nicolet FTIR 670 NEXUS spectrophotometer at room temperature. The thermal gravimetric analyses (TGA, TG209 T1) were used to characterize the thermal performance of original fiber at a heating rate of 10℃/min under flowing nitrogen, and the temperature rose from room temperature to 900℃. The rheological measurements were carried out on a rotational rheometer (ARES-RFS, TA company), the concentric parallel plate geometry (diameter: 25mm) was utilized, the chosen gap was 1mm for all measurement. Steady shear profiles were examined at constant temperature of 60 ± 0.01℃ covering a shear-rate range from 0.1-100Hz.The mechanical properties were tested by single fiber strength instrument(LLY-06,China).The microstructure was examined using a scanning electron microscope (SEM, TM-1000, Japan).

Results and Discussion

The Effect of Concentration of Pore-forming Solution on Spinning Performance

In this experiment, K30 and Ni(acac)2 as pore-forming agent had important influence on the spinning performance. The slurry was prone to crust in the air and water which would lead to spinneret block and affecting spinning. The dosage of K30 and Ni(acac)2 were determined through testing the thickness of slurry block.

Prepare different mass concentration of the solution of K30/ Ni(acac)2/DMSO by 18%, 9%, 5%, 1% respectively. Pour the solution on the glass plate and observe the crust phenomenon. The result was shown in table 1.

TABLE 1 THE CRUST EXPERIMENT ON DIFFERENT CONCENTRATIONS OF K30/ NI(ACAC)$_2$/ DMSO SYSTEM

Solution	Concentration[%]	The thickness of crust
K30 /Ni(acac)2/DMSO	18	thicker
	9	thick
	5	thin
	1	less

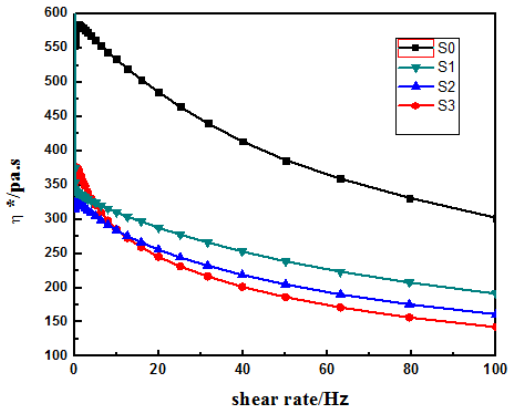
Table 1 showed that the crust phenomenon were more serious in the dense solution, but the voids content of mesoporous activated carbon fibers would be affect if the concentration was too small. Above all, the concentration of 5% was the optimum condition of spinning. The concentration of K30 /Ni(acac)2/DMSO was 5% in the following experiment.

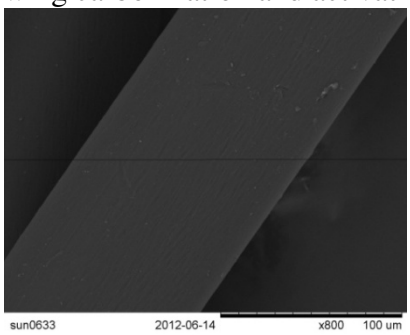
The Rheology of Spinning Solution

Rheology was a significant property of slurry. Through testing the rheology of different ratios of PAN to K30 /Ni(acac)2, the optimum condition of spinning can be achieved. Prepare different ratios of PAN to K30 /Ni(acac)2 with 10:0(S0), 9:1(S1), 8:2(S2), 7:3(S3) [8-9]respectively.

Fig.2 showed the effect of different ratios on the complex viscosity of slurry. From the curves, the complex viscosity (η*) heavily decreased with the increase of shear rate and gradually went back to a point. This might be the reason for the orientation of polymer, polymer molecular chain tended to be orientation under shearing force, so the movement of molecular chain enhanced which led to the decrease of complex viscosity.

Fig.1 shown that the complex viscosity (η*) decreased with the dosage of K30 /Ni(acac)2 increasing. The reason was that when mixed K30/ Ni(acac)2 with PAN, some PAN chains broke up which leaded to moving easily. The more the dosage of K30/ Ni(acac)2 was, the more easily the chains moved[10-13]. According to experiment data, when the mass of PAN to K30 /Ni(acac)2 was 7:3, the complex viscosity was so little that it was the optimum condition of spinning.





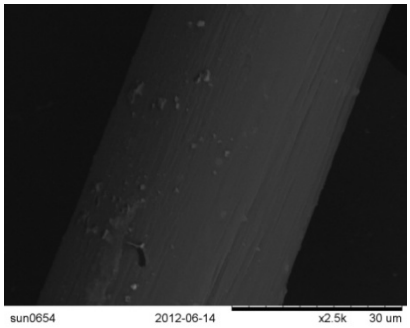


Fig.1 The Influence of Different Ratios on the Complex Viscosity

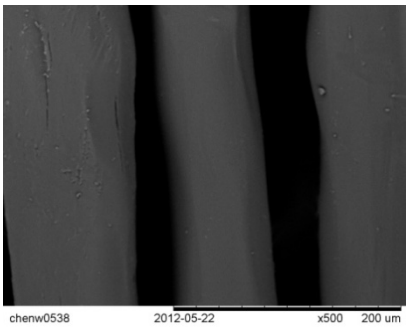
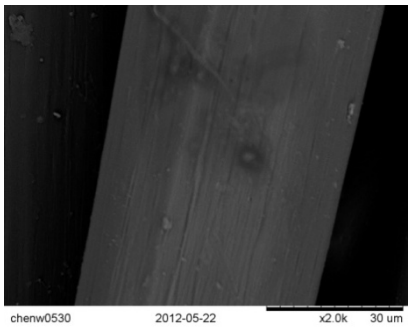
Morphology of PAN/K30 /Ni(acac)$_2$ fiber



The fiber uniformity could improve strength, from SEM the microstructure can be clearly seen. SEM images of PAN/ K30 /Ni(acac)2 fiber were shown in Fig.2, It should be noted that fiber were mostly smooth and round and texture was clear along the axial direction which would be helpful for the following carbonization and activation.



(a) PAN Fiber Precursor

(b) m(PAN):m(K30/Ni(acac)2)=7:3

(c) m(PAN):m(K30/Ni(acac)2)=8:2 (d) m(PAN) : m(K30/Ni(acac)2)=9:1

Fig.2 The SEM Images of PAN/ K30 /Ni(acac)2 Fibers

Mechanical Properties of Single Fiber

The strength of fiber usually refers to the relative strength, which was also the fracture point of unite load. The strength of fiber was mostly caused by the flaws, namely the starting point of fracture. The data of the testing was shown in table 2. It was clearly observed that the presence of K30 /Ni(acac)2 led to deterioration of tensile properties. Moreover, the strength of fiber decreased heavily with the increase of K30 /Ni(acac)2 which were closely related to the morphology in previous section. Enhance the strength of the fiber by improving the draw ratio.

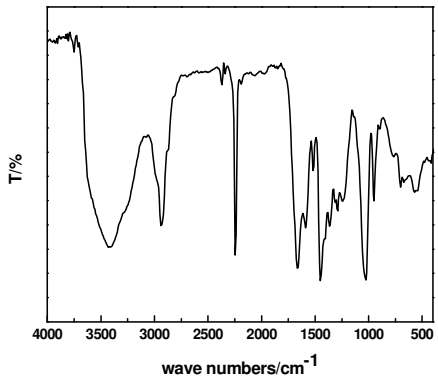


TABLE 2 THE STRENGTH TEST OF SINGLE FIBER

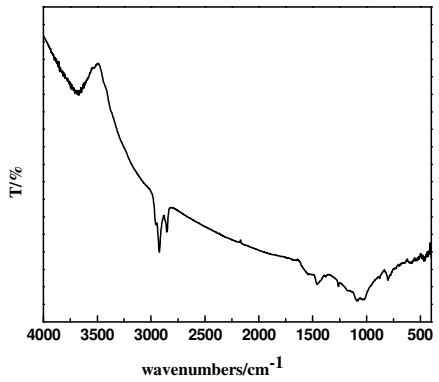

NO.	Strength[CN]	Breaking elongation[%]	Line density [dtex]	Modulus [CN/dtex]
S0(1)	142.64	27.3	40.5	3.52
S0(2)	106.00	44.27	29.70	4.80
S1(1)	54.62	18.65	46.28	1.18
S1(2)	58.61	17.68	32.92	1.78
S2(1)	37.67	15.41	26.89	1.40
S2(2)	33.29	13.29	23.69	1.41
S3(1)	38.64	13.69	37.05	1.04
S3(2)	34.29	13.69	31.75	1.08

Note:(1) stands for that draw ratio is one, (2) stands for that draw ratio is two.

FTIR Analysis[5-7]

Fig.3 shows FTIR spectra of fiber precursor and carbon fibers.

(a) Fiber precursor (b) Carbon fibers

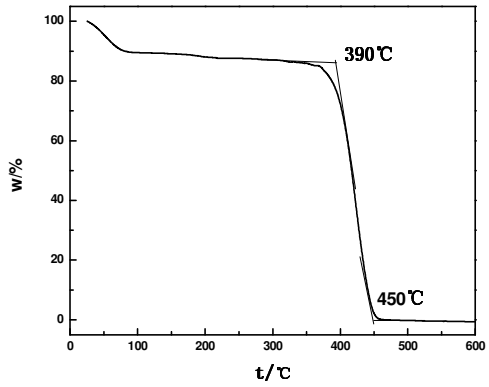

Fig.3 FTIR spectra of fiber precursor(a) and carbon fibers(b)

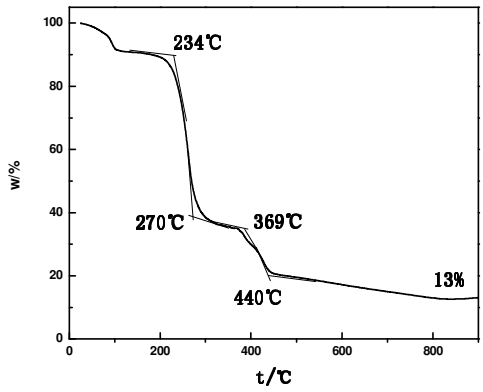
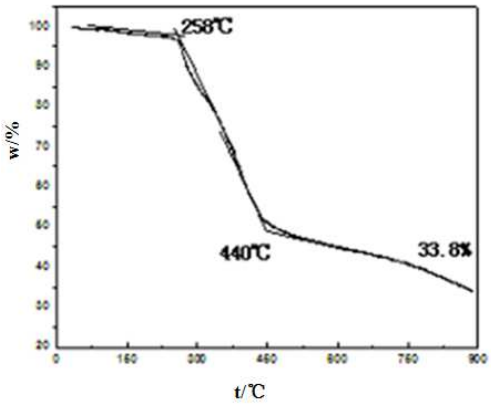
Fig.3 shows that most of the functional groups disappeared after pre-oxidation, carbonization and activation, the residual functional groups were the basic carbon skeleton. It indicated that the pore-forming agents were decomposed in the process of carbonization and activation.

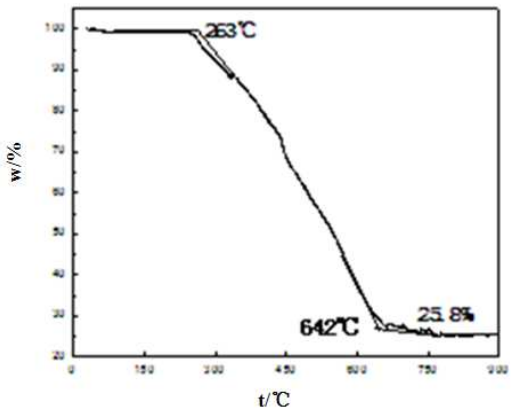


TG-DT Analysis

The TG analysis on the material had an important effect on carbonization and activation. Fig.4 showed TG-DT analysis of K30, Ni(acac)2 and carbon fibers. It can be seen from the curve that the onset decomposition temperature of K30 was 390℃, when the temperature rised to 450℃, the decomposition rate of K30 reached the maximal nearly 100%, the decomposition rate of Ni(acac)2 reached about 87% at 600℃, so K30 and Ni(acac)2 as pore-forming agent were suitable for mesporous activated carbon fibers.



It can be seen from Fig.5(d), the decomposition rate of precursor fiber reached about 74.2% after 900℃, which was much high compared with the decomposition rate of fiber(c).



(a) TG Analysis of Raw Material K30

（b） TG Analysis of Raw Material Ni(acac)2

（c） Precursor Fiber without Pore-forming agent

（d） TG Analysis of Precursor Fiber with K30/Ni(acac)2

Fig.4 The TG test of Raw Material and PAN Precursor Fiber

Static Benzene Adsorption of Carbon Fibers

TABLE 3 THE VALUES OF STATIC BENZENE ADSORPTION

NO.	S0	S1	S2	S3
Value of static benzene adsorption [%]	0.15	8.5	13.6	29.8

Table 3 showed the values of static benzene adsorption increased by adding K30/ Ni(acac)2. It indicated that K30/Ni(acac)2 played the role of pore-forming agent which influenced the pore size distribution.

Conclusions

(1) The best condition of spinning was achieved with the concentration of K30 and Ni(acac)2 of 5% and the mass ratio of K30/Ni(acac)2 to PAN of 7:3.

(2) The spinning solutions exhibited appreciable shear thinning behaviors in a high rate range with the dosage of PAN increased.

(3) The morphology of K30/ Ni(acac)2 /fiber was smooth and round ,which would be appropriate for following carbonization and activation and the fiber precursor had excellent properties.

(4) The value of static benzene adsorption greatly increased by adding pore-forming agent.

Morphology and Conductivity of Self-Assembled Pyrene-Perylenetetracarboxylic diimide Dyad

Yan Shi , Xiyou Li[a]

Key Laboratory of Colloid and Interface Chemistry, Ministry of Education, Department of Chemistry, Shandong University, Jinan, 250100, China

[a]xiyouli@sdu.edu.cn

Keywords: Perylenetetracarboxy diimides, Self-assembly, Morphology, Conductivity

Abstract. One perylenetetracarboxylic diimide (PDI) derivatives (**PDI 1**) linked with pyrene by flexible chain at the bay positions was synthesized and the molecular structure was characterized by ^{1}H NMR, MALDI-TOF mass spectra as well as elemental analysis. The molecular self-assembly were prepared from solution via a slow evaporation of solvent. The properties of these molecular aggregates were studied by electronic absorption and fluorescence spectra. The morphologies and structures were examined by scanning electronic microscopy (SEM) and X-ray diffraction (XRD) techniques. The conducting properties were evaluated by current–voltage (I–V) measurements. The results revealed highly ordered structure for these molecular self-assembly. The thin solid film fabricated from these molecular self-assembly show an electric conductivity as high as 4.85×10^{-4} S cm^{-1} under the ambient light, which means this compound might be used as a semiconductor in nano-electronics.

Introduction

Perylenetetracarboxylic diimide derivatives (PDIs), as an important functional dye with outstanding photo and chemical stability as well as interesting photophysical and photochemical properties, have been intensively studied for several decades [1]. Because of their great potential application as organic semiconductors in different molecular electronic devices, the fabrication of ordered nanostructures of this functional molecular material has become an attracting research area recently [2]. Studies have revealed that the self-assemble process of PDI molecules is dominated by π–π interactions between the conjugated perylene rings [3]. Increase the molecular interaction by introducing different side groups is proved to be an efficient way to achieve an ordered structure with novel electronic or photophysical properties [4].

Pyrene is a well known fluorescent molecule, which has been widely used as fluorescent sensors or as organic semiconductors in solar cell. A recent review has described the recent progress of the pyrene based organic electronic materials [5]. Pyrene is proved to be an electron or energy donor when it is connected with PDI [6]. More importantly, pyrene has very strong π-π interactions and form self-assembly easily in solution. Therefore, it is expected that connection of pyrene with PDI might lead to a new molecule with novel self-assemble and physical properties.

In this letter, we report a new PDI molecule, which linked with a pyrene group by a flexible linkage at the bay position, **PDI 1** (Fig. 1). Introduction of pyrene, which can be an electron or energy donor, can bring some new photophysical process for this molecule. More importantly, the strong π-π interactions between the pyrene units can tune the self-assemble process of PDI, which may lead to a new nanostructure for the self-assembly of this compound.

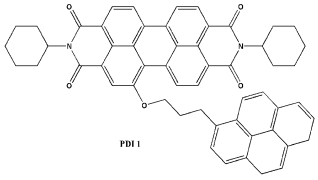

Fig. 1 The molecular structure of **PDI 1**

Results and Discussion

Electronic Absorption and Fluorescence Spectra. The absorption spectra of **PDI 1** in $CHCl_3$ solution and the aggregates on the SiO_2 surface by using solution-based quasi-Langmuir-Shäfer (QLS) [7] are shown in Fig. 2A. In chloroform, the absorption at about 553 and 519 nm can be attributed to the 0-0 and 0-1 vibronic band of the $S_0 - S_1$ transition, respectively, while the observed absorption band around 407 nm is attributed to the electronic S_0-S_2 transition [8]. The absorptions peaks at 345 and 328 can be attributed to the absorption of pyrene. In the QLS aggregates, an enhanced 0-1 vibronic band at 524 nm is observed. Such a spectral change implies strong molecular stacking between the PDI skeletons and the formation of face-to-face stacked structure (H-aggregate) [9]. Beside the changes on the absorption spectrum of PDI part, the absorption of pyrene part at about 350 nm red-shifted for about 6 nm in the solid film compared with that in solution, which means that the pyrenes are also interacted with each other in the solid films. Consistent with the absorption measurement, the emission spectrum of the aggregates of **PDI 1**, as shown in Fig. 2B, shows one new emission band at approximately 707 nm, which should be attributed to emission from the excimer-like states of the molecular aggregates formed by the co-facial arranged adjacent **PDI 1** molecules [10].

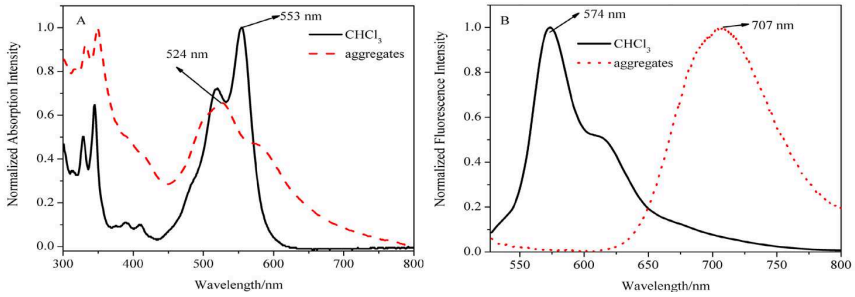

Fig. 2 Normalized electronic absorption (A) and fluorescence emission (B) spectra of **PDI 1**. The excited wavelength was 500 nm.

X-ray diffraction patterns of the aggregates. The internal structure of self-assembled nanostructures of this compound was investigated by XRD analysis. As shown in Fig. 3, in the low angle range, the XRD diagram shows one clear diffraction peak at $2\theta = 4.54°$(1.95 nm), which is close to the length of molecule (2.0 nm) read from the minimized molecular structure. This results suggest that the molecules in the aggregates take an edge-on configuration with the long axis of the molecule perpendicular to the surface of the substrate. Due to the direction of the face-to-face stacking parallel to the surface of the substrate, the in plane charge moving in this solid film should be favorable [11]. In the wide angle region, the XRD pattern presents additional diffraction at 0.31 nm, which can be attributed to the π–π stacking distance of PDI rings between the adjacent molecules [12]. This is in line with the conclusion resulted from the electronic absorption spectroscopic properties as detailed above.

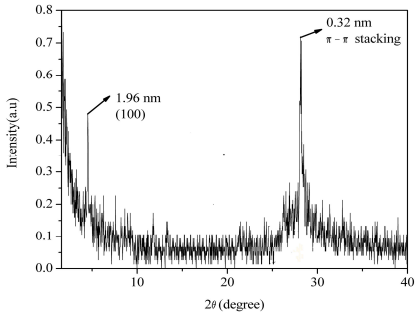

Fig. 3 X-ray diffraction patterns of the nanostructures of **PDI 1** by QLS method.

Morphology of the Aggregates. The morphology of the aggregates formed was examined by scanning electron microscopy (SEM). Fig. 4 displays SEM images of the molecular aggregates. **PDI 1** assembled into nanostructures with belt-like morphology with uniform size. The nanobelts were

over 50 μm in length with average width of ca. 230 nm, leading to an aspect ratio (length over thickness) of 200. This one dimensional structure is favorable for the device application in photovoltaics and field effect transistors [13]. It is worth noting that the size- as well as morphology-adjustable nanomaterials are highly desired for fabricating nanoscale molecular (opto) electronic devices which often require a wide variety of channel dimensions to achieve the optimum gate or optical modulation.

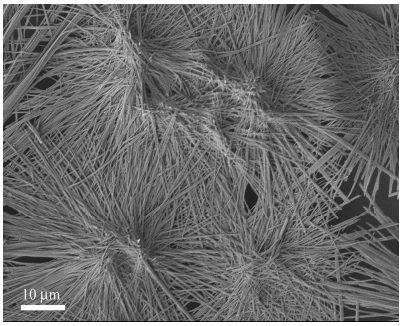

Fig. 4 SEM images of the nanobelts of **PDI 1** fabricated by QLS method.

I–V properties. The uniform aggregates of **PDI 1** with well-defined nanostructures would be promising candidates for applications in electronic devices. To demonstrate the potentials of these nanostructures, the molecular aggregates of **PDI 1** prepared by QLS method was suspended into methanol and carefully dropped onto glass substrates with ITO IDEs. After complete evaporation of the solvents, densely packed nanostructural films remained and adhere to ITO IDEs/glass substrate tightly. The electron conductivity measurement was then performed for this film. Fig. 5 shows the current-voltage (I-V) characteristics of nanobelts of **PDI 1**. According to the equation reported in the literatures [7], the electronic conductivity is calculated to be around 4.85 × 10^{-4} S cm^{-1} for the nanobelts of **PDI 1** under the ambient light, whereas the same device in dark shows an electronic conductivity of 1.31× 10^{-6} S cm^{-1}. The electronic conductivity on/off ratio is ca. 3×10^{2}, which is expected to be much larger if higher power irradiation and/or longer electrode pairs were employed for the photocurrent measurement [14]. This unexpected good conductivity of the nanobelts of **PDI 1** might be attributed to both readily π-stacks with adjacent planar molecules and higher-ordered crystalline molecular arrangement [15]. When the perylene cores of **PDI 1** are organized in one-dimensional and stack into nanobelts, they may show favorable charge transport. The interactions between the π systems of pyrene as revealed by the absorption spectra might also benefit the charge transport. These aggregates with highly current modulation could be useful for a wide range of electronic and sensor devices. The efforts to explore such opportunities are underway.

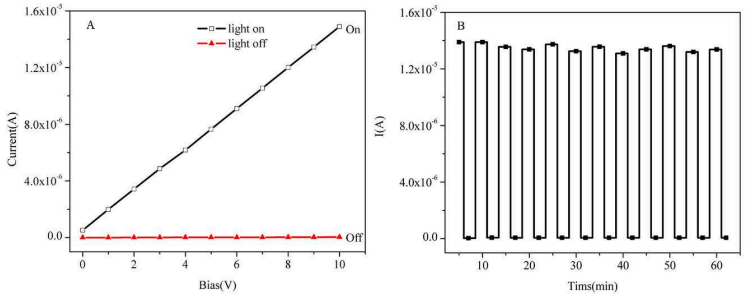

Fig. 5 (A) I-V curves measured on nanobelts from **PDI 1** under ambient light(□) and in the dark(▲). (B) photocurrent (at 10 V) in response to turning on and off the irradiation (white light).

Summary

Aggregates of **PDI 1**with ordered nanobelt structure was controllably prepared by QLS method. The I-V experimental results revealed good semiconductivity for this material and suggest that this PDI molecules might serve as a functional material for nano-electronics. It will be valuable for the design and preparation of PDI-based nano-electronic and nano-optoelectronic devices.

Keywords: [piperazine-1,4-diyldi(methylene)]bis(phosphonic acid); zinc organophosphonate; Solvothermal synthesis.

Abstract. A novel zinc organophosphonate was synthesized under solvothermal conditions by using [piperazine-1,4-diyldi(methylene)]bis(phosphonic acid) as a organic ligand. Single-crystal X-ray diffraction analysis reveals that compound 1 crystallized in the triclinic space group P-1 (No. 2). Compound 1 formulated as $Zn(O_3PCH_2NHC_4H_8NHCH_2PO_3)\cdot H_2O$. Compound 1 featured a 3D open-framework. Notably, the structure of compound 1 featured one-dimensional channel in the [001] direction. Water molecules were located in these channels. Further characterizations of compound 1 have been performed, including X-ray powder diffraction, IR, ICP and CHN analyses.

Introduction

In the past two decades, hybrid organic - inorganic porous materials exhibiting open architectures have been widely investigated for their potential applications in gas adsorption, asymmetric catalysis, ion exchange and proton conduction [1-5]. Organic phosphonic acid have been extensively studied as primary building blocks to synthesize hybrid metal phosphonate for their strongly coordinated ability , diverse coordination modes and high thermal stability [6-10] . [piperazine-1,4-diyldi(methylene)]bis(phosphonic acid), formulated as $H_2O_3PCH_2NC_4H_8NCH_2PO_3H_2$, was explored to construct novel metal phosphonate complexes in the literature[11-18]. Here, A novel zinc organophosphonate, $Zn(O_3PCH_2NHC_4H_8NHCH_2PO_3)\cdot H_2O$ (**1**), was synthesized under solvothermal conditions by using [piperazine-1,4-diyldi(methylene)]bis(phosphonic acid) as a organic ligand. Synthesis, structure and characterization of **1** were reported in this paper.

Experiment

Synthesis

Compound **1** was synthesized under solvothermal conditions: 30 mg $ZnNO_3\cdot 6H_2O$, and 54 mg $H_2O_3PCH_2NC_4H_8NCH_2PO_3H_2$ were dispersed into a mixture of 5 mL H_2O and 5 mL DMFwith stirring. Then, 10 mg of 2, 2′-bipy was added. After stirring for 30 min, the mixture was transferred into a sealed Teflon-lined steel autoclave and heated at 180^{o}C for 5 days. Colorless block-like crystals of **1** were collected and air-dried at room temperature (67% yield based on zinc).

Determination of Crystal Structure

Suitable single crystal of **1** (0.23 × 0.19 × 0.16 mm^3) was selected for single-crystal X-ray diffraction analyses. The data was collected on a Rigaku RAXIS-RAPID IP diffractometer (λ(Mo-Kα) = 0.71073Å). A total of 5872 reflections with 2680 unique reflections (R_{int} = 0.0461) were collected. Data processing was accomplished with the Process-auto processing program. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXTL-97 software package. First, the Zn and P atoms were located, followed by location of O, N and C atoms. The hydrogen atoms from guest molecules and organic phosphonic acid were placed geometrically. All the non-hydrogen atoms were refined anisotropically for the final refinement. Detailed crystallographic data for **1** was presented in Table 1.

Results and Discussion

Description of Crystal Structure for 1

Single-crystal X-ray diffraction analyses reveals that **1** crystallizes in the triclinic space group *P*-1 (No. 2), formulated as $Zn(O_3PCH_2NHC_4H_8NHCH_2PO_3)\cdot H_2O$. As shown in figure 1a, each asymmetric unit contains one crystallographically independent Zn atoms, one crystallographically independent organic phosphonic acid and one guest water molecule. Zn (1) atom was tetrahedrally coordinated, which was coordinated with four different organic ligands through O(1), O(3), O(4) and O(6) atoms. The average bond lengths of Zn (1)-O were in the range of 1.920(3)–1.956(3) Å. All bond lengths and angles in the crystal structure of **1** were similar to those reported in the literature[11-18].

In the structure of **1**, the organic phosphonic acid adopted two similar coordinated environments. one chelated with two Zn (1) atoms through O(1) and O(3), resulting a 8-rings described as P(1) – O(1) – Zn (1) – O(3) – P(1) – O(1) – Zn (1) – O(3); another one chelated with two Zn (1) atoms through O(2) and O(4), resulting a 8-rings described as P(2) – O(4) – Zn (1) – O(6) – P(2) – O(4) – Zn (1) – O(6). The 8-rings interconnect each other base on vertex-sharing resulting in 1D chain (figure 1b). These 1D chains were further constructed into the open architectures of **1** by piperazine from the organic ligand. Guest water molecules were deposited in the 1D channels in the [001] direction (figure 1c).

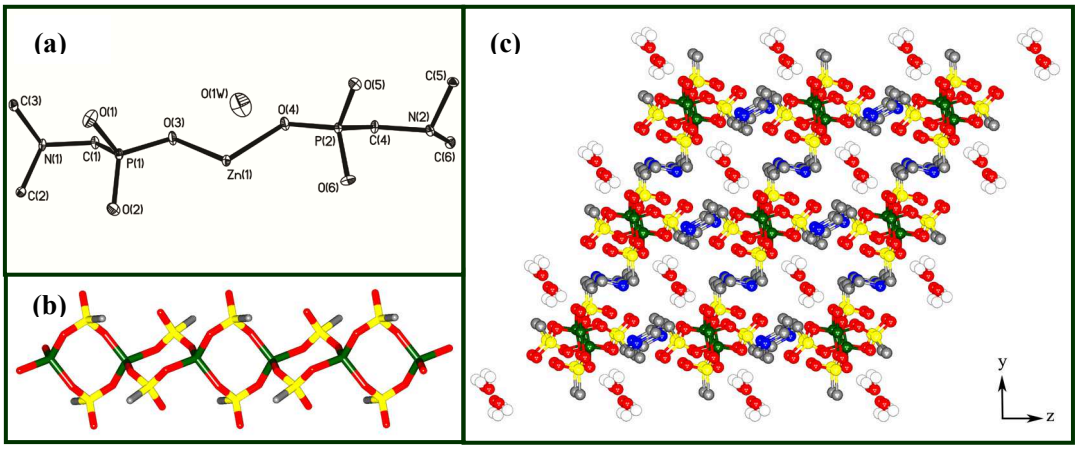

Figure 1 (a) ORTEP view of the asymmetric unit of 1; (b) 1D chain in the structure 1; (c) open architectures of 1 with water molecules deposited in the channels.

Characterization for Compound 1

The purity of **1** was confirmed by comparison of the experimental PXRD pattern to the calculated ones based on single-crystal structure (as shown in figure 2). The result of elemental analysis for **1** was consistent well with the theoretical values. Analysis found (%): Zn, 40.12; P, 17.64; C, 20.24; H, 4.20; N 7.62. Calcd. (%): Zn, 40.40; P, 17.42; C, 20.27; H, 4.54; N 7.88.

IR spectrum for **1** was shown in figure 2, The bands of 3026, 3025 and 2895 cm^{-1} were associated with stretching vibrations of O-H, N-H and C-H groups. The multi-fold bands in the region of 1600-1300cm^{-1} were ascribed to bending vibrations of O-H, N-H and C-H groups. The stretching and bending vibration absorption peaks for CPO_3, N–C and C–C were featured in the region of 1200-900 cm^{-1} and 600–400 cm^{-1}, respectively.

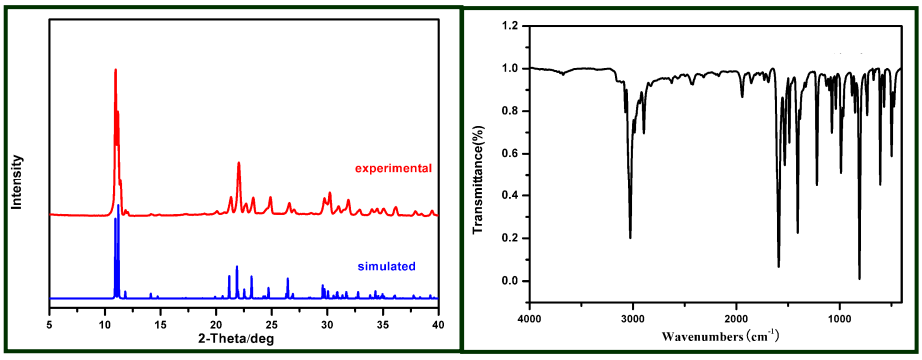

Figure 2 Simulated and experimental PXRD patterns for 1(left) ; IR spectrum for 1(right)

Conclusion

In conclusion, a novel zinc organophosphonate exibiting open architectures was synthesized under solvothermal conditions by using [piperazine-1,4-diyldi(methylene)]bis(phosphonic acid) as a organic ligand. The coordination of organic phosphonic acid with zinc resulted the assembly of 3D structure for **1**. The guests water molecules were deposited in these 1D channels. Further investigations on assembly novel metal organophosphonate and potential applications for these materials are underway.

Keywords: hydrothermal modification; flame retardant magnesium hydroxide; ammonia gas; high slurry concentration

Abstract: Regular hexagonal plates of magnesium hydroxide with high slurry concentration were prepared by hydrothermal reaction without any organic additive or catalyst using bischofite and ammonia as raw materials. The effects of hydrothermal temperature, stirring speed, hydrothermal duration, and dilution multiple on the preparation of $Mg(OH)_2$ flame retardant were investigated. Scanning electron microscopy, X-ray diffraction, and laser particle analysis were performed to characterize the product morphologies, structures, and size distributions. Results indicated that the growth direction of $Mg(OH)_2$ crystal changed, and the regular hexagonal plates of $Mg(OH)_2$ with uniform particle size and high dispersion characteristic formed after hydrothermal modification treatment. A mass fraction of 15.50% $Mg(OH)_2$ of magnesium hydroxide slurry was obtained by high-concentration (4.30mol/L) magnesium chloride and ammonia as the raw materials.

Introduction

Magnesium hydroxide (MH) is an important multifunctional material that has elicited scientific interest[1–3] and is widely used in flame retardants[4,5], wastewater treatment[6], flue gas desulfurization[7,8], medicines[9], etc. MH produces an environment-friendly flame retardant that simultaneously acts as a smoke suppressant, with no evolution of hazardous by-products[10,11]. Caustic soda method[12–14], lime cream method[15], and ammonia method[16,17] are the three important methods for preparation of MH. Among these three methods, the ammonia method for MH synthesis is used predominantly in industrial production. However, $Mg(OH)_2$ particles synthesized at room temperature are usually ready to aggregate with each other because of poor crystal formation and small particle size, which cause a lack of compatibility and reduce the mechanical properties of the corresponding composite. One of the effective approaches to improve the dispersion of $Mg(OH)_2$ is to recrystallize the particles at hydrothermal[18] conditions. The hydrothermal technique facilitates the processing of monodispersed and highly homogeneous particles and is defined as any heterogeneous reaction in the presence of aqueous solvents or mineralizers under high pressure and temperature conditions that dissolve and recrystallize materials that are relatively insoluble under ordinary conditions.

Jin et al.[19] obtained an $Mg(OH)_2$ product that exhibits a uniform lamella-like hexagonal structure with approximately 40 nm thickness after hydrothermal modification at 150 °C for 24 h. Henrist et al. [10] obtained larger, well-defined $Mg(OH)_2$ particles after hydrothermal treatment at 170 °C for 7 d. An overall enhancement of the crystallinity is clearly visible because the intensity of the diffraction peaks is remarkably increased in the curve from X-ray diffraction (XRD) patterns of the sample. Wu et al. [20] obtained dispersive $Mg(OH)_2$ particles with an average particle size of

approximately 0.3 μm-0.7 μm, an average agglomerate size of 1.2 μm, and Brunauer-Emmett-Teller surface area of 10.5 m^2/g after hydrothermal treatment in 1.0 g/L $CaCl_2$ aqueous solution at 200 °C for 4.0 h. Ji et al.[21] prepared a spherical crystalline MH that has a symmetrical and regular crystal morphology when the reaction temperature is 180 °C and the reaction time ranges from 4 h to 8 h, the MH and organic modifier solution concentrations were 5% and 4 mol/L, respectively. Yan et al.[22] obtained $Mg(OH)_2$ with mean size of 400 nm and a thickness of 60 nm after hydrothermal treatment at 150 °C for 6 h at pH 11 with Mg^{2+}/CTAB molar ratio of 80. Chen et al.[23] obtained 90 nm-130 nm thickness of the $Mg(OH)_2$ plates after hydrothermal modification at 200 °C for 6 h in solutions containing 4 mol/L KOH.

However, the MH slurry concentration synthesized is too low when aqueous ammonia, NaOH aqueous solution, and lime milk were used for precipitation. High MH slurry concentration can be prepared if NH_3 is chosen as precipitant because no water was channeled when the precipitant NH_3 was introduced into the reaction system. The optimum processing conditions through the direct precipitation method without any additives were obtained in the Pre-Work. In the present study, we performed hydrothermal modification and characterization of the synthesized MH slurry in the optimum processing conditions. The effects of hydrothermal temperature, stirring speed, hydrothermal duration, and dilution multiple were investigated for preparation of $Mg(OH)_2$ flame retardant.

Experimental

Materials

Bischofite ($MgCl_2$•$6H_2O$ 95.62%) was obtained from Qinghai Kunlun magnesium Co., LTD. Ammonia (NH_3 99.15%) was obtained from Qinghai LaoQian gas Co., LTD. All the chemical reagents used in this experiment were analytical grade.

Experimental Procedures

Ammonia was used as precipitating agent for MH preparation and bischofite, which is abundant in salt lakes, was used in the experiments as raw material. The detailed synthesis procedures will be described in the following section.

A solution with 4.30 mol/L concentration of bischofite was prepared and insoluble impurities were removed through filtration. Ammonia was then added to the prepared solution via a gas flowmeter working at a discharge rate of 320 ml/min whereas the suspension was maintained at 60 °C with constant stirring at 350 r/min. After the addition of the ammonia gas, the slurry was aged for 90 min at 60 °C and 350 r/min. The MH slurry was transferred into a teflon-lined high pressure reaction kettle. The high-pressure reaction kettle was then maintained at 100 °C-180 °C with stirring at 0 r/min-700 r/min for 0.5 h-4 h. After passively cooling down to 60 °C, the white powders were collected, filtered, and washed with deionized water. Finally, the samples were air-dried at 110 °C for 10 h.

Analysis And Characterization

The morphology of the particles was analyzed using a scanning electron microscope (JSM-5610LY, Japan). The crystalline form of the sample was characterized by XRD (X'PRO Pert, USA) using Cu Kα radiation (λ=0.154 nm) with an X-ray tube at 40 kV and 30 mA. XRD data were collected at room temperature over the 2θ range from 5° to 80° at a step size of 0.0167°/s. The particle size and distribution of the sample were measured with an ultrasonic particle size analyzer (BT-9300S, China).

Results and Discussion

Effect Of Hydrothermal Temperature

The particle size distribution patterns of the products of different hydrothermal temperatures are shown in Fig. 1. The hydrothermal modifications of MH were done at 100, 130, 160, and 180 °C with stirring at 500 r/min for 4 h. As shown in the particle size distribution pattern, particle size distribution changed after hydrothermal modification. The mean sizes of particles were 1.08, 1.24, 1.93, and 2.40 μm at 100, 130, 160, and 180 °C, respectively, and it was 1.38 μm before hydrothermal modification. Therefore, hydrothermal temperature had an important effect on particles size. Higher hydrothermal temperature results in bigger particles. Thus, the hydrothermal modification of $Mg(OH)_2$ may be performed via the dissolution-precipitation mechanism. The intergranular reunion and coupling of the normal temperature product were destroyed in the initial stage, the smaller particles were dissolved in hydrothermal media, and then deposited on the larger particle surface with a certain pattern because smaller particles have large specific surface area and high reactivity. High hydrothermal temperature results in faster dissolution-recrystallization process and bigger particles.

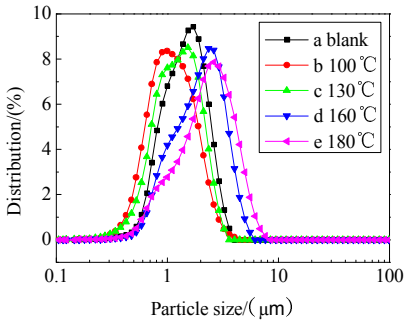

Fig. 1 Particle size distribution pattern of products of different hydrothermal temperatures, blank: without hydrothermal modification.

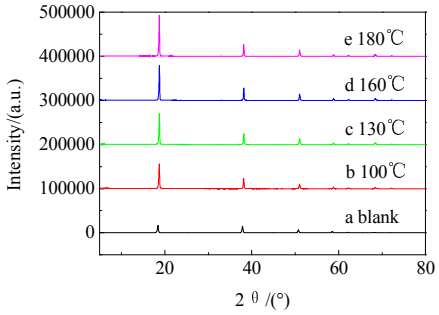
The XRD patterns of the products of different hydrothermal temperatures are shown in Fig.2. As shown in the XRD patterns, all diffraction peaks of each sample could be indexed as the hexagonal structure of MH with lattice constants comparable to the values of JCPDS 7-239. No XRD peaks arising from impurities were detected. Therefore, the synthesis phase corresponds to pure MH, which suggests a complete synthesis reaction. The intensity of each peak of the sample synthesized at room temperature is weak, and the peak strength of the (001) plane, a non-polar plane, was similar to that of the (101) plane, a polar plane. However, the intensity of each peak of the sample is stronger after hydrothermal treatment, and the strength of the (001) plane became remarkably stronger than that of the (101) plane. Thus, the $Mg(OH)_2$ powder is well-crystallized and the weakening of the polarity of $Mg(OH)_2$ after hydrothermal modification was favorable for the dispersion of $Mg(OH)_2$ particles. Further analysis of the XRD data in Fig. 2 indicated that the strength of the (001) plane increased with the increase in hydrothermal temperature, which results in the decrease in micro-strain, increase in the thickness, and improvement of the dispersion of $Mg(OH)_2$ particles with the increase in hydrothermal temperature.



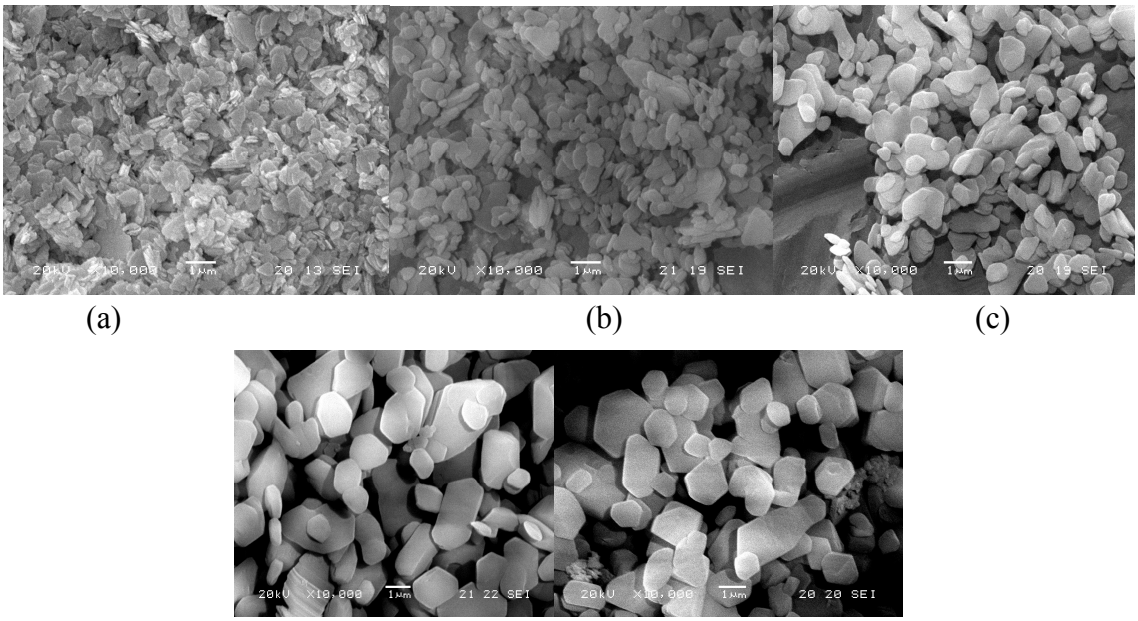


Fig. 2 XRD pattern of the products of different hydrothermal temperatures.

The morphologies of the products of different hydrothermal temperatures are shown in Fig. 3. The shape evolution process of particles at various temperatures was noted. Based on the morphology, self-aggregation of $Mg(OH)_2$ particles occurred and only minimal single $Mg(OH)_2$ particles with precipitates formed at room temperature because of their higher surface energy. By contrast, $Mg(OH)_2$ particles are modified after hydrothermal treatment; thus, the self-aggregation of the particles disappears and results in better dispersion. The gradual formation of the bigger plates and the disappearance of the smaller plates confirmed that the hydrothermal modification of $Mg(OH)_2$ may be performed via the dissolution-precipitation mechanism. The increase of temperature from 100°C to 180°C resulted in the formation of $Mg(OH)_2$ plates with bigger size, more regular hexagonal plates, increased thickness, and better dispersion. These results are consistent with the XRD and SEM data.

Effect of Stirring Speed

The particle size distribution patterns of the products at different stirring speeds are shown in Fig. 4. Hydrothermal modification of MH was performed at 0, 300, 500, and 700 r/min at 160 °C for 4 h. The mean sizes of particles were 1.14, 1.93, 1.93, and 1.96 μm for the 0, 300, 500, and 700 r/min speeds, respectively. The particle size produced without stirring was smaller than the particles size produced with stirring. Thus, the diffusion velocity of the solute molecules is too slow without

stirring, which slows down the dissolution-recrystallization process, especially for the recrystallization process, because the diffusion of solute molecules has greater effect on recrystallization. The mean size of the particles increased minimally with increasing stirring speed, which could be because the solution viscosity decreases with rising temperature. The solution viscosity decreased by approximately two orders of magnitude at these high hydrothermal temperatures compared with room temperature. Therefore, the dielectric constant of the solution decreased considerably, diffusion coefficients increased considerably, and the apparent concentration decreased considerably, which usually lead to the minimal increase in dispersive effect of the solution with increasing stirring speed. All these factors could have contributed to the minimal increase in mean particle size with stirring speed.

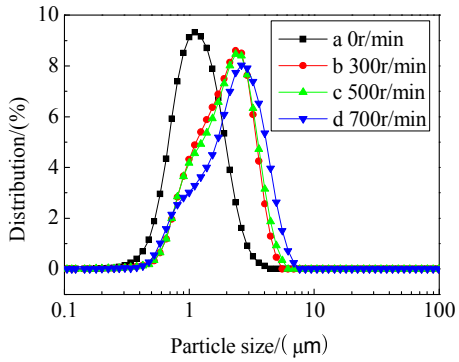

Fig. 4 Particle size distribution pattern of products of different stirring speeds.

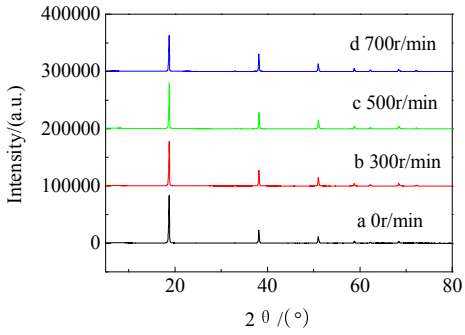
The XRD patterns of the products at different stirring speeds are shown in Fig. 5. The intensity of each peak of the sample increased minimally with increasing stirring speed. However, when the stirring speed was increased up to 700 r/min, the strength of the (001) plane of the product was slightly less compared with the particles obtained with other stirring speeds. This result might be attributed to the spatter of the $Mg(OH)_2$ slurry under such high stirring speed. It is speculated that less strength of the (001) plane results in bigger and thinner particles under the same size distribution.



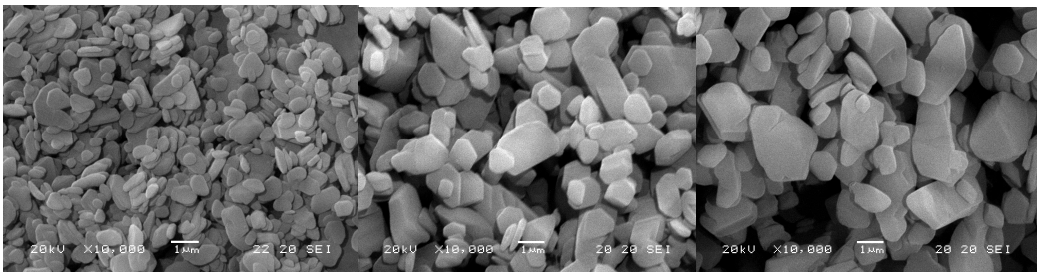


Fig. 5 XRD pattern of the products with different stirring speeds.

The morphologies of the products at different stirring speed are shown in Figs. 6 and 3d. These results are the same as the experimental results of SEM wherein the mean size of the particles produced without stirring is smaller than the particles size produced with stirring. The difference is that the product of hydrothermal modification at 700 r/min is bigger and thinner than at 300 and 500 r/min. This difference could be because the mean size of the equivalent volume sphere was

measured with laser diffusion on a suspension in water and the size and thickness were measured by image analysis on the basis of SEM micrographs taken on the dry powder. However, the XRD pattern of products reflects that hydrothermal modification at 700 r/min produced different results compared with the 300 and 500 r/min modifications.

(a) (b) (c)

Fig. 6 Morphologies of products of different stirring speeds: (a) 0 r/min, (b) 300 r/min, (c) 700 r/min.

Effect of Hydrothermal Duration

The particle size distribution patterns of the products of different hydrothermal durations are shown in Fig. 7. Modifications of hydrothermal durations of MH were performed at 0.5, 2, and 4 h at 160 °C and 500 r/min. The mean sizes of particles were 1.24, 1.36, and 1.93 μm, respectively. At 0.5h, the particle size distribution of the product was uneven and had two peaks; at 2 h, the product had small size and narrow size distribution; and at 4 h, the product had larger size. These results could be because of the requirement of sufficient time to finish processes. If sufficient time is allowed, intergranular reunion and coupling of the normal temperature product will be destroyed, smaller particles will be dissolved, and particles can grow to larger sizes. Thus, not enough time was allowed to form a better crystal, and the intergranular reunion and coupling still exist at 0.5 h. However, as the duration was extended to 2 h, destruction of the intergranular reunion and coupling has been basically completed and the smaller particles were dissolved, which allowed continuous growth of larger particles. Thus, the self-aggregation of particles disappears and the formation of $Mg(OH)_2$ plates is enhanced. In longer durations, the dissolution of smaller particles and growth of larger particles mainly occur; thus, particles size is increased.

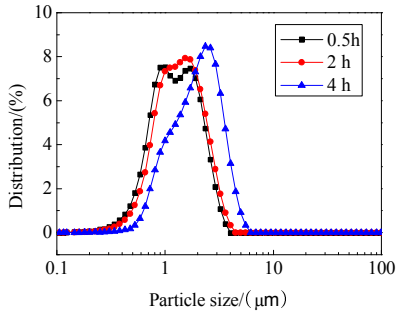

Fig. 7 Particle size distribution pattern of the products of different hydrothermal durations.

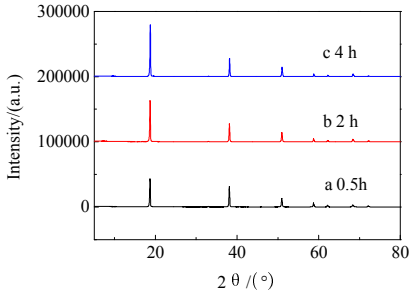
The XRD patterns of the products of different hydrothermal durations are shown in Fig. 8. Based on the XRD patterns, the strength of the (001) plane increased and the (101) plane decreased with increase in hydrothermal duration. This result leads to the decrease in micro-strain, increase in thickness, and improvement of the dispersion of $Mg(OH)_2$ particles accompanying the increase in hydrothermal duration.



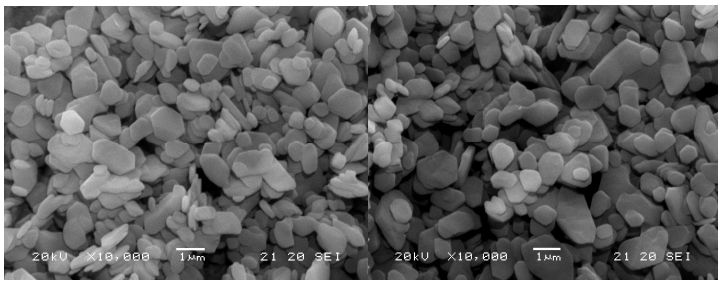


Fig. 8 XRD patterns of products of different hydrothermal durations.

The morphologies of the products with different hydrothermal durations are shown in Figs. 9 and 3d. As shown in the XRD patterns, particles are thin and the intergranular reunion and coupling still exist at 0.5 h. Moreover, the extent of time from 0.5 h to 4 h resulted in the formation of $Mg(OH)_2$ plates with bigger size, more regular shape, increased thickness, and better dispersion. This result is consistent with XRD and SEM data.

(a) (b)

Fig. 9 Morphologies of products of different hydrothermal durations: 0.5 h, (b) 2h.

Effect of Dilution Multiple

Results of different dilution multiples are summarized in Figs. 10, 11, 12 and 3d. The dilution multiple of the MH slurry was diluted five times (20% of original slurry), thrice (33.33% of original slurry), and once (100% of original slurry) at 160 °C and 500 r/min for 4 h. The mean sizes of the particles were 1.95, 1.98, and 1.93 μm, respectively. The intensity of each peak of the samples and the XRD patterns was minimally changed. Thus, the impact of dilution multiple on hydrothermal modification of MH is minimal. This minimal effect could be attributed to the drop in solution viscosity of approximately two orders of magnitude at these high hydrothermal temperatures compared with room temperature. This change favors electro-static interactions, lowers kinetic barriers, and accelerates the ripening processes. Therefore, the dispersive effect of the solution minimally increases with increase in dilution multiple.

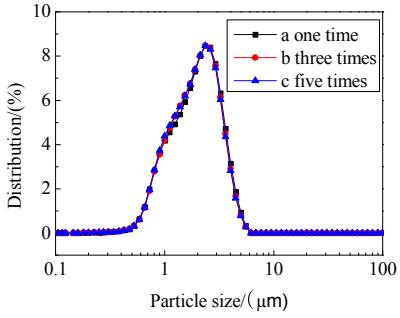

Fig. 10 Particle size distribution patterns of the products of different dilution multiples.

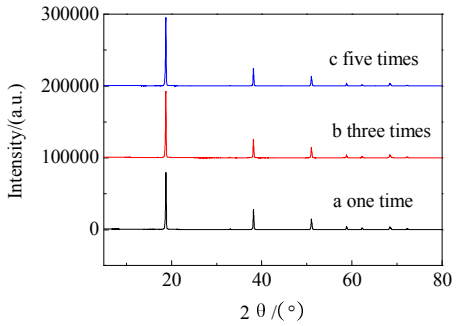

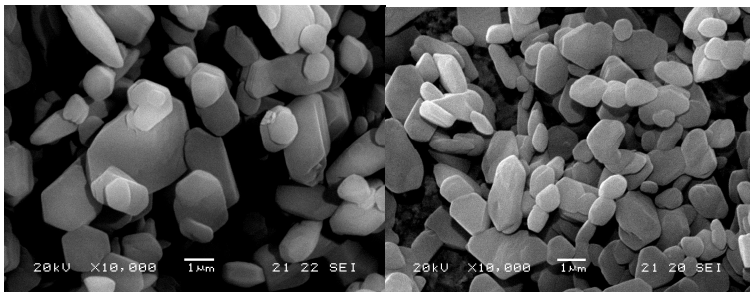

Fig. 11 XRD patterns of the products of different dilution multiples.

(a) (b)

Fig. 12 Morphologies of the products with different dilution multiples: (a) three times, (b) five times.

MH slurry concentrations were 15.50%, 5.12% and 2.71% when the slurry was diluted once, thrice, and five times, respectively. In this paper, a mass fraction of 15.50% $Mg(OH)_2$ in the MH slurry was obtained by high concentration (4.30 mol/L) magnesium chloride and ammonia as the raw materials. The concentration of magnesium chloride was high and did not attract water when the precipitant ammonia was introduced into the reaction system. Therefore, this study produces high yield with unit equipment.

Conclusions

In this study, uniform lamellar hexagonal structure MH at high slurry content was prepared using bischofite and ammonia as raw materials. The influences exerted by several hydrothermal modification parameters on the size distribution, structure, and morphology of MH particles precipitated were studied. The intensity of each peak of the sample was strong and the strength of the (001) plane became stronger than that of the (101) plane after hydrothermal treatment. Self-aggregation of the particles disappears, MH hexagonal structures form, and disperses better after hydrothermal treatment. Hydrothermal temperature exhibits important effects on size distribution, structure, and morphology of the particles. The increase in temperature resulted in the formation of $Mg(OH)_2$ plates with bigger size, more stable structure, more regular shape, increased thickness, and with better dispersion. Stirring speed also has some effect on MH crystals. Particles size produced without stirring is smaller than particles size produced with stirring. However, the minimal increase in MH crystal size with stirring speed as solution viscosity significantly decreases at these high hydrothermal temperatures compared with room temperature. Hydrothermal duration exhibits important effects on MH crystals. If hydrothermal duration was too short, the intergranular reunion and coupling still exist and the recrystallization process is not complete. With longer durations, $Mg(OH)_2$ plates formed with bigger size, more stable structure, more regular shape, increased thickness, and better dispersion. The effect of the dilution multiple of hydrothermal

modification on MH is small. In this paper, mass fraction of 15.50% $Mg(OH)_2$ of MH slurry is obtained by high concentration magnesium chloride of 4.30 mol/L and ammonia as raw materials. Therefore, this study demonstrated that bigger size, more stable structure, more regular shape, increased thickness, and better dispersion of the hexagonal structure of MH at high slurry content was obtained by hydrothermal modification.

Keywords: swelling; core-shell microspheres; Janus; solubility parameter; polar fraction

Abstract. Janus particles have particular properties and potential application for their asymmetry dual-faced structure. In this report, we study the effect of the solubility parameter and the polar fraction of solvent on the swelling assisted with protrusion of polystyrene @ titanium dioxide (PS@TiO_2) core-shell microspheres. The resultant titanium dioxide/polystyrene (TiO_2/PS) Janus particles were characterized by scanning electron microscope. Results indicated that solvent with the solubility parameter of about 9.3 $(cal/cm^3)^{1/2}$ and with low polarity such as dimethylbenzene, carbon disulfide and methyl methacrylate exhibited the preferable swelling efficiency.

Introduction

Janus particles are regarded as some of the most complicated colloidal particles in existence. Janus particles with different composition and structure may have different assembly behaviors and properties such as surfactants [1], biosensors [2], directional catalysis [3], biological probe [4], electronic devices and photonic crystal [5] and so on. Many synthesis approaches have been developed for the fabrication of Janus particles, including biphasic grafting [6], the Pickering emulsion method [7-9], asymmetric wet-etching [10-12], solvent-free method [13], and seeded emulsion polymerization [14]. However, these methods are difficult to achieve accurate control of the surface chemical partition and microstructure of Janus particles, also unable to undertake large-scale production. Recently, Yang [15,16] synthesized the polymer/inorganic asymmetric Janus particles by emulsion swelling core-shell composite particle. This method is not only easy to operate but also provides possibility of mass production. In this report, we synthesized titanium dioxide/polystyrene (TiO_2/PS) Janus particles by using single solvent with different solubility parameter and polar fraction to swell core-shell microspheres and investigated the effect of solvent properties on the swelling assisted with protrusion of polystyrene @ titanium dioxide (PS@TiO_2).

Experimental

Materials

Ethanol, styrene, n-hexane, acetone, dimethylbenzene, carbon disulfide, methyl methacrylate, butyl alcohol and sodium dodecyl sulfate (SDS) were all A. R. and purchased from Sinopharm Chemical Reagent Co., Ltd.

Synthesis of the Janus composite particles of TiO_2/PS

The core-shell composite particles of PS@TiO_2 were prepared by the method reported in the literature [17]. 0.05 g of freeze-dried PS@TiO_2 composite particle was dispersed in 5 mL of aqueous solution containing 10 $mg \cdot mL^{-1}$ of SDS. 0.2 mL of different kind of solvent and 5 mL of aqueous solution containing 10 $mg \cdot mL^{-1}$ of SDS were emulsified at ambient temperature under ultrasonication for 5 min. The emulsion was added into the composite dispersion within 1 min

under stirring at ambient temperature, and the system stood there for 20 min to control swelling extent. The swelling was terminated by adding excess ethanol. The samples were centrifuged and washed with ethanol to remove solvent. The Janus composite particles of TiO_2/PS were obtained after freeze-drying.

Characterization

The morphologies of the Janus composite particles of TiO_2/PS swelling by the single solvent were performed on a JSM-7500F scanning electron microscope (SEM) at an accelerating voltage of 5 kV.

Results and discussion

Effect of the solubility parameter of solvent on swelling

The solubility parameter and polar fraction of the solvents were listed on Table 1. The SEM images of the Janus composite particles of PS@TiO_2 swelled by the emulsion of different solvents for 20 min at room temperature were shown in Fig. 1. The solubility parameter of PS is about 9.3 $(cal/cm^3)^{1/2}$. When the solvent with low solubility parameter such as n-hexane which solubility parameter is 7.3 $(cal/cm^3)^{1/2}$ was used to swell PS@TiO_2 core-shell structure, the inner osmotic pressure could not increase sufficiently to crack the TiO_2 shell. The PS core could not protrude under swelling (Fig.1 a). With the increase of solubility parameter of solvent, swelling ability of solvent improved obviously so the inner osmotic pressure would enhance sufficiently to form a tiny crevice on the surface of TiO_2 shell. Part of the PS core was protruded through the crevice and formed a lobe anchored onto the surface of TiO_2 shell [8] (Fig.1 b and Fig.1 c). However, when the gap of solubility parameters between solvent and PS became larger, the heat of mixing of PS largen and the swelling ability of solvent decreased (Fig.1 d).

Effect of the polar fraction of solvent on swelling

The solvents with weak polarity, such as dimethylbenzene and methyl methacrylate, are beneficial to preparing TiO_2/PS Janus particles by swelling the core-shell microspheres (Fig.1 b and Fig.1 e) because the polarity of PS is low. The TiO_2/PS Janus particles could not obtain when the core–shell composite particles of PS@TiO_2 were put into the single solvent which has large polarity (Fig.1 f), for example, the butyl alcohol that the polarity is 11.4 $(cal/cm^3)^{1/2}$.

TABLE 1 THE SOLUBILITY PARAMETER AND POLAR FRACTION OF THE SOLVENTS

Solvent	Solubility parameter/ $(cal/cm^3)^{1/2}$	Polar fraction
n-hexane	7.3	0
dimethylbenzene	8.8	0
carbon disulfide	10.0	0
methyl methacrylate	8.7	0.149
acetone	10.0	0.695
butyl alcohol	11.4	0.096

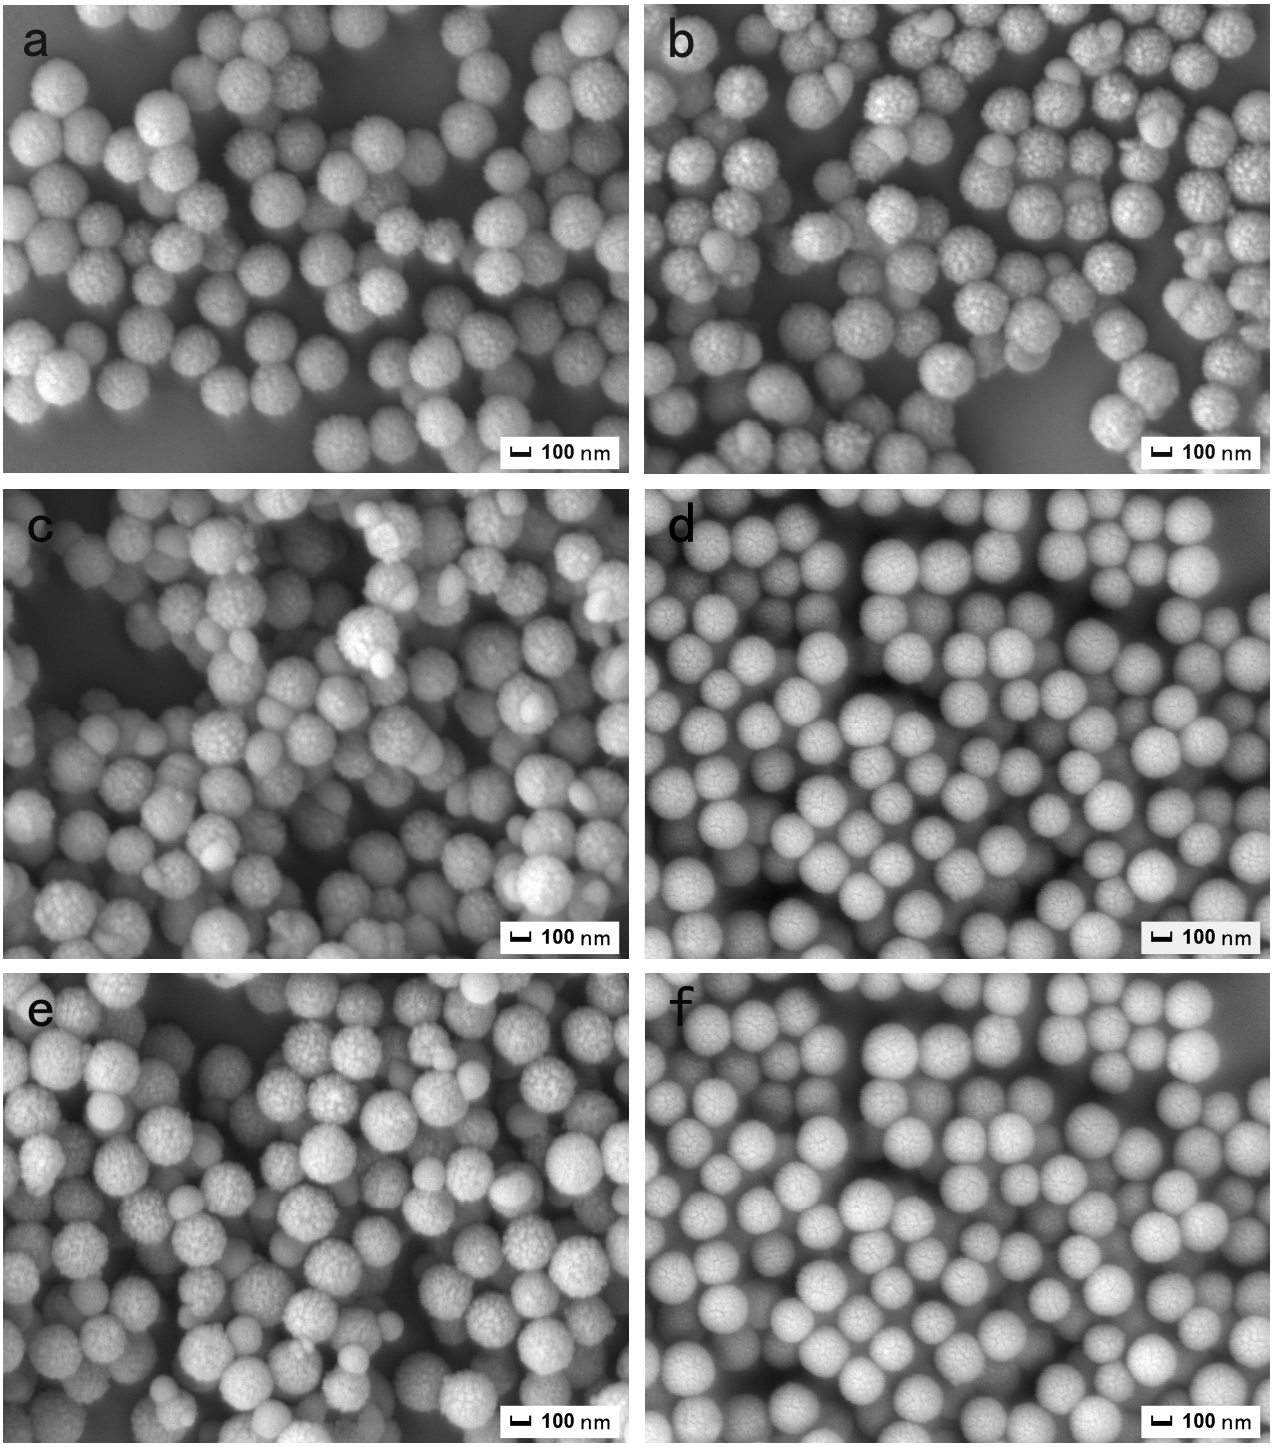

Fig. 1 SEM images of the TiO_2/PS Janus particles prepared with different solvent. (a) n-hexane; (b) dimethylbenzene; (c) carbon disulfide; (d) butyl alcohol; (e) methyl methacrylate; (f) acetone

Conclusion

The core of PS in the shell of TiO_2 is more likely to swell and form the TiO_2/PS Janus particles when solvent has the similar solubility parameters with PS which solubility parameter is about 9.3 $(cal/cm^3)^{1/2}$. Moreover, solvent with low polarity is benefit for the formation of Janus particles because PS is a kind of polymer with low polarity.

Keywords: semi-aromatic polyamide, non-isothermal crystallization kinetics, heat treatment, mechanical properties.

Abstract: In order to meet the new requirement of polyamide materials on the thermal behavior, the aromatic rings were introduced into the main chain to synthesize semi-aromatic polyamide. In this paper, the non-isothermal crystallization kinetics of semi-aromatic polyamide was studied with Mo method. It was found that the crystallization rate slowed down with the increase of crystallinity. Spinning experiments showed that the semi-aromatic polyamide fibers could be prepared by melt spinning. Heat treatment can improve the mechanical properties of the as spun fibers obviously. Considering the impact on the mechanical properties, heat treatment time under 60 min was optimum.

Introduction

At present, the main varieties of semi-aromatic polyamides are nylon MXD6, PA6T, PA9T, PA10T[1-2] and so on. Semi-aromatic polyamide has many outstanding properties, for example, good heat resistance, excellent chemical resistance, high fracture strength and perfect electrical insulation. Now, this new type of polyamide possessing both the advantages of aromatic and aliphatic polyamide has become a hot research area. In this paper, the non-isothermal crystallization kinetics of the semi-aromatic polyamide was analyzed. The fibers of semi-aromatic polyamide were made through melt spinning and the effects of heat treatment time on mechanical properties of semi-aromatic PA fibers were also studied.

Experimental

Materia

The sample of semi-aromatic polyamide was provided by School of Chemical Engineering Donghua University with a melt index of 17.72 g/min.

Non-Isothermal Crystallization Measurement

Non-isothermal crystallization kinetics was carried out using a differential scanning calorimeter (DSC, TA2910, USA). The non-isothermal crystallization was performed as follows: the sample was heated to 350℃ at the heating rate of 20℃/min, stayed there for 2 min, then cooling the melt to crystallize at cooling rates of 10,15,20 and 25 ℃/min.

Melt Spinning

The dried semi-aromatic polyamide chips were put into the screw extruder to melt and extruded through spinneret. The screw extruder temperatures were set as 290, 295, 305, 310, 315℃, respectively from the inlet to the outlet. The winding speed was set at 450m/min and the metering pump rotation speed was 12.5 rpm. At last heat treatment was required to enhance mechanical properties of the as spun fiber. Some groups of as spun fibers were kept in the vacuum oven under a sustained stress of 40cN to heat. The heat treatment time was set as 20,40,60,90 min under the unchanged heat treatment temperature of 160℃， respectively.

Results and Discussions

Non-Isothermal Crystallization Kinetics

Figure 1 shows the DSC crystallization exothermal curves of semi-aromatic polyamide samples at different hearting rate.

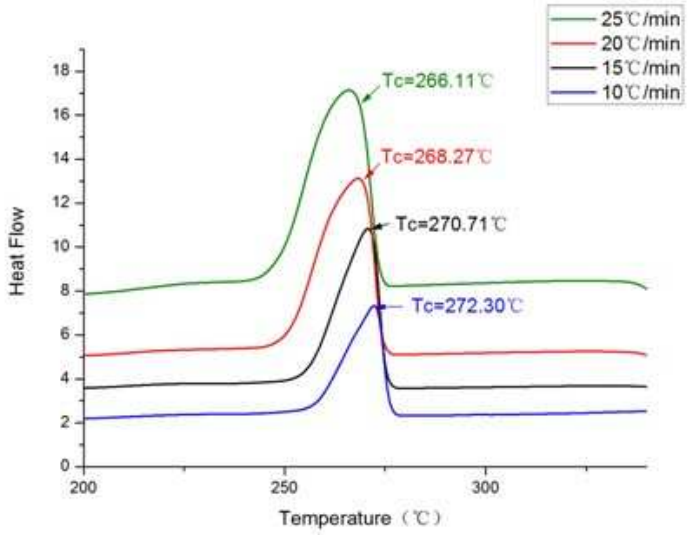

Fig.1 Non-isothermal crystallization curves of semi-aromatic polyamide

As seen from Fig 1, the crystallization exotherm becomes broader and shifts to lower temperatures with the increase of cooling rate. The reason may be that, at a lower cooling rate, polymer chain has enough time to transfer from the melt to the surface of the crystal [5]. So crystallization can occur at higher temperature.

The non-isothermal crystallization kinetics of semi-aromatic polyamide fibers was studied with Mo method[4,5] in this paper. Based on the assumption that the degree of crystallinity is correlated to the cooling rate and crystallization time, the non-isothermal crystallization process can be effectively characterized by using the combined Avrami/Ozawa equation[6],that is Mo method. The Avrami[7] equation is expressed as,

$$1-\mathrm{X(t)} = \exp(-\mathrm{Z}_t t^n). \quad (1)$$

Taking a double logarithm of Eq. (1) gives:

$$\lg[-\ln(1-X(t))] = \lg Z_t + n\lg t. \quad (2)$$

where n is the Avrami exponent, which depends on the nucleation mechanism and growth geometry, Zt is the crystallization rate constant, X(t) is the relative degree of crystallinity at certain time.

Ozawa[8] equation is an extension of the Avrami equation to the non-isothermal condition. In the Ozawa approach, the time variable in the Avrami equation is replaced by the cooling rate. Thus the relative crystallinity degree is described as a function of constant cooling rate:

$$1-X_t=\exp(-K(T)/\theta^m)\,. \tag{3}$$

Using Eq. (3) in double-logarithmic form:

$$\lg(-\ln(1-X_t))=\lg K(T)-m\lg\theta\,. \tag{4}$$

Where K(T) is a function of temperature, m is the Ozawa exponent, and θ is the cooling rates. Merging the Eqs. (2) and (4) in the following form:

$$\lg Z_t+n\lg t=\lg K(T)-m\lg\theta\,. \tag{5}$$

And by rearrangement:

$$\lg\theta=\lg F(T)-a\lg t\,. \tag{6}$$

where the kinetic parameter $F(T)=[K(T)/Z_t]^{1/m}$ refers to the cooling rate that needs to be selected within a unit of crystallization time when the measured system amounts to a certain degree of crystallinity, and a is the ratio of the Avrami exponent n to the Ozawa exponent m. The value of a is closely related to the fitness of the Mo method. According to Eq.6, for a given relative crystallinity, from the plot of lgθ against lg t, the values of F(T) and a can be determined from the intercept and the slope of the line, respectively. The plot of lgθ versus lgt for semi-aromatic polyamide with different crystallinity was given in Fig. 2. The values of F(T) and a were listed in Table 1.

TABLE 1 NON-ISOTHERMAL CRYSTALLIZATION KINETIC PARAMETERS OF SEMI-AROMATIC PA

X_t (%)	a	lg F(T)
20	1.43	0.93
40	1.45	1.06
60	1.46	1.12
80	1.46	1.15

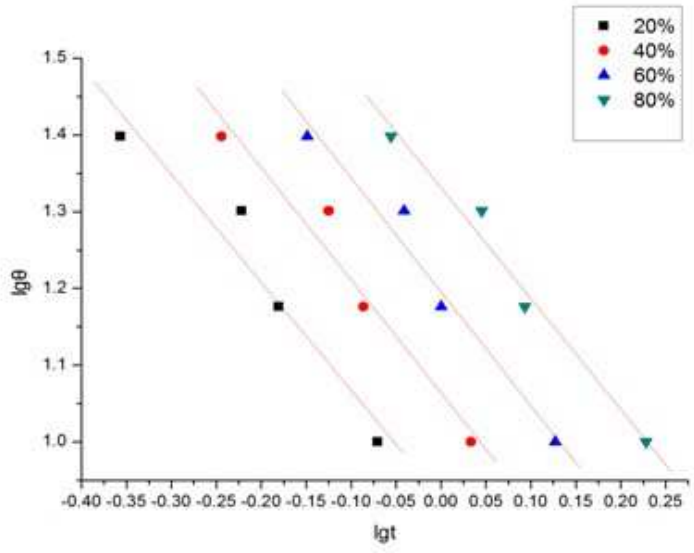

Fig.2 The plots of $\lg\theta$ versus log t for semi-aromatic polyamide

Table 1 shows that the values of a are in the range of 1.43~1.46 with the average of 1.45, changing slightly at different relative crystallinity. It means this method has been proven to be applicable for the crystalline process of semi-aromatic polyamide. It also can be seen that the values of lg F(T) become larger with the relative crystallinity increasing, which shows that the cooling rate should be increased to achieve a higher relative crystallinity in unit crystallization time.

The Mechanical Properties of the Semi-aromatic PA Fiber

The mechanical properties of the fibers under different heat treatment time were tested and listed in Table 2. The heat treatment temperature was set at 160℃, and remained unchanged.

TABLE 2 THE MECHANICAL PROPERTIES OF THE FIBERS UNDER DIFFERENT HEAT TREATMENT TIME

Heat Treatment Time (min)	Tensile Strength (MPa)	Young's Modulus (GPa)	Elongation at break (%)
as-spun fiber	357.86	5.38	63.8
20	660.91	10.32	8.7
40	692.68	10.82	7.6
60	760.04	12.33	6.2
90	749.85	11.88	6.6

Table 2 shows that the tensile strength and the modulus of the fibers increase obviously with the increase of heat treatment time at first. When the time was 60min, the tensile strength and the modulus reached the highest point. It is because the molecular chain starts to reorganize and orient along the fiber direction. So the optimal heat treatment time of the fibers is about 60min. Then the values decrease with the time extension because of the disorientation caused by the too long time in high temperature.

Conclusions

(1) Mo method can describe non-crystallization kinetics of semi-aromatic polyamide well. To realize a higher relative crystallinity in unit time, a faster cooling rate is needed.

(2) The semi-aromatic PA fiber can be prepared by melt spinning, with a winding speed of 450m/min. Heat treatment can improve the mechanical properties of the fibers obviously. The results demonstrate that 60min is the best heat treatment time, under which the tensile strength can reach to 760MPa and the modulus can reach to the maximum of 12.3GPa.

Keywords: recycled cellulose aerogel, water absorption

Abstract: By applying sodium hydroxide/urea and a sample freeze drying method, we successfully synthesized green cellulose aerogel from paper waste for the first time. We adjusted the cellulose concentration from 1.5 percents to 4 percents in the initial hydrogel. They yielded densities changing from 0.03-0.1 g/cm^3.The absorption capacities varied from 9 to 20 times of their own weight. To investigate the water absorption capacity in relationship with the initial chemical dosage, we changed the input amount of urea and sodium hydroxide, which is the first study ever. The thermal conductivity of the 2 percents sample ranged from 0.029-0.032 W/mK. Besides, the material has a high potential to be used in diaper industry as it is biodegradable which is better than most super absorbent polymers.

Introduction

Most diapers in market are composed of super absorbent polymers, which are not biodegradable. Averagely a baby needs more than 5,000 diapers before it is potty-trained [1]. Adult diapers are also requested in large amount every day. Huge amount of diapers is consumed daily in this world. Nowadays, as super absorbent polymer is not biodegradable. The used diapers waste large amount of land to store them. Our paper gives a potential alternative of traditional diapers-Cellulose aerogel, which with high absorbent capacity (almost 20 times) and also biodegradable can be used to replace the non-biodegradable super absorbent polymer. Cellulose aerogel can be derived from paper. Only United States alone used 85.5 million tons of paper per year [2]. This huge amount of used paper needs to be recycled and functions as useful material to prevent waste. Our group converts the recycled cellulose to cellulose aerogel. Aerogel is porous material with more than 90 percents pores in the volume. Most aerogel are silica or carbon aerogel. Cellulose aerogel is a new material.

Materials and Chemicals

Sodium hydroxide, urea, and ethanol are purchased from Sigma-Aldrich. Commercial recycled cellulose fibers are donated by Insul-Dek Engineering Pte. Ltd., Singapore.

Synthesis Procedure

For standard sample, urea (13.7 wt%, 5.025g) and sodium hydroxide (1.9 wt%, 0.725g) were dispersed in DI water (30g), which is dispersed by a magnetic stir. Recycled cellulose (2 wt%, 0.75g) was added to the transparent solution, pre-cooled in ice/water bath for 10 minutes, then

sonication for 10 minutes. Thereafter, the solution was placed in refrigerator for more than 24 h to allow gelation of the solution. After the solution was frozen, it was then thawed at room temperature and then followed by immersing into ethanol (99 vol %) for coagulation for two days. After coagulation, solvent exchange was carried out by immersing the gel in de-ionised (DI) water for 2 days. The sample was then frozen in a freezer at – 18 ℃ for 24 h. After that, freeze drying is carried out for 2 days with a ScanVac CoolSafe 95-15 Pro freeze dryer (Denmark) to obtain the desired aerogel. Other samples were prepared by the same method by varying one component of the standard sample. Detail refers to the Table 1.

TABLE 1 PARAMETERS USED IN MORPHOLOGY CONTROL OF CELLULOSE AEROGEL

Group 1	cellulose amount	cellulose concentration
G1_015	0.5444[g]	1.50%
standard	0.75[g]	2%
G1_03	1.1057[g]	3%
G1_04	1.4896[g]	4%
Group 2	urea amount	urea concentration
G2_10	3.4972[g]	10%
standard	5.025[g]	13.76%
G2_15	5.5544[g]	15%
G2_20	7.8688[g]	20%
Group 3	NaOH amount	NaOH concentration
G3_015	0.5448[g]	1.50%
standard	0.725[g]	1.90%
G3_025	0.9173[g]	2.50%
G3_03	1.1064[g]	3%

Characterization

Thermal conductivity measurement.

C-Therm TCi Thermal Conductivity Analyzer (C-Therm Technologies, Canada) was used to measure the thermal conductivity of the aerogel.

Water absorption test.

This test was carried out in DI water, followed by modified ASTM D570-98 standard, refer to Figure.1.

Figure 1 The setting of water absorption test

Results and Discussion

The thermal conductivity of the standard sample was 0.03 $Wm^{-1}K^{-1}$. It is comparable to silica aerogels (0.026 $Wm^{-1}K^{-1}$) and wool (0.03-0.04 $Wm^{-1}K^{-1}$) [3].

TABLE 2 CELLULOSE CONCENTRATION AFFECTS WATER UPTAKE RATIO AND POROSITY

Sample No	Dry Weight [g]	Wet Weight [g]	Water uptake Ratio	Porosity	Density [g/cm^3]
G1_015	0.3928	8.3431	20.24	0.984	0.03
Standard	0.7280	13.4140	17.43	0.978	0.04
G1_03	0.8976	12.3885	12.80	0.970	0.05
G1_04	2.4507	24.4634	8.98	0.935	0.10

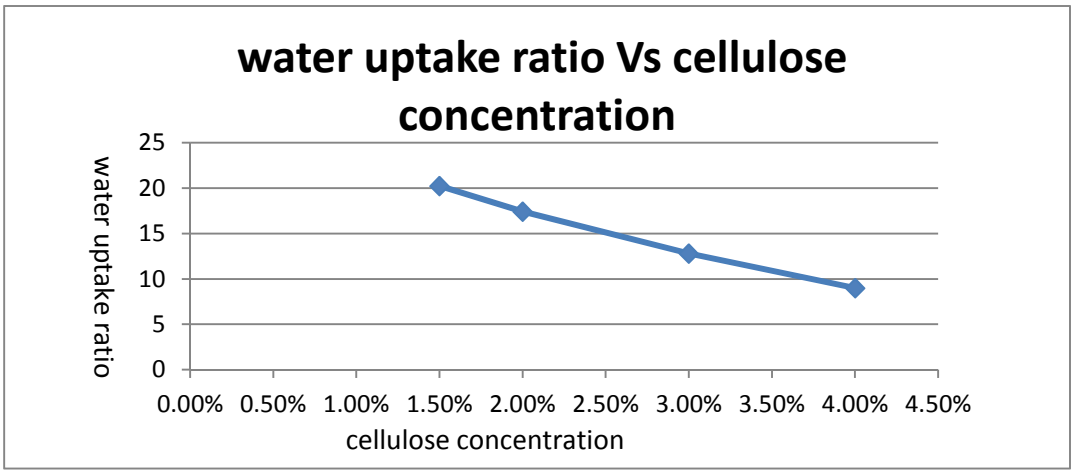

Figure 2 The water uptake ratio change with cellulose concentration

Cellulose concentration varies from 1.5% to 4%, while the water uptake ratio drops from 20 to 9. Their relationship is quite linear. By increasing cellulose content in one sample, the density of the solution is also increased, but the structure of the aerogel is more compacted. Hence, the porosity is decreased (see Table 2), resulting in less space for water molecular being taken in. As the result, Water uptake ratio linear decrease with an increase cellulose concentration, referring to Figure. 2.

TABLE 3 UREA AMOUNT AFFECTS WATER UPTAKE RATIO AND POROSITY

Sample No	Dry Weight [g]	Wet Weight [g]	Water uptake Ratio	Porosity
G2_10	0.6712	14.1073	20.02	0.978
standard	0.7280	13.4140	17.43	0.978
G2_15	0.7532	14.5129	18.27	0.975
G2_20	0.6985	13.1829	17.87	0.978

Urea forms urea hydrate in the solution. Urea hydrate helps prevent cellulose molecule come near to each other. Hence, urea restrains the formation of hydrogen bond among cellulose. The experiment results about water up take ratio are without much difference in this group. It may be caused by the urea amount that plays an insignificant role about porosity. However, the porosity is not as the same as the water up take ratio results suggest, referring to Table 3. It is may be due to measure errors, as the porosity is calculated by weight divided by volume. Volume is derived from diameter and height of the cellulose samples, and then determined by cylinder volume calculation formula. The diameter is determined by the average of three readings. Errors may be generated in the process, as the sample is not exactly cylindrical shape. However, we could see all the data are the same in the first two digits regards to porosity.

Part of sodium hydroxide can be bound to cellulose, which improves the dissolve of cellulose. More sodium hydroxide causes less hydrogen bonding among cellulose, which leads to less porosity and thus less water uptake ratio, referring to Table 4. However, when sodium hydroxide changes from 2.5 percents to 3 percents, the water uptake ratio does not drop further. It is due to 2.5 percents of sodium hydroxide is the maximum amount needed to bound with cellulose. More sodium hydroxide will not further the reaction.

TABLE 4 SODIUM HYDROXIDE AMOUNT AFFECTS WATER UPTAKE RATIO AND POROSITY

Sample No	Dry Weight [g]	Wet Weight [g]	Water uptake Ratio	Porosity
G3_015	0.5925	11.9001	19.08	0.983
standard	0.7280	13.4140	17.43	0.978
G3_025	0.7639	12.6251	15.53	0.974
G3_03	0.7066	11.3263	15.03	0.976

Summary

Our group successfully synthesized recycled cellulose aerogel from paper waste. The newly developed material is with high absorption capacity. Sodium hydroxide amount and cellulose concentration alter the water uptake ratio of cellulose aerogel greatly, while urea amount do not play a significant role in the water uptake ratio.

Keywords: Monolithic column; Polyacrylate; Adjustable porous properties; Porogenic system

Abstract. Porous properties have notable effect on separating effect of organic polymer-based monolithic column. Different applications of monolithic columns require tailored pore size distributions. On account of that, P(GMA-co-EGDMA) monolithic columns were prepared with novel ternary porogenic agents. Glass tubes was chosen as polymerization mold. Moreover, factors influencing the inner pore morphology, pore size and specific surface area were investigated systematically. The results showed that the increasing of the solubility of porogenic agents and the amount of crosslinker, the decreasing of the amount of porogenic agents and temperature rising all could give rise to the decreasing of pore size. Remarkably, the effect of initiator was studied for the first time. The results showed that amount of initiator had no remarkable influence on porous properties. By controlling effect factors, P(GMA-co-EGDMA) Monolithic Columns with pore size from dozens to thousands of nanometer, which can be applied in separation of molecules with different size.

Introduction

Organic polymer-based monolithic columns can be used as stationary phase of various chromatography with its widespread sources of raw material, large range of pH, excellent biocompatibility and accessibility for chemical modification[1-4]. Its typical preparation process is as follows: homogenous polymerization mixture of monomers, porogenic agents, crosslinker and initiator is put into a mold which polymerization reaction takes place in. Due to its formed interconnected pore and channels, it allows high flow velocity under moderate pressure[5,6]. Common materials of the mold include stainless steel [7], glass [8], silica capillary [9] and so on. In recent years, organic polymer-based monolithic columns are applied in the area such as separation of biomacromolecule[10-15], inorganic ion[16] and detection in solid phase[17,18] by virtue of its high efficiency, high throughput and low back pressure in the process of separation.

Porous properties have great effect on separating effect of organic polymer-based monolithic column. Different applications of monolithic columns require tailored pore size distributions. The monolithic with dozens nanometers pore size can be used for separation of small molecules, such as aminoacid[19]; micrometer-scale pore is for separation of large molecules, just like proteins[20]. Therefore, it is of great importance to realize the preparation of controllable pore structure.

Based on the above knowledge, P(GMA-co-EGDMA) monolithic columns, which are most widely applied, were prepared choosing glass tube as polymerization mold. Meanwhile, influencing factors on the porous properties of P(GMA-co-EGDMA) monolithic columns were investigated systematically, including kind and amount of porogenic agents, amount of crosslinker, amount of initiator and reaction temperature. The aims of this work were revealed the influence law of these reaction conditions and technology. So as to laid the foundations for preparation of P(GMA-co-EGDMA) monolithic columns with controllable pore structure.

Experimental

Materials

Glycidyl methacrylate(GMA, AR) and ethylene glycol dimethacrylate(EGDMA, AR) were purchased from SARTOMER; cyclohexanol(AR), 1,4-butanediol(AR), 1-propanol(AR), 1-dodecanol(AR), acetone(AR) and azobisisobutyronitrile(AIBN, CP) were purchased from Sinopharm Chemical Reagent Co.,Ltd. The water used throughout the work was produced by AJY-2002-U ultra-pure water machine from Aquapro.

Preparation of P(GMA-co-EGDMA) monolithic columns

The homogenous mixtures consisting of GMA, EGDMA, 1-propanol, 1-dodecanol, water and AIBN were injected into glass tubes after being sparged with nitrogen for 10 min. The sealed glass tubes were then put straightly into an electric blast drying oven to polymerize for 24 h at 50 ℃. The resulting monolithic columns were washed by acetone and water successively, and vacuum dried for later experiment.

Monomer(2.06 g of GMA), crosslinker(0.50 g of EGDMA) and initiator (24 mg of AIBN) were dissolved in a ternary porogenic mixture consisting of 1-propanol(1.69 g), water(0.30 g) and the third component(1.22 g). Cyclohexanol, 1,4-butanediol, 1-dodecanol were chosen as the third component respectively.

Determining 1-dodecanol as the third component, we investigated the effects of proportion of porogenic agents, amount of initiator，crosslinking degree and reaction temperature on the porous properties of monolithic columns systematically. The dosage of components and reaction conditions were as shown in Table1.

Table 1 Dosage of each components and reaction conditions of P(GMA-co-EGDMA) monolithic columns with porogenic system of 1-dodecanol

Sample	GMA [g]	EGDMA [g]	AIBN [mg]	1-propanol [g]	1-dodecanol [g]	Water [g]	TA[a] [g]	Tempreture [℃]

MC-18	2.06	0.50	24	1.69	1.40	0.30	3.39	60

Characterization

The microstructure of the monolithic columns was characterized by a Scanning Electron Microscope (SEM, JEOL JSM-6700F). The porous properties was measured by means of a mercury porosimeter instrument (AutoPore IV 9500, USA). The pressure range was 0.10~60000.00 psia; the equilibration time was 10 seconds.

Results and discussion

Different porogenic system effect on porous properties

The porous properties of the monolithic columns prepared by changing the third component are as shown in Table2. From Table2 it can be seen that the order of pore size is: 1-dodecanol > 1,4-butanediol > cyclohexanol. Fig.1 shows the pore size distribution curves of the monolithic columns with three different porogenic systems. It can be seen that the pore size of the monolithic column with porogenic system of cyclohexanol distributed dispersedly around 0~100 nm. The monolithic column with porogenic system of 1,4-butanediol had a pore size of about 120 nm at the highest peak in the distribution profile curve. Compared to the former two columns, the monolithic column with porogenic system of 1-dodecanol had a larger pore size of about 300 nm at the highest peak. As shown in Fig. 2 cumulative pore area changes as a function of pressure. As can be seen, the monolithic column with porogenic system of cyclohexanol had the largest cumulative pore area, and its cumulative pore area increased steadily with the increasing of pressure, which indicated that its pore distributed dispersedly. Otherwise than that, the monolithic column with porogenic system of 1-dodecanol had the smallest cumulative pore area, and its cumulative pore area didn't change much after the pressure reached 2500 psia, which indicated that its pore size had the characteristics of concentrated distribution. The curve of 1,4-butanediol presented two platforms, indicating that there were two kinds of pore with different size, which is consistent with the information presented by the pore size distribution curves.

All the results above can be explained by phase separation theory and swelling theory[1]. A poorer solvent to the system results in an earlier phase separation in the polymer. The new phase swells with the monomers because these are thermodynamically better solvents for the polymer than the porogenic solvent. Therefore, the local concentration of monomers in the swollen gel nuclei is higher than that in the surrounding solution and the polymerization reaction proceeds mainly in these swollen nuclei rather than in the solution. Those nuclei formed are likely to be adsorbed by the large preglobules developed earlier by coalescence of many nuclei, increasing the size of the preglobules. Thus, the globules formed in the system are larger and the voids between pores are larger as well. Contrarily, if the solvent quality improves, the good solvent competes with monomers in the solvation of nuclei, the local monomer concentration is lower and the globules are smaller. As a result, porous polymers formed have smaller pores. The order of compatibility to the system is cyclohexanol > 1,4-butanediol > 1-dodecanol. Through the theoretical analysis, the order of pore size should be 1-dodecanol > 1,4-butanediol > cyclohexanol, which consistents with the results from the experiments.

Table 2 Porous properties of the monolithic columns with different porogenic systems

Porogenic system	cyclohexanol	1,4- butanediol	1-dodecanol
Specific surface area[m^2/g]	85.62	46.05	18.89
Average pore size[nm]	26.9	105.0	308.8

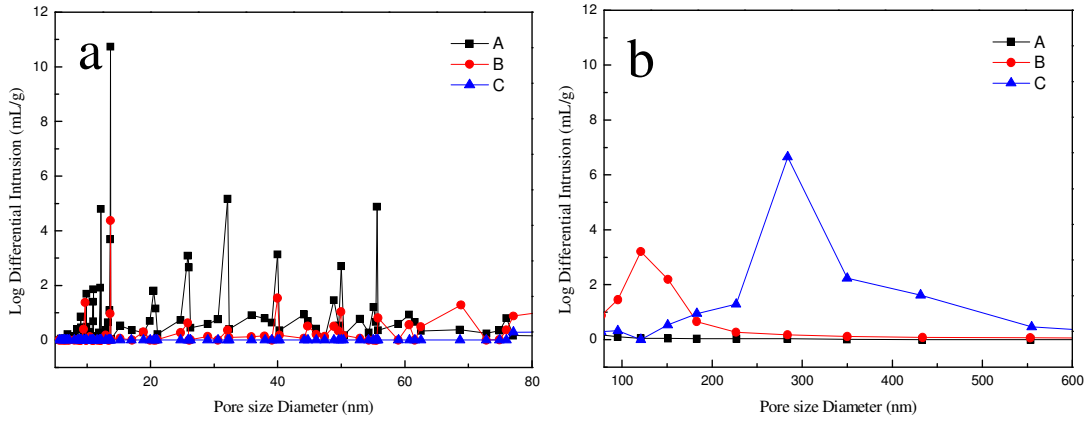

Fig. 1 Pore size distribution curves of the monolithic columns with three different porogenic systems（a: 5-80 nm, b: 80-600 nm）: cyclohexanol（A）; 1,4-butanediol（B）; 1-dodecanol（C）

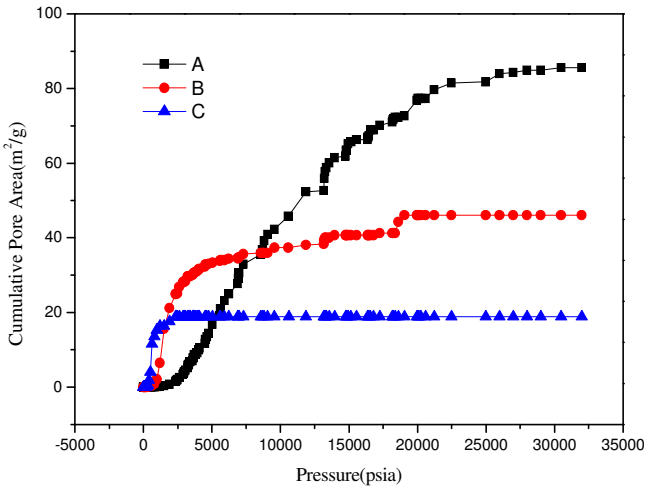

Fig. 2 Cumulative pore area changing as a function of pressure: cyclohexanol(A);1,4-butanediol（B);1-dodecanol（C）

Addition amount of porogenic agents effect on porous properties

The effects of amount of porogenic agents on porous properties were investigated by regulating the amount of 1-dodecanol of ternary porogenic system. Table3 gives the data of porous properties. As can be seen, as the amount of 1-dodecanol increased, the average pore size increased while the specific surface area decreased. Fig. 3 shows the pore size distribution curves of the monolithic columns with different amount of 1-dodecanol. The pore of MC-1 mainly distributed on the small pore interval(0~75 nm). MC-2 had a pore size of 300 nm at the highest peak in the distribution profile curve with a narrow distribution. MC-3 and MC-4 had a similar pore size distribution. Both of them had peaks in the interval of 0~15 nm and 2000~6000 nm, and most of pores distributed in the large pore interval. On the one hand, increasing the amount of porogenic agent could increase the porosity. On the other hand, the compatibility of the system to polymer decreased with the increasing of amount of 1-dodecanol. Consequently, those nuclei formed are likely to absorb monomers in the surrounding solution to increase their size. Thus, the globules formed are larger and the voids between pores are larger as well while the specific surface area decreasing.

Table 3 Pore properties of monolithic columns with different amount of 1-dodecanol

Sample	1-dodecanol[g]	Specific surface area[m^2/g]	Average pore size[nm]
MC-1	1.00	38.58	131.4
MC-2	1.22	18.87	308.8
MC-3	1.40	12.99	509.0
MC-4	1.60	12.00	630.8

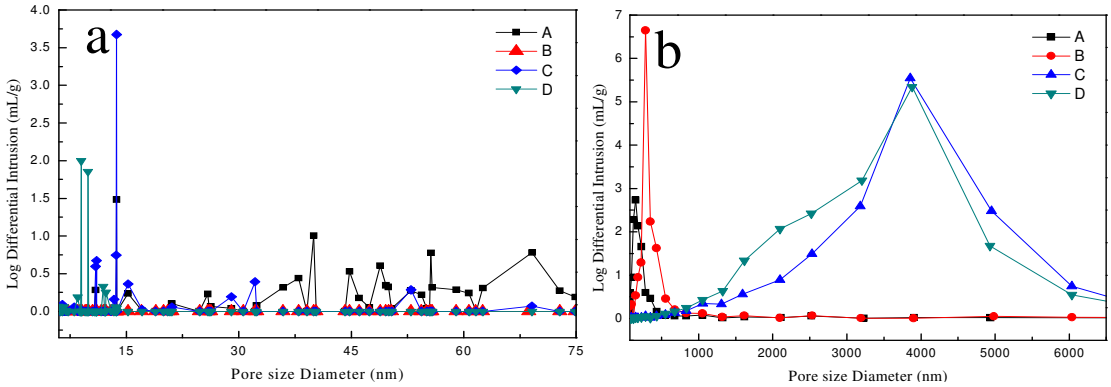

Fig. 3 The pore size distribution curves of the monolithic columns with different amount of 1-dodecanol（a: 5-75 nm, b: 75-6500 nm）, A：MC-1；B：MC-2；C：MC-3；D：MC-4

Proportion of porogenic agents effect on porous properties

As in Fig. 4, the SEM images of monolithic columns prepared by changing the proportion of porogenic agents. As shown, due to the increasing of compatibility of the system to polymer, with the increasing of amount of 1-propanol pore size decreased. Furthermore, the average pore size of MC-8 is 307.4 nm, and the specific surface area is 19.22 m2/g.

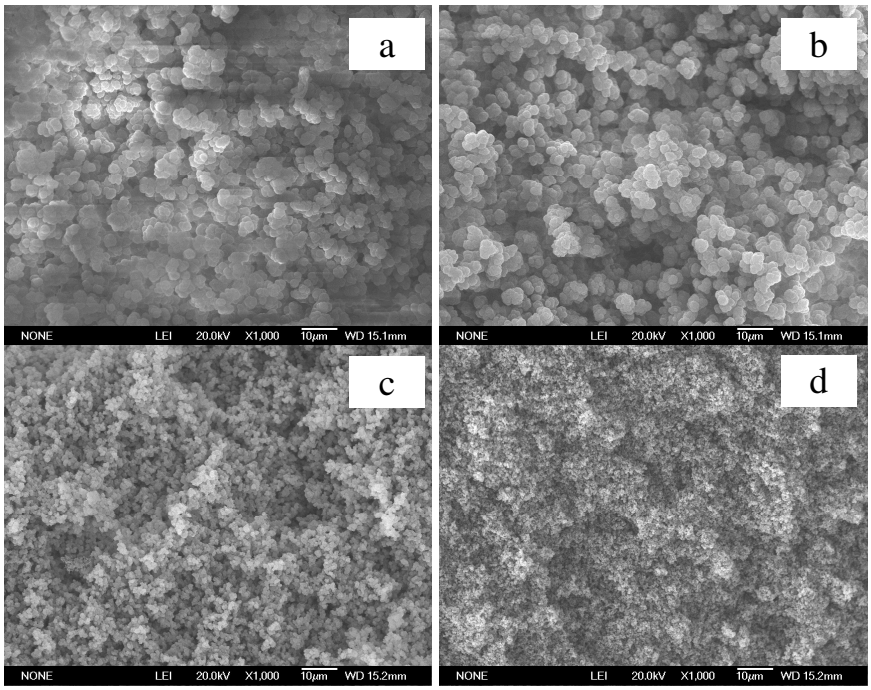

Fig. 4 The SEM images of monolithic columns prepared by changing the proportion of porogenic agents, a：MC-5；b：MC-6；c：MC-7；d：MC-8

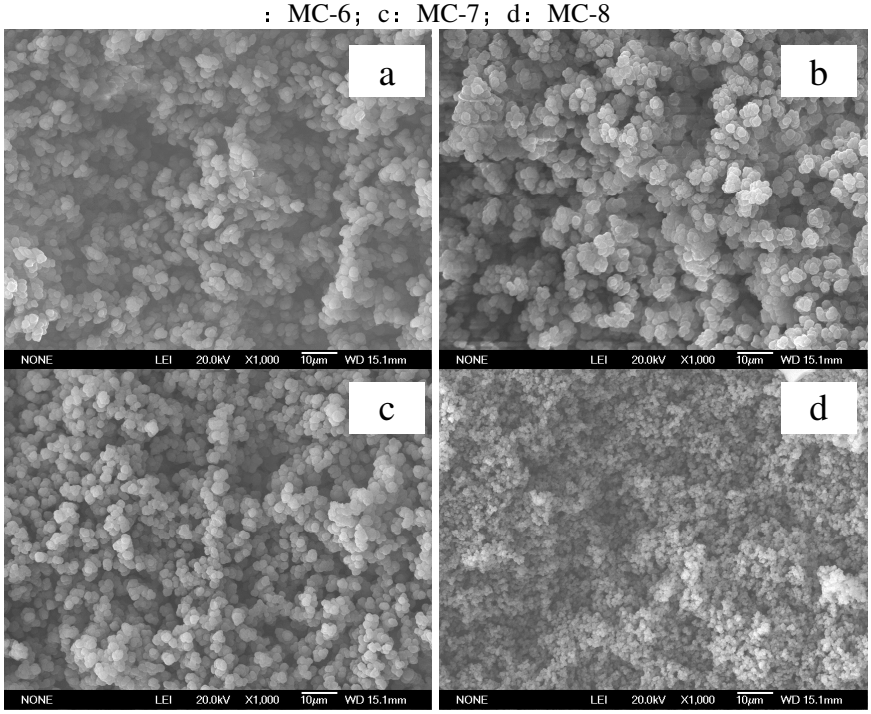

Fig. 5 The SEM images of monolithic columns prepared by changing the amount of crosslinker, a：MC-9；b：MC-10；c：MC-11；d：MC-12

Addition amount of crosslinker effect on porous properties

Fig. 5 shows the scanning electron microscopic images of monolithic columns prepared by changing the amount of crosslinker. As shown, pore size decreased with increasing of proportion of EGDMA, meanwhile, it had a more compact structure. Increasing the proportion of EGDMA resulted in an earlier phase separation in the polymer hence forming more nuclei. Besides, the increasing of crosslinking density restricted swelling of nuclei. Consequently, the globules formed in the system became smaller and the voids between them are smaller as well. The conclusion drawn is that increasing the proportion of crosslinker resulted in the decreasing of pore size. The average pore size of MC-12 is 438.4 nm, and the specific surface area is 14.88 m2/g. The pore size distribution curve of MC-12 is shown as Fig. 6. From Fig. 6 it can be seen that it had two remarkable peaks at about 11 nm and 1000 nm. It makes a conclusion that larger pores were formed by stacking of globules while smaller pores were within globules.

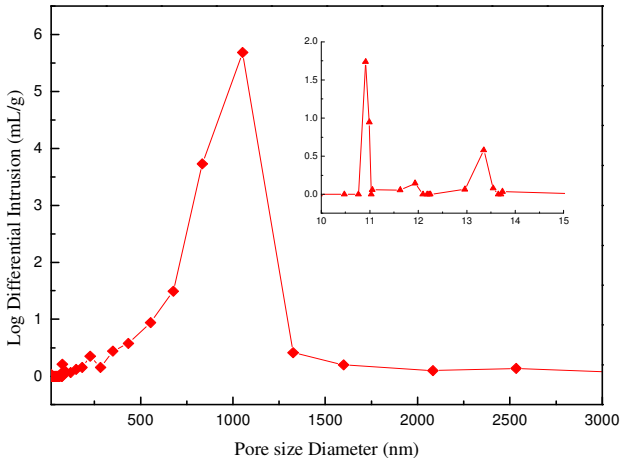

Fig. 6 The pore size distribution curve of MC-12

Addition amount of initiator effect on porous properties

Fig. 7 shows the SEM images of monolithic columns prepared by changing the amount of initiator. As shown, with increasing of amount of AIBN, pore size didn't change much. However, contrasting MC-13 and MC-16 it can be seen that MC-16 had a relatively smaller pore with a more compact structure. It can be explained that the increasing of initiator increased the amount of free radicals during the early stage of reaction. Consequently, more globules formed and the size of them decreased, which resulted in a smaller pore size. It makes a conclusion that increasing the amount of initiator results in a smaller pore size while the effects are not remarkable.

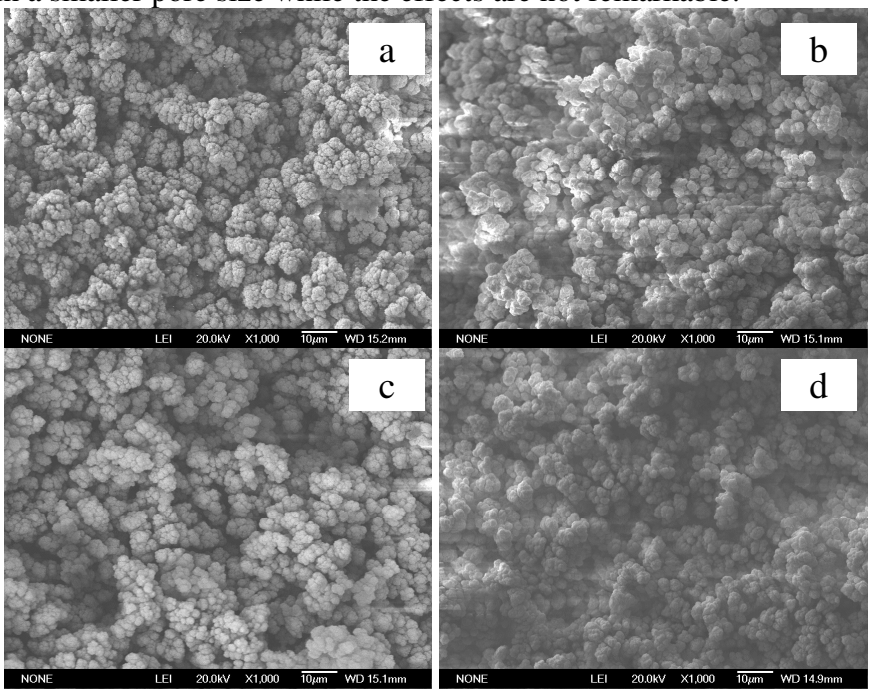

Fig. 7 The SEM images of monolithic columns prepared by changing the amount of initiator, a: MC-13; b: MC-14; c: MC-15; d: MC-16

The effects of reaction temperature on porous properties

Preparing monolithic columns at 40 ℃, 50 ℃ and 60 ℃ respectively to investigate the effects of reaction temperature on porous properties, the results indicated that MC-17 reacted incompletely as a result of the slow reaction rate. MC-18 and MC-3 reacted completely, and their SEM images were shown in Fig. 8. MC-3 had smaller globules, nevertheless, those small globules formed large clusters which made a more compact structure. The higher the reaction temperature, the greater the number of free-radicals generated per unit of time and the greater the number of nuclei and microspheres formed. Increasing the number of nuclei and microspheres necessarily decreases their size. Those nuclei preferred to gather into clusters before increasing their size. Besides, clusters formed went against

swelling. All of above restricted increasing of globules. Consequently, increasing the number of globules necessarily decreased their size so that smaller voids or pores between them appeared in the final copolymer.

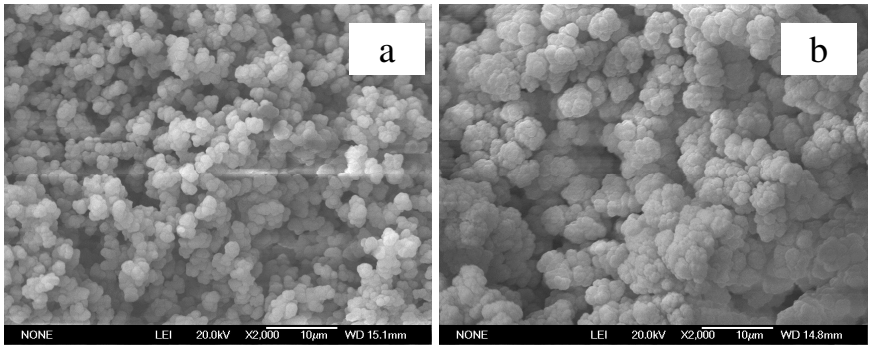

Fig. 8 The SEM images of monolithic columns prepared by changing reaction temperature, a：MC-3；b：MC-18

Conclusions

By means of investigating the effects of kind and amount of porogenic agents, amount of crosslinkers, amount of initiator and reaction temperature on porous properties of monolithic columns systematically, the influence rules of those factors were obtained. Results indicated that pore size decreased with the solubility of porogenic agents getting better. Monolithic columns prepared by the porogenic system of 1-dodecanol had the largest pore size, and increasing the amount of 1-dodecanol made the pore size increase with the largest average pore size reaching 630.8 nm. Increasing the amount of porogenic agents, decreasing the degree of crosslinking and decreasing the reaction temperature all could make pore size increase obviously. However, the amount of initiator didn't influence porous properties so much.

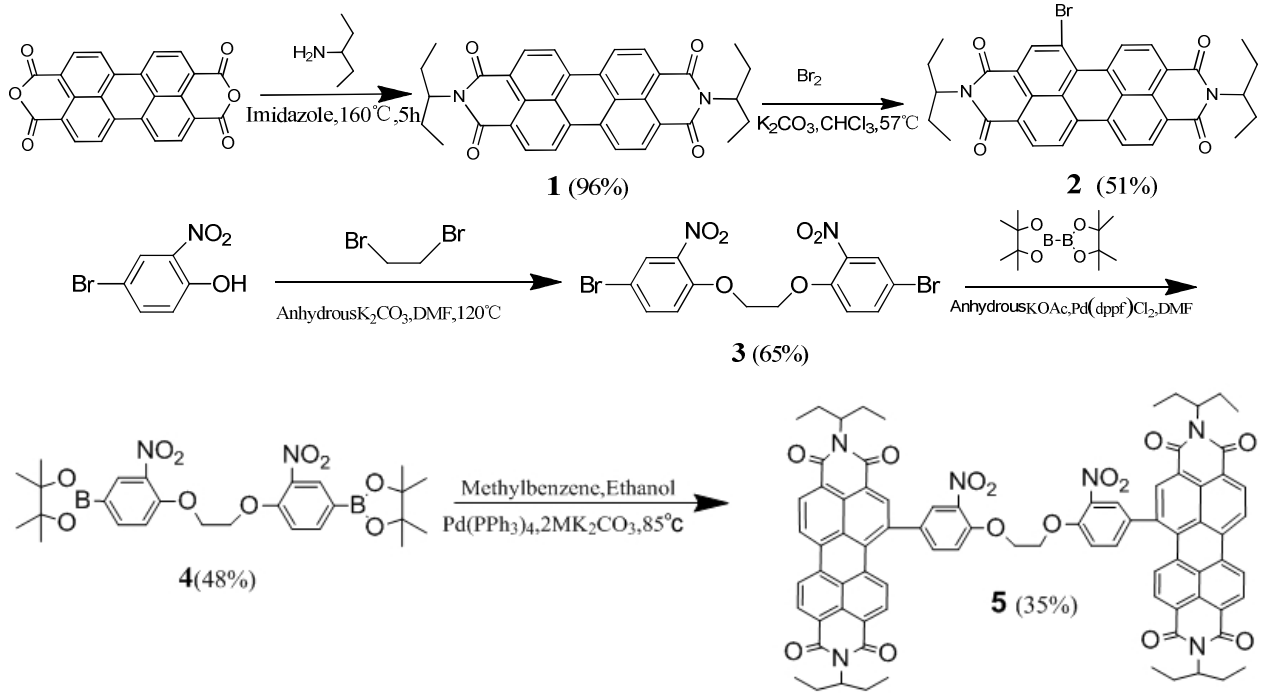
Keywords: Perylene dicarboximide, Electron withdrawing groups, Optoelectronic properties, Extinction coefficient, Fluorescence quantum yield.

Abstract: Perylene dicarboximide dimer with electron withdrawing groups were synthesized and fully characterized by ^{1}H-NMR and ^{13}C-NMR spectra. The effects of the substituted groups on the optical and electrochemical properties of the two compounds were investigated. The π–π* absorption peak of the perylene dicarboximide dimer compounds were red shifted from 525nm to 535nm. The band gaps of the dimer could be tuned from 2.28 eV to 2.13 eV. The first reduction wave of the dimer with electron withdrawing groups is shifted by 60 mV to more positive potential compared to that of perylene dicarboximide, suggesting the enhanced electron affinity. Furthemore, the dimer exhibited intermolecular aggregation, and decrease fluorescence quantum yield.

Introduction



Rylenes and their dicarboxylic imide derivatives are key chromophores due to their excellent chemical and photostability [1,2]. The absorption, and emission behavior of this class of materials can be efficiently controlled by functionalization using a variety of different synthetic procedures[3]. Up to now, perylenebis(dicarboximide) and higher rylenes, namely terrylene, quaterrylene, pentarylene, and hexarylene, have been synthesized[4,7]. Perylene dicarboximide *(PDIs)*, the well-known rylenes, have received considerable attention in dye chemistry, supramolecular assemblies, and optoelectronic applications because of their exceptional properties, such as photochemical stabilities, high quantum yields[8], and ability to self-assemble into ordered supramolecular structures[9]. Modifications of PDIs have been concentrated on the bay regions, at which chemical substitution can dramatically alter the intermolecular interactions, and the optical electronic properties[10,11]. Furthermore, the core-extended of PDIs attract huge interest and offer access to various biological [12] as well as organic electronic applications[13].

Our current interests are development of the new rylenes dicarboxylic imide compounds with functional groups for use as stable fluorophores[14,15,16]. In this paper, the synthesis of the perylene diimides dimer with electron withdrawing groups was present, and their optical and electrochemical properties were further investigated.

Results and Discussion

The synthetic approach of compound 1 and 5 is outlined in Scheme 1. Compound 1 and Compound 2 were synthesized according to literature methods. Imidazole melting method between

perylene tetracarboxylic acid dianhydride and 3-aminopentane to give compound 1, which was brominated to afford compound 2. Electrophilic substitution between 4-bromo-2-nitrophenol and 1,2-dibromoethane gave the intermediate compound 3 (1,2-bis(4-bromo-2-nitrophenoxy)ethane) in a yield of 65%. Conversion of 3 into diboronate ester 4 was achieved under Miyaura reaction conditions in the presence of bis(pinacolato)diborane, $Pd(dppf)_2Cl_2$ and KOAc with dry DMF as the solvent. The objective product compound 5 was obtained by Pd-catalyzed Suzuki coupling reaction between compound 2 and compound 4. After purification by silica gel column chromatography, pure compound 5 was obtained in good yield of 35%. Structures of all these products were confirmed by ^{1}H-NMR and ^{13}C-NMR spectra.

Scheme.1, Synthetic sequence of perylene dicarboximide dimer compound.

The absorption of compound 1 and 5 was recorded in dichloromethane (Fig. 1, A). The absorption bands of compound 1 with peak at 525 nm are attributed to the perylene dicarboximide core π–π* transition, along with two higher vibronic transitions located at 495 and 462 nm, which is a typical dissolved PDI molecule (Fig. 1, A). Compared with compound 1, the π–π* transition absorption of compound 5 are red shifted from 525 nm to 535 nm. This is because the reinforcing of the conjugation between perylene diimides core and benzene on the bay region. The compound 1 exhibits a very high fluorescence quantum efficiency, almost 100%. When the solution concentration increases from 10^{-5}mol L^{-1} to 10^{-4}mol L^{-1}, the fluorescence quantum efficiency of compound 1 almost unchanged. The compound 5 exhibited a 62% fluorescence quantum yield in a low concentration of 10^{-5}mol L^{-1}. However, at a high concentrations of 10^{-4}mol L^{-1}, the fluorescence quantum efficiency reduced to 45%(Fig. 1, B). This is due to the behavior of dimer intermolecular aggregation , leading to a decrease in the fluorescence quantum efficiency.

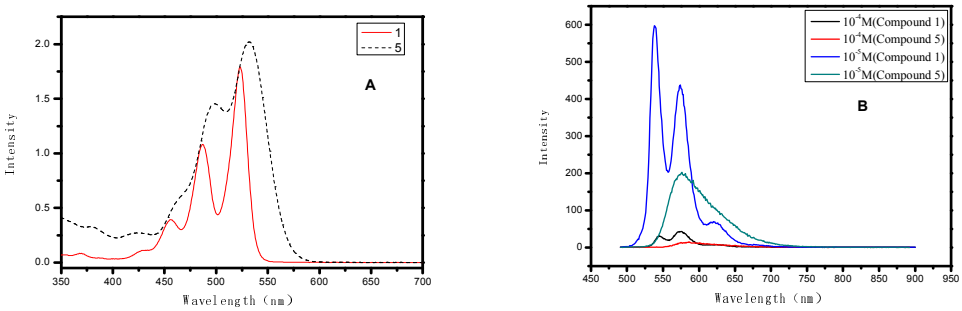


Fig. 1, The absorption spectra(A) and fluorescence emission spectrum(B) of compounds 1 and 5 in CH_2Cl_2 solution with a concentration of 2×10^{-5}mol L^{-1}.

The aggregation behaviors of PDIs in dichloromethane solution were studied by the concentration-dependent UV-vis absorption spectroscopy (Fig. 2). The aggregation in CH_2Cl_2 solution was further supported by the changes in the absorption extinction coefficient at different concentrations. Upon increasing the concentration range from 1.0×10^{-5} mol L^{-1} to 1.0×10^{-4}mol L^{-1}. the extinction coefficient (0–0 transition) of compound 1 did not change. Due to the aggregation, a non-Lambert–Beer law behavior was observed for the investigated compound 5. In the same concentration range, the extinction coefficient (0–0 transition) of compound 5 decreased by 33% (14.7×10^{-4} $M^{-1}cm^{-1}$ to 9.9×10^{-4} $M^{-1}cm^{-1}$). This indicates, the dimer molecule exhibited aggregation behavior in a relatively high concentration.

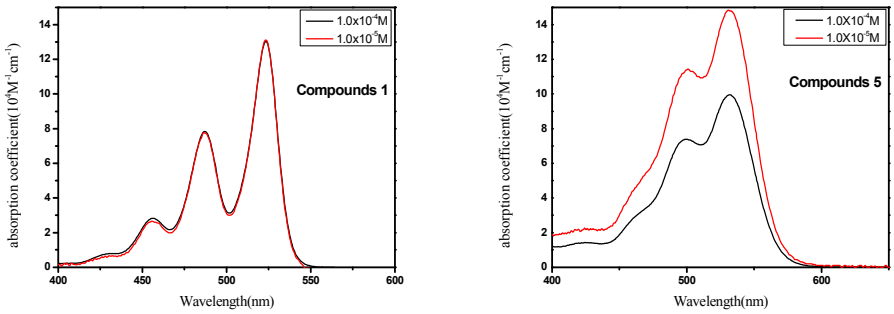

Fig. 2, Concentration-dependent UV-vis absorption spectra of compound 1 and 5 in CH_2Cl_2 solution at 20℃.

The electrochemical properties of compounds 1 and 5 were studied by cyclic voltammetry (CV)experiments. Cyclic voltammetry was performed on a CHI-660b electrochemical analyzer with a three-electrode cell in 2-3mg/mL compound dichloromethane solution with 0.1 M tetrabutylammonium hexafluorophosphate at a scan rate of 100 mV/s. A Pt disk (2-mm diameter) was used as working electrode with a Pt wire as the counter electrode and a calomel electrode as the reference electrode. The redox potential was calibrated with ferrocene/ferrocenium (0.44 V vs Calomel). The corresponding data are collected in Table 1. Figure 3 shows the cyclic voltammograms of compound 1 and 5. The CV scan for compound 1 and 5 with anodic scanning from 0 to 2 V shows no peaks. On cathodic scanning, compound 1 exhibits one reversible reduction wave at -0.66 V versus Calomel and the second irreversible reduction wave at -0.89 V. Compounds 5 also exhibit two reduction waves. The first reduction wave of compound 5 is shifted by 60 mV to more positive potential compared to that of compound 1, suggesting the enhanced electron affinity. Compound 5 has one electron-withdrawing groups in the bay region of the PDIs, which is a polarized species and enhanced the reduction potentials dramatically.

The optical band gap (E^o_g) levels, the lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO) of these compounds were determined from their

electrochemical data and their absorption data. Optical band gap was obtained from the Eq. 1. The LUMO was estimated from the onset reduction potentials(Eq. 2), and the HOMO of these compounds was estimated from the Eq. 3. The E^o_g levels of compound 5 are shifted from 2.28 to 2.13eV compared with compound 1. The LUMO of compound 5 is -3.80eV , reduced 60mV compared with compound 1. The HOMO of compounds 1 and 5 are -5.93 and -6.02 eV, respectively. In comparison, compound 5 has relatively lower LUMO and small band gap. This indicates that the LUMO lie on the polarized electron-deficient parts of compound 5, and the HOMO lie on the perylene dicarboximide core.

TABLE 1 OPTICAL AND ELECTROCHEMICAL PROPERTIES AND BAND GAP DATA OF COMPOUND 1 AND 2

Compound	λ_{onset}(nm)	E^0_g(eV)	LUMO(eV)	E_{red}(eV)	HOMO(eV)
1	543.93	2.28	-3.74	-0.66	-5.93
5	581.40	2.13	-3.80	-0.60	-6.02

$$E^o_g = 1240/\lambda^{abs}{}_{onset}. \quad (1)$$

$$LUMO = -(4.40 + E_{red}). \quad (2)$$

$$HOMO = LUMO - E^o_g. \quad (3)$$

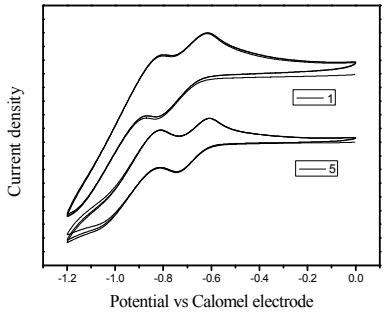

Fig. 3, Cyclic voltammograms of compounds 1 and 5 were performed with a three-electrode cell in dichloromethane solution.

Conclusions

In summary, the perylene dicarboximide dimer with electron withdrawing groups have been successfully designed and synthesized. The optical and electrochemical properties and band gap of the dimer and compound 1 were investigated. Introduction of aromatic substituent on the bay of the perylene dicarboximide resulted in the red shifted π–π* transition absorption and smaller band gap. The dimer molecule exhibited aggregation behavior, which lead to low extinction coefficient and fluorescence quantum efficiency. The addition of electronwithdrawing groups onto the lead to a high electron-accepting capability and lower LUMO level.

Keywords: polyanilne fibres, electrochemical polymerization, p-aminodiphenylamine, oligomer; conductive polymer

Abstract: In this paper, polyaniline(PANI) fibres were prepared by electrochemical polymerization from the solutions of aniline and hydrochloric acid in the presence of different concentrations of aniline oligomer. The influences of adding a small amount of aniline oligomeric additives, such as p-aminodiphenylamine (PADPA), p-phenylenediamine (PPDA) to the electrochemical polymerization system of aniline on polyaniline fibres have been investigated. Change in fibre diameter with the concentration of aniline oligomer were investigated. Morphologies of PANI fibres were characterized by scanning electron microscopy (SEM). Electrochemical behaviors of PANI fibres were studied by cyclic voltammetry (CV). The results show that with the addition of PADPA, PPDA to aniline polymerization system, the rate of polymerization increases greatly, and more lower potentials can be applied to generate electroactive PANI fibres with more finer and uniform structure.

Introduction

It is known that the polymerization of aniline is an autocatalytic process[1]. With potentiostatic techniques the initial formation of PANI on the surface of the electrode is slow, but the initially formed PANI accelerated the polymer growth greatly. However, the quantitative description and interpretation of this process are still unclear. The role played by PADPA during the electrochemical polymerization of aniline in acid medium on platinum electrodes was proposed for the first time by Mohilner in the early 1960s[2]. The polymerization mechanism involved a so-called “head-to-tail” coupling of two aniline radical cations that, as it was pointed out, gave rise to the PADPA and subsequently to an oligomeric growth. This hypothesis was confirmed some years later by Bacon and Adams, who identified PADPA as the main product formed during the initial stages of aniline oxidation on carbon paste electrodes[1]. In the present paper, a small amount of aniline oligomeric additives, such as PADPA , PPDA is intentionally introduced in the aniline polymerization system. The effects of the additives on the rate of electrochemical polymerization of aniline are investigated. The morphologies of the PANI prepared in the presence of the additives are studied by scanning electron microscopy. The results are discussed in relation to the mechanism of polymerization of aniline.

Experimental Section

Aniline was purchased from Sinopharm Chem. Reagent Co. Ltd (Beijing, China) and were doubly distilled under reduced pressure before use. The PADPA, PPDA supplied by Aldrich were used without further purification. The monomers employed for the polymerization reaction were of reagent grade. Electrochemical polymerization of aniline was performed by CHI660D electrochemistry work-station (Shanghai Chenhua Instrument CO., Ltd.) under programmed computer control. A three-electrode cell was employed with a saturated calomel electrode (SCE) as reference electrode. Platinum foils were used as both the counter electrode (3.0 cm^2) and the working electrode whose size varied in each specific experiment. Platinum electrodes were pretreated by dipping in hydrochloric acid for 1 minute, followed by wash in acetone and deionized water. PANI were prepared on a

platinum working electrode in a 1.0 M hydrochloric acid, 0.2 M aniline aqueous solution with 0-2.0 mM additives at room temperature.

Results and Discussion

Effects of PADPA and PPDA on electrochemical polymerization of PANI

The anodic peak at near 0.18 V vs SCE in Fig. 1(a) has been well understood as the oxidation of PANI deposited on the electrodes which corresponds to the conversion of amine units to radical cations. At this potential, neither polymerization of aniline nor other side reactions were observed. The peak current increased continually with successive potential scans, indicating the build up of the electroactive PANI in the solution. However, the corresponding reduction peak is not obvious. It can been seen that there is no PANI formed on the electrode surface without additives when switch potential is 0.8V.

When the electrochemical polymerization switch potential is increased to 1.0V, as shown in Fig. 1(b), the redox peaks of aniline in the electrochemical polymerization are greatly increased. This indicates that the rate of the electrochemical polymerization increased significantly. In the first scan of Fig. 1(c), an anodic peak due to the oxidation of the PADPA appeared at +0.48 V vs. SCE, whereas no reaction occurs at this potential for the system without PADPA. In general, characteristics of the cyclic voltammograms are similar in this systems. The anodic peak at +0.17-0.19 V can be assigned to the oxidation of PANI deposited on the electrode, corresponding to the conversion of amine units to radical cations in the polymer chain. It was found that the mass and thickness of the PANI film formed on the electrode are proportional to the anodic peak current at +0.18 V[13]. Therefore, the rate of polymerization can be measured by the rate of increase in this peak current. There are two pairs of redox peaks, at 017-0.19/0.03V, 0.48/0.44V, corresponding to the different redox patterns, respectively, as shown in Fig. 1(c). This indicates that the presence of PADPA will lower the polymerization potential and accelerate the rate of polymerization, which would produce more finer fibres. Fig.1(d) indicates that the addition of PPDA to the aniline system will increase the rate of polymerization and lower the polymerization potential[4, 5]. In addition, more finer and longer fibres could be obtained.

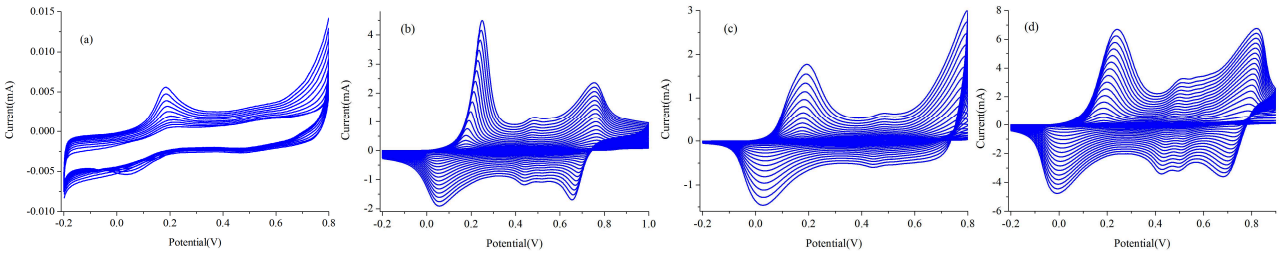

Fig. 1 Cyclic voltammograms of aniline polymerization in a 1.0 M HCl aqueous solution containing 0.2 M of aniline at 50 mV·s-1, (a) no additives, scanning between -0.2 and 0.8V, (b) no additives, scanning between -0.2 and 1.0 V, (c) 2.0 mM PADPA, scanning between -0.2 and 0.8V, (d) 5.0 mM PPDA, scanning between -0.2 and 0.9V.

It is apparent that the growth of the PANI film is faster for the system with the additives than that without the additives. Similar to what has been usually accepted for PANI, it can be assumed that the mass of the PANI film deposited onto the electrode surface is proportional to the peak current measured on the cyclic voltammograms. When the amount of PANI deposited on the electrode is higher, the rate of polymer formation slows down. This could be attributed to an increase in the film thickness as the amount of polymer on the electrode increases. Thus, in order to accelerate the polymerization, the polymer has to be in contact with the solution, i.e., with the monomer. When the polymer film thickness increases, the polymer that has been produced during the earlier period of reaction will be covered by the polymer that has been produced later, even though the effective surface area of the polymer may increase with the reaction time due to a fibrillar morphology. As a result, the polymer deposited earlier will no longer be in contact with solution, and it will contribute no effect to the reaction rate.

Morphology and structure of PANI

Scanning electron microscopy was used to examine the morphology of PANI prepared with different concentrations of PADPA, PPDA additives. A fibrillar morphology was observed for all the samples. The PANI film prepared with the PADPA, PPDA was more finer than that without the additives. Furthermore, the uniformity of the film also increased with an increase in the switch potential. These results agree well with the proposed mechanism. Thus, both the addition of the additives and the higher switch potential would result in more initiation species on which the polymer chains grow. Fig. 2 show the SEM of PANI prepared by potentiostatic 0.8 V for 2000 s, in 1 M HCl and 0.3 M aniline solution containing different concentrations of PADPA. As can be seen in Fig. 2, the diameter of the PANI fibres become smaller with the increasing of PADPA. At 0.3 mM PADPA, the PANI fibres are wider in diameter. From 0.3 mM to 2.4 mM, the diameter of the PANI fibres is decreasing. This indicates that the PADPA could accelerate the polymerization rate and make the fibres more finer.

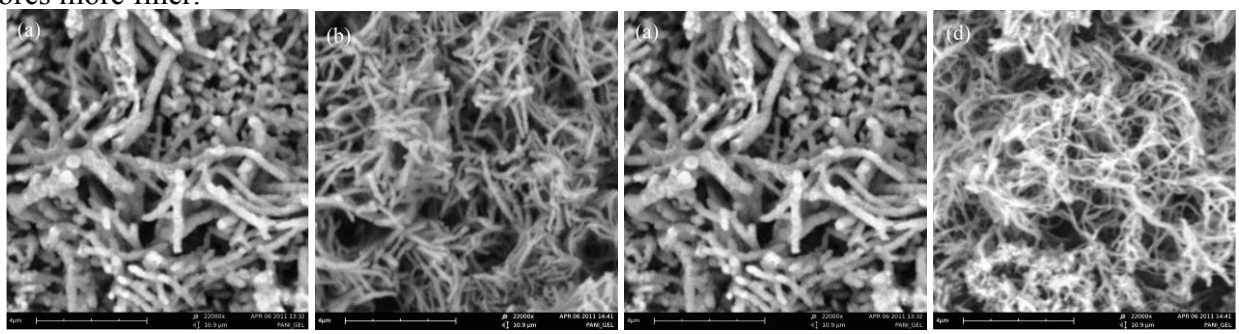

Fig. 2 SEM of PANI prepared by potentiostatic 0.8V for 2000s, in 1M HCl and 0.3M aniline solution containing PADPA: (a) 0.3 mM, (b) 1.0 mM, (c)1.7 mM, (d)2.4 mM.

Fig. 3 shows the SEM of PANI prepared by potentiostatic 0.8 V for 2000 s, in 1 M HCl and 0.3 M aniline solution containing different concentrations of PPDA. As can be seen in Fig. 3, the diameter of the PANI fibres become finer with the increasing of PPDA. However, this trend is not very obvious compared to PADPA. It shows that, compared with the PADPA, PPDA has more effect on the length of the fibres. In the presence of PPDA, the length of the PANI fibres formed is obvious longer than in the presence of PADPA. The growing mechamism for longer fibres is probably related to the two amidos of PPDA which give it more reaction positions. This makes it possibility that more uniform PANI could be obtained.

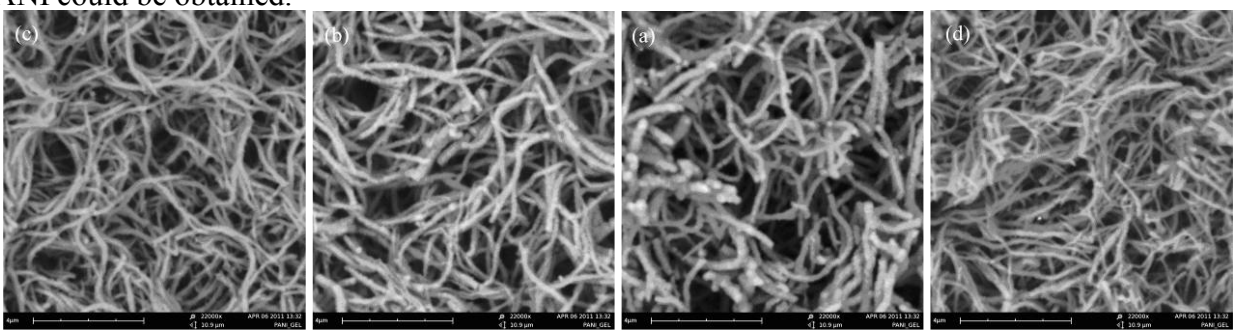

Fig. 3 SEM of PANI prepared by potentiostatic 0.8 V for (a) 2000 s, (b) to (e) 1000 s, in 1 M HCl and 0.3 M aniline solution containing PPDA (a) 0.3 mM, (b) 1.0 mM, (c) 1.7 mM, (d) 2.4 mM.

It can be seen that the fibre will become finer with the addition of oligomeric additives, such as PADPA, PPDA. As for PADPA in Fig.4, the diameter decreases greatly from about 480 nm to 220 nm with the concentrations of PADPA increasing from 0.1 mM to 1.0 mM. The fibre decreases slowly to 160 nm in diameter when PADPA was 2.4 mM. As for PPDA, the diameter decreases greatly from about 480 nm to 321 nm with the concentrations of PPDA increasing from 0.1 mM to 0.5 mM. Then the fibre decreases slowly to 208 nm in diameter when PADPA was 2.4 mM. It can be concluded that the addition of PADPA or PPDA could modify the diameter of the PANI fibres.

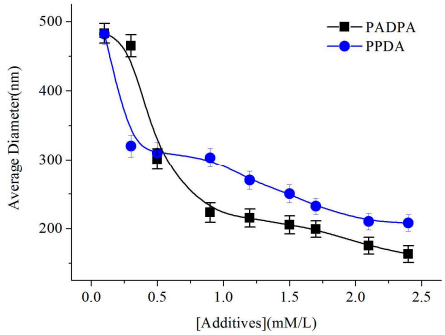

Fig. 4 The average diameter of the PANI fibre.

Electrochemical characterization of the PANI formed

Fig. 5 shows that cyclic voltammograms of PANI at a scan rate of 50 mV·s-1 in 1.0 M HCl aqueous solution without aniline. Fig. 5(a) is cyclic voltammograms of PANI formed according to electrochemical polymerization conditions of Fig. 1(b) without additives. Fig. 5(b) and (c) is in the presence of 2.0 mM PADPA and 1.2 mM PPDA, respectively. In comparison with these three Fig.s, it can be seen that the anodic peaks at 0.24, 0.21 and 0.23 V respectively. It indicates that the polymerization potential is lower about 30 mV in the presence of 2.0 mM PADPA. The results obtained confirm the earlier established catalytic effect on the potential of the redox reaction by shifting it to more negative values. In the presence of PPDA, the potential of the redox reaction did not change much, however, the fibres will grow more longer and finer. This has been proved by the SEM data.

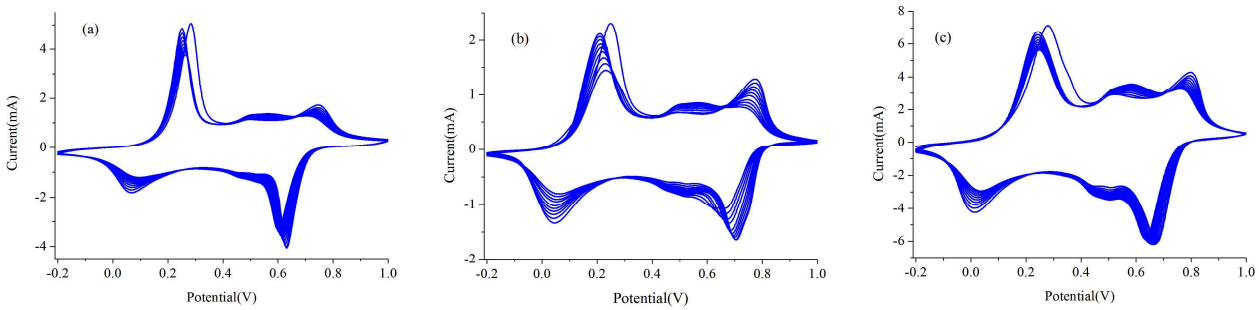

Fig. 5 Cyclic voltammograms of PANI at 50 mV·s-1 in 1.0 M HCl aqueous solution without aniline. PANI formed (a) no additives, polymerization conditions of Fig. 1(b); (b) with 2.0 mM PADPA, Fig. 1(c); (c) with 1.2 mM PADPA , polymerization conditions of Fig. 1(d).

The effects of switch potential on the rate of polymerization with or without the additives are compared. In general, a higher rate of polymerization can be achieved by increasing the switch potential, at the risk, however, of polymer degradation and other undesired side reactions. The polymerization of aniline in the presence of the PADPA, PPDA can proceed at lower switch potentials without sacrificing the rate of polymerization. PANI was formed at a potential as low as +0.55 V in the presence of the PADPA, whereas no polymer formed at this potential in the absence of the PADPA within a reasonable time span. When the switch potential was increased to +0.9 V or above, the rates of polymerization became essentially the same for the system with the additives and for that without.

Conclusions

The results of these investigations confirm that the addition of PADPA, PPDA to aniline monomers polymerization solution can fast the polymerization rate, lower the polymerization potential, and produce electroactive PANI with more finer or longer fibrillar structure. The PADPA have more effect on forming finer fibres and PPDA is contribute to form longer fibres. This results in a more compact, uniform and finer PANI compared to pure aniline solution, indicating that by administering a predetermined concentration of PADPA, PPDA, the morphology and structure of the resulting PANI could be tailored.

Keywords: polyaniline fibres, electrodeposition, cyclic voltammetry, morphology

Abstract. Electroactive polyaniline fibres have been prepared by eletrodeposition in aniline and hydrochloric acid aqueous media. The influence of applied potential and polymerization time on the electrochemical polymerization of polyaniline fibres have been investigated. Morphology and structure of PANI were characterized by scanning electron microscopy. Electrochemical behaviors of PANI were studied by cyclic voltammetry. The results show that the applied potential and the polymerization time have a crucial influence on the polymerization rate and conductivity of the PANI prepared. It indicates that the properties, as well as the morphology of PANI, could be changed by applied potential and po-lymerization time, etc. This change might result in the quality of PANI suitable for specific applications.

Introduction

Among all of CPs, PANI is a particularly attractive material because it has a moderately high electrical conductivity upon doping with protonic acids and its interesting electrochemical behavior [1, 2]. PANI can be prepared either chemically or electrochemically. Although polyaniline have been studied much, many problem are still not solved about polyaniline fibres which quality suitable for specific ap-plications.

In the present paper, the influence of applied potential and polymerization time on the electrochemical polymerization of polyaniline fibres have been investigated. With hydrochloric acid, as doping acids, the polyaniline fibres were obtained. The structure and morphology of PANI were characterized. The elec-trochemical properties of the polyaniline fibres were studied by CV. The results are discussed in relation to the mechanism of polymerization of aniline.

Experimental Section

Materials

Aniline (analytical pure grade) was purchased from Sinopharm Chem. Reagent Co. Ltd (Beijing, China) and were doubly distilled under reduced pressure before use. Hydrochloric acid (analytical pure grade) were bought from Beijing Chem. Reagent Co. (Beijing, China) and were used without further purifica-tion.

Preparation and characterization of polyaniline fibres

Electrochemical polymerization of aniline was performed by CHI660D electrochemistry work-station (Shanghai Chenhua Instrument CO., Ltd.). A three-electrode cell was employed with a saturated calomel electrode (SCE) as reference electrode. Platinum foils were used as counter electrode and working elec-trode. Platinum electrodes were pretreated by dipping in hydrochloric acid for 1 minute, followed by wash in acetone and deionized water. Polyaniline fibres were prepared on a platinum working electrode in a 0.5 M aniline aqueous solution with 1.0 M hydrochloric acid at room temperature. The electrochemical properties of the polyaniline fibres were characterized in an aniline free, 1.0 M hydrochloric acid aqueous solution. The microstructure of the PANI was examined by SEM.

Result s and Discussion

Electrochemical polymerization of polyaniline

Fig. 1(a) shows the cyclic voltammogram transients traced during the PANI polyaniline fibres with Pt electrode at a scan rate of 20 mV/s in an solution of 0.5 M aniline and 1 M HCl, scanning beween 0.2 V and 1.25 V. It can be seen in Fig. 1(a) that there are three anodic peaks, and these anodic peak current is gradually increased with the scanning numbers. The peak potentials are shifting to more positive potential with scanning cycles. This indicates that the quantity of PANI formed is increasing, and the electrochemical stability is improved. As the energy barrier which initiates the polymerization is higher than the energy barrier which maintains the reaction, polymerization proceeds slowly in the initiation stage. PANI polymerization is a selfcatalytic reaction process, and the generated PANI could accelerate the following reaction. In the fifth cycle, the first anodic peak is at 0.57 V, the second anodic peak is at 0.83 V and the third anodic peak is at 1.17 V. However, in the twentieth cycle, the first anodic peak is at 0.74 V, the second anodic peak is at 0.94 V and the third anodic peak is at 1.15 V. This indicates the changes of the electroactivity of PANI fibres formed. PANI prepared by electrochemically is fibrous morphology. Compared with the electrochemical and chemical polymerization methods, the fibres formed by electrochemically is longer than formed by chemically. It indicates that uniform and conductive PANI fibres was easy to be produced by electrochemical methods.

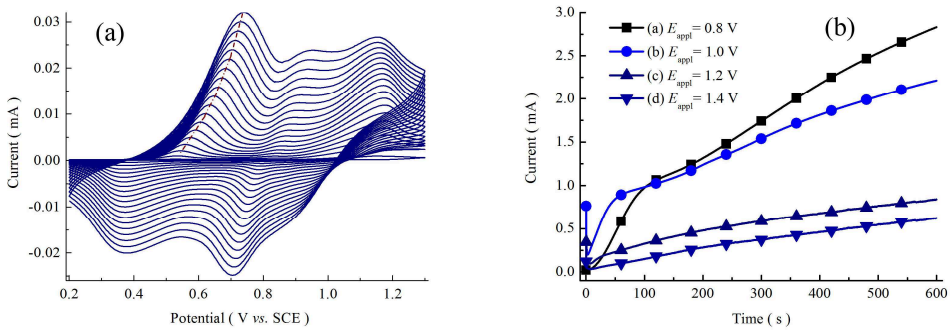

Fig. 1 (a) Cyclic voltammogram transients traced during the PANI fibres polymerization in 0.5 M aniline and 1 M HCl, v =20 mV/s, 20 cycles.(b) Potentiostatic current-time curves of the PANI fibres electrosynthesis process in 0.3 M aniline and 1 M HCl solution at different applied potentials(E_{appl}).

When the amount of PANI deposited on the electrode is higher, the rate of polymer formation slows down. This could be attributed to an increase in the film thickness as the amount of polymer on the electrode increases. Thus, in order to accelerate the polymerization, the polymer has to be in contact with the solution, i.e., with the monomer[3, 4]. When the polymer film thickness increases, the polymer that has been produced during the earlier period of reaction will be covered by the polymer that has been produced later, even though the effective surface area of the polymer may increase with the reaction time due to a fibrillar morphology. As a result, the polymer deposited earlier will no longer be in contact with solution, and it will contribute no effect on the reaction rate.

Previous studies have shown that when PANI polymerization potential is higher than 0.8 V, the π conjugated structure of polymer could be partly destroyed for the overoxidation, which could reduce it's conductivity[5]. However, when the polymerization potential is lower than 0.6 V, the electrosynthesis is difficult to proceed and could not form a film on the electrodes effectively. Fig. 1(b) shows the potentiostatic currenttime curves of the PANI fibres electrosynthesis process in a 0.3 M aniline and 1 M HCl solution at different applied potentials. It is accepted that the reaction current is proportional to the rate of polymerization[6]. Then, it could be concluded that the reaction rate is decreasing with the increasing of applied potentials from 0.8 V to 1.4 V. As for 1.4 V, the rate of polymerization is the lowest. Considering the polymerization rate, electrical conductivity and other physical and chemical properties, PANI polymerization potential is generally between 0.7-1.0 V, and the optimized applied potential is about 0.7-0.8 V.

Morphology and structure of PANI

Scanning electron microscopy was used to examine the morphology of PANI fibres with different applied potential and polymerization time. It was observed that the PANI prepared with hydrochloric acid was fibrillar morphology. Fig. 2 shows the SEM images of PANI electrodeposited on Pt at different constant potential in an solution of 0.3 M aniline and 1 M HCl. The morphology of the PANI prepared at different applied potential is similar to each other. However, the fibres prepared at 0.8 V is finer and sparseness compared to others formed at higher applied potential. The electroactive area of the PANI is decreasing with the increasing of the applied potential from 0.8 V to 1.4 V. At 1.2 V, the diameter of the fibre is wider than low potential produced. In order to obtain large electroactive area and high conductivity of PANI, the optimized applied potential is between 0.8 V and 1.0 V.

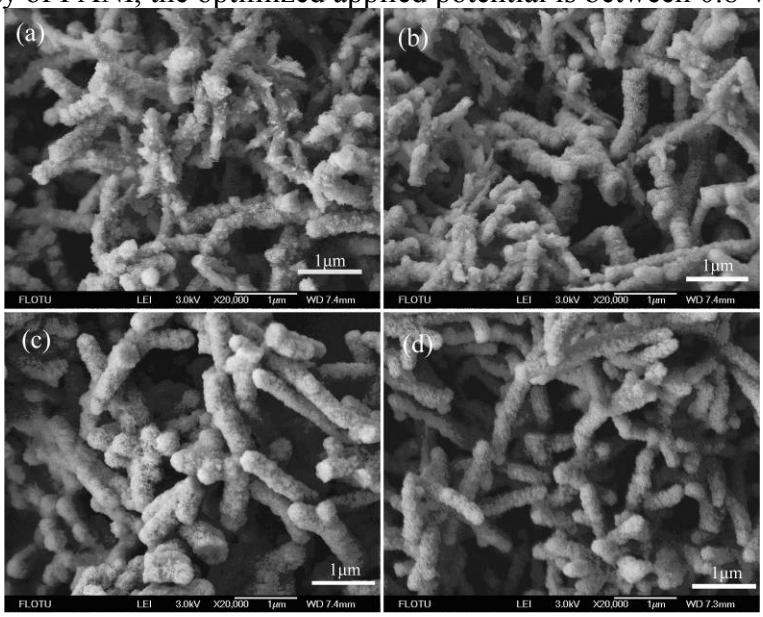

Fig. 2 SEM images of PANI fibres electrodeposited on Pt at different constant potential Eappl in an solution of 0.3 M aniline and 1 M HCl.: (a) 0.8V, (b) 1.0 V, (c) 1.2V and (d) 1.4V, time (a)-(c) 600s, (d) 300s.

Fig. 3 shows the SEM images of PANI electrosynthesized on Pt at 0.85 V for different time in an solution of 0.3 M aniline and 1 M HCl. As can be seen in Fig. 3, the diameter of the PANI fibres become wider with the polymerization time increasing. The PANI fibre is fine and short when polymerization 180s. With the polymerization time increasing, the fibre is becoming more and more wider in diameter and longer in length. It indicates that the molecular weight grows with the polymerization time. As Fig. 3(d) shows, the fibre is about 500 nm in diameter and is longer than 5 μm in length. In this view, the solubility and physical property could be modulated.

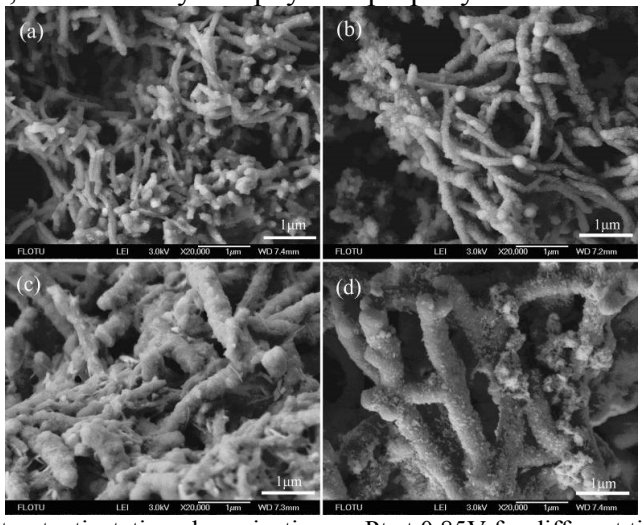

Fig. 3 SEM images of PANI at potentiostatic polymerization on Pt at 0.85V for different time in an solution of 0.3 M An and 1 M HCl.: (a) 180s, (b) 360s, (c) 720s and (d) 1440s.

Electrochemical characterization of the PANI

Fig. 4 shows cyclic voltammograms of PANI fibres synthesized by potentiostatic method at different applied potential, where the electrode potential was continuously swept between -0.2 and 1.0 V vs SCE at a scan rate of 100 $mV \cdot s^{-1}$. As can be seen in Fig. 4, with different synthesized potential, the peak potential will shift. When the synthesized potential is 0.8 V, anodic peak potential is about 0.17 V, the peak current is 0.71 mA. As for PANI fibres prepared at 1.1 V, the anodic peak potential is shift to 0.27 V, and the peak current is increasing to 0.83 mA. With the synthesized potential increasing to 1.4 V, the anodic peak potential is about 0.26 V, however, the peak current is decreasing much to 0.39 mA. Fig. 4 shows that the anodic peak potential of PANI fibres synthesized at 0.8 V is more negative than that synthesized at 1.1V and 1.4V. Compared with the Fig. 4(b) and (c), it can be observed that the peak current of 1.4V is lower than that of 1.1V. This indicates that PANI fibres synthesized at about 0.8 V has lower anodic peak potential and have good electroactivity. When the potential is higher than 1.1 V, the peak current is decreasing and it will damage the electroactivity and conductivity. The optimized applied potential is between 0.7-0.9 V vs SCE. In general, a higher rate of polymerization can be achieved by increasing the synthesize potential, at the risk, however, of polymer degradation and other undesired side reactions. When the potential was increased to +1.1 V or above, the rates of polymerization is fast, which could be attributed to that the amount of oligomer species generated from the oxidation of aniline itself was sufficient enough to sustain the polymerization at the high applied potentials. It indicates that the properties, as well as the morphology of PANI, could be changed by applied potential and polymerization time, etc. This change deserves to be studied, because it might result in the quality of PANI fibres suitable for specific applications.

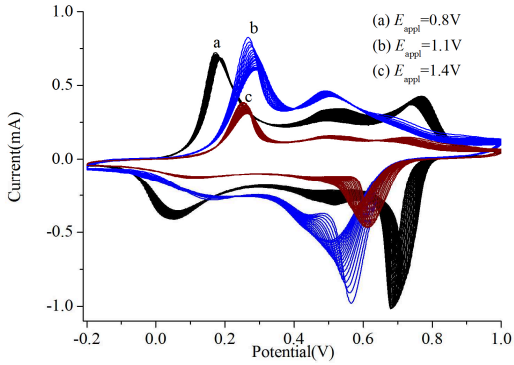

Fig. 4 Cyclic voltammogram of PANI fibres in an solution of 1M HCl, with Potentiostatic synthesized (a)0.8V, (b)1.1V, (c)1.4V, -0.2 V to 1.0 V, v = 100 mV/s.

Conclusions

The results show that the applied potential and the polymerization time have a crucial influence on the polymerization rate and the conductivity of the PANI fibres prepared. PANI prepared with hydrochloric acid was fibrillar morphology, the diameter of the PANI fibres become wider with the polymerization time increasing, the optimized applied potential is between 0.8 V and 1.0 V. It indicates that the properties, as well as the morphology of PANI fibres, could be changed by applied potential and polymerization time, etc. This change deserves to be studied, because it might result in the quality of PANI suitable for specific applications.

Abstract: A study for electrocatalytic hydrogenation of oxalic acid has been reported using the self-organized TiO_2 nanotube electrode prepared by anodic oxidation method. The prepared electrode was characterized by SEM and XPS. The electrocatalytic activity of the TiO_2 nanotube electrode was evaluated by CV and galvanostatic electrolysis. The CV studies and electrochemical experiments showed that TiO_2 nanotube electrode exhibited high electrocatalytic activity. In addition, the surface of TiO_2 nanotube electrode developed into a periodic lattice of nanopores after electrolysis, which makes it find a potential application as electrocatalysts.

Introduction

Since electrochemical methods are simple and considerably avoid environmental pollution, many organic compounds are synthesized by such methods[1, 2]. Organic electrosynthesis is a method of the sustainable development of green chemistry, owing to its distinct properties such as environmental friendly and mild reaction conditions which has become one of the important frontiers of chemical research. The indirect electrosynthesis using mediator as oxidant and reductant is mostly homogeneous electrocatalytic process. Heterogeneous catalytic hydrogenation is widely used for the addition of hydrogen to olefinic (C=C), carbonyl (C=O) groups[2-5]. Compared with homogeneous catalysis, heterogeneous catalysis has more significant advantages. For instance, it can be performed at more mild conditions (room temperature and normal pressure)[6]. In most cases, industry favors heterogeneous over homogeneous catalysts because of the formers ease of handling and simple work-up[7].

Electrocatalytic reduction of maleic acid, oxalic acid and other unsaturated carbon bonds compounds using the lead cathode have been studied[8-11]. But the lead cathode can be easily deactivated[12, 13] which is the key problem and has been incompletely resolved. So, it is very necessary to find replaceable cathode materials for the reduction of these compounds. Some researchers have proposed to use the TiO_2 film electrode replacing lead electrode to electroreduction of these compounds[5, 14, 15]. In addition, our previous work using TiO_2 film electrode prepared by anodic oxidation method to electrocatalytic reduction of maleic acid and oxalic acid have been reported[3, 5]. Consequently, we found that the TiO_2 film electrode with a high electrocatalytic activity is attributed to the function of $TiO_2/Ti(OH)_3$ redox couple and its larger surface area which have many active sites[16]so that substances can be adsorbed in large quantities onto the TiO_2 surface.

In this paper, we first use the self-organized TiO_2 nanotube electrode to study the electrocatalytic hydrogenation of oxalic to glyoxylic acid. The mechanism of oxalic acid reduction on the self-organized TiO_2 nanotube electrode has been discussed. The prepared electrode exhibited higher electrocatalytic activity for the reduction of oxalic acid than that of the polished Ti electrode. Using this heterogeneous catalyst with higher electrocatalytic activity would contribute to starting a new research field for the application of TiO_2 nanotube electrode in other organic electrosynthesis.

Experimental

Preparation Of Tio_2 Nanotube Electrode

Titanium foils (0.5 mm, 99.6% purity) were polished in a mixed solution of 6 mL nitric acid, 6 mL hydrogen peroxide, 2.5 g ammonium fluoride and 0.15 g urea for 30 seconds. Then the polished titanium foils were ultrasonically cleaned in acetone and deionized water followed by rinsing with deionized water. The TiO_2 nanotubes were prepared by means of an anodic oxidation developed in glycerol solution with 0.2 M Na_2SO_4 and 0.5 wt% NaF at 20 V for 1.5 h.

Characterization

The morphology of the electrode surface was characterized using a Hitachi s-4700 field emission scanning electron microscope (FE-SEM). The analysis of the surface valence state of titanium was conducted by X-ray photoelectron spectroscopy with a Kratos Axis Ultra DLD spectrometer using a focused monochromatized Al Kα operated at 300 W.

Cyclic Voltammetric Studies

Cyclic voltammetry measurements were carried out using CHI660D electrochemical analyzer. The TiO_2 nanotube electrode and polished Ti sheet (surface area of 1 cm^2) served as the working electrode, a platinum sheet and a saturated calomel electrode（SCE）served as the counter electrode and reference electrode respectively. All CV experiments were performed in three electrochemical cells at a constant temperature of 20 ℃.

Preparative Electrolysis Experiments

The electrolysis on a preparative scale was carried out according to previous report[5]. The concentration of titanium ion during the electrolysis processes were monitored and analyzed by ICP (Inductively Coupled Plasma).

Results and discussion

Sem And Xps Characterization Of Tio_2 Nanotube Electrode

Fig.1 show the top-view morphology of TiO_2 nanotube by anodization and polished Ti sheet. It confirmed the formation of self-organized oxide layers on Ti sheet. It was found that the self-organized tubes were formed with the average diameter of 90 nm (Fig. 1A). After electrolysis experiments with the TiO_2 nanotube and polished Ti electrode, the surface of TiO_2 nanotube electrode developed into a periodic lattice (Fig.1 B) . Comparing to the nanotube electrode, surface of the polished Ti sheet remained little change (Fig.1 C and D).

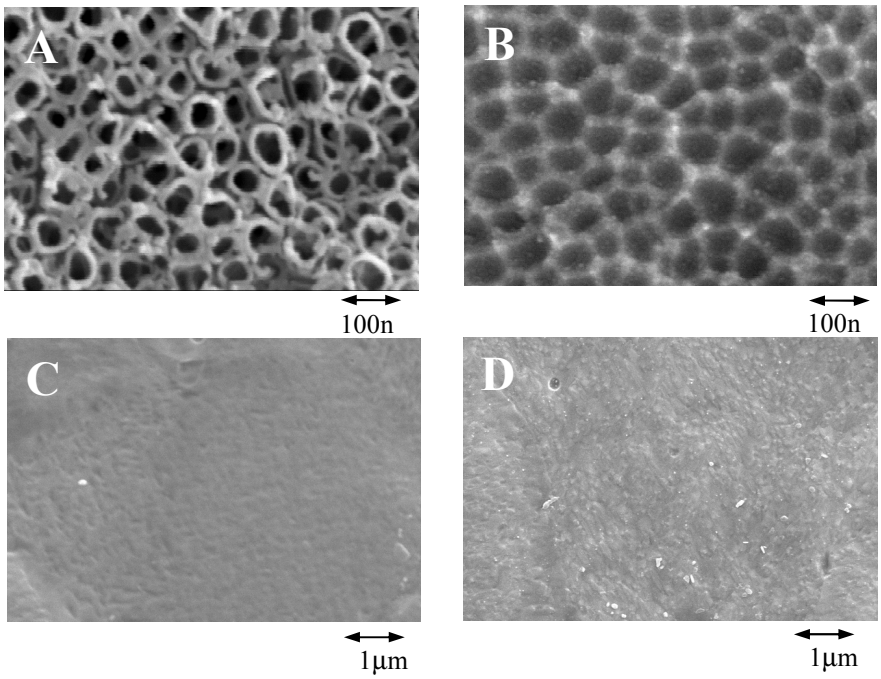

Fig.1 SEM of TiO_2 nanotube before electrolysis(A) and after electrolysis(B); polished Ti sheet before electrolysis(C) and after electrolysis(D).

XPS characterization was carried out to explore the valence state of titanium on surface of TiO_2 nanotube before and after electrolysis. The corresponding titanium 2p1/2 and 2p3/2 peaks before electrolysis were centered at 461.1 eV and 455.4 eV and after electrolysis two peaks for the titanium 2p of the electrodes were observed at 461.9 eV and 455.6 eV, which are assigned to Ti^{4+} species[17] and the other valence state of titanium was not found from Fig.2. These results further confirmed that the surface of nanotube electrode was composed of TiO_2 before and after electrolysis.

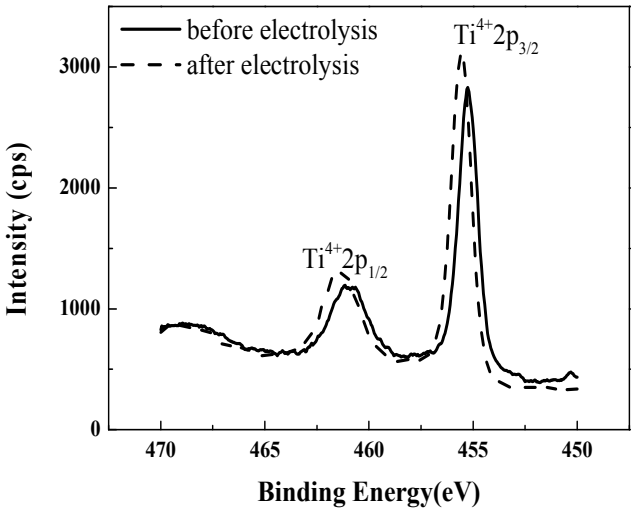

Fig. 2 XPS spectra of the TiO_2 nanotube electrode

Cyclic Voltammetric Studies

The cyclic voltammograms of the TiO_2 nanotube electrode in 1M sulfuric acid solution and 1M sulfuric acid + 1M oxalic acid solution at a scan rate of 0.05 V/s are shown in Fig. 3 (a). It can be seen that the reduction peak of the TiO_2 nanotube electrode was characterized by an irreversible reduction. Compared the reduction peaks, we found that there were two reduction peaks in 1M sulfuric acid + 1M oxalic acid solution which illustrated that the reduction of oxalic acid occurred on the surface of TiO_2 nanotube electrode.

Fig. 3 (b) shows cyclic voltammograms obtained in 1 M oxalic acid solution at TiO_2 nanotube electrode and polished Ti electrode with the scan rate of 0.05 V/s. As can be seen, an irreversible reduction peak of the TiO_2 nanotube electrode was characterized. However, this irreversible reduction peak cannot be observed at the polished Ti electrode. The irreversible reduction peak was attributed to the following reaction:

$$TiO_2 + H_2O + H^+ + e \rightarrow Ti(OH)_3 \quad (1)$$

Then the Ti (Ⅲ) species reduced the oxalic acid to gelyoxylic acid and Ti (Ⅳ) was regenerated. It's obviously that the reduction process of oxalic acid at the TiO_2 nanotube electrode was different from that at the polished Ti electrode. The results showed that the TiO_2 nanotube electrode have higher electrocatalytic activity for the reduction of oxalic acid. The increase of current value may be due to the large amount of Ti (Ⅳ) species generated instantaneously by the fast chemical reaction[3, 18]. The TiO_2 nanotube electrode with a higher peak current may attribute to its special structure which is good for the adsorption the Ti (Ⅲ) species and reduction the oxalic acid. The CV studies have revealed that TiO_2 nanotube electrode behaves higher electrocatalytic activity than the polished Ti electrode.

The CV behavior of the TiO_2 nanotube electrode in 1M oxalic acid solution and 1M oxalic + 1M sulfuric acid solution at the scan rate of 0.05 V/s are shown in Fig. 3 (c). It can be seen that the initial potential of reduction peak in 1M oxalic acid solution move negatively. This illustrated that the polarization effect of the TiO_2 nanotube electrode was higher in 1M oxalic acid solution than that in 1M oxalic acid + 1 M sulfuric acid solution.

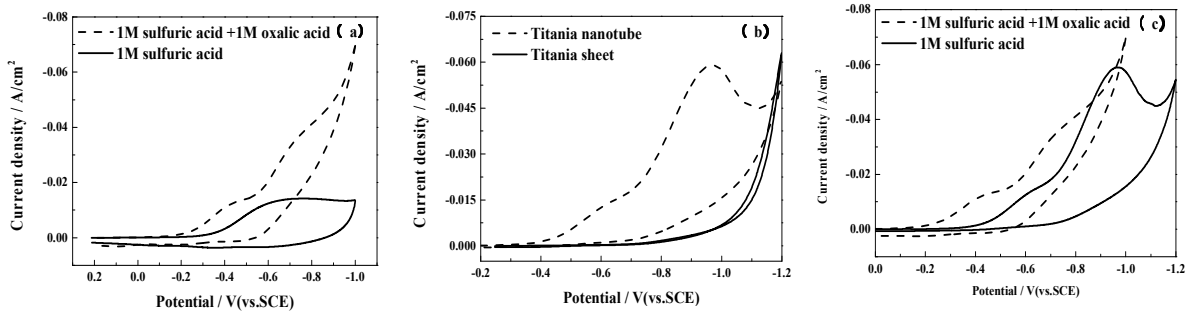

Fig.3 CV behavior of (a) TiO_2 nanotube electrode in 1M sulfuric acid and 1M sulfuric acid+1M oxalic acid; (b) TiO_2 nanotube and polished Ti electrode in 1 M oxalic acid solution; (c) TiO_2 nanotube electrode in 1M oxalic acid solution and 1M oxalic +1M sulfuric acid solution.

The whole CV studies have revealed that the TiO_2 nanotube electrode behaves as a good heterogeneous catalytic electrode and the reduction mechanism of oxalic acid at the the TiO_2 nanotube electrode is proposed as follow:

$$TiO_2 + H_2O + H^+ + e^- \longrightarrow Ti(OH)_3 \qquad (2)$$

$$HOC(=O)-COH + Ti(OH)_3 + H^+ \longrightarrow TiO_2 + HOC(=O)-CH + 2\,H_2O \qquad (3)$$

Preparative Electrolysis Studies

The electrolysis on a preparative scale was carried out at constant current density 30 mA/cm^2 for 4 hours in different oxalic acid solutions at 20℃. The results of the preparative electrolysis experiments are reported in table1. It was found that the current efficiency increased with the oxalic acid concentration. While the yield of glyoxylic on the TiO_2 nanotube electrode showed a trend of first increase and then decrease. The maximum yield was 72.05% in 0.3 M oxalic acid. The electrodes were characterized by SEM after electrolysis (Fig.1B and D). On the surface of TiO_2 electrode, the self-organized nanotubes developed into a periodic lattice of nanopores (Fig. 1B). However the surface of the polished Ti electrode did not change after electrolysis (Fig. 1D). The reason of the changes was that the TiO_2 as the active centers were reduced to $Ti(OH)_3$ and dissolved, then $Ti(OH)_3$ reduced oxalic acid to glyoxylic acid[[5]]. In addition, the nanopores structure was good for adsorption of the electrogenerated Ti (Ⅲ) species and reduction of oxalic acid which can improve the electrochemical activity of the TiO_2 nanotube electrode[19, 20]. Based on the results above, it is strongly suggested that the special surface structure change will benefit the application of the TiO_2 nanotube electrode in organic electrosynthesis.

TABLE 1. ELECTROLYSIS RESULTS ON TIO_2 NANOTUBE AND POLISHED TI ELECTRODE, T = 4 [H], T = 20 [℃], I = 30 [MA/CM^2]

Electrode	$C_{0\ \text{oxalic acid}}$ [mol/l]	Conversion [%]	Yield [%]	Current efficiency [%]

Summary

In this paper, the TiO_2 nanotube electrode was obtained by anodic oxidation method. XPS results showed that the surface of nanotube was composed of TiO_2 before and after electrolysis. The SEM confirmed that the surface of TiO_2 nanotube electrode developed into a periodic lattice of nanopores after electrolysis which was good for adsorption of the electrogenerated Ti (Ⅲ) species and reduction of oxalic acid which can improve the electrochemical activity of the TiO_2 nanotube electrode. The CV studies and electrochemical experiments presented that the electrocatalytic activity of the TiO_2 nanotube electrode was higher than that of the polished Ti electrode. These results demonstrated that the TiO_2 nanotube electrode is a useful electrode material for reducing oxalic acid and it is also a potential candidate as a heterogeneous catalytic for the electroreduction.

Key words: Zircon; Whiskers; Non-hydrolytic sol-gel process; Molten salt method

Abstract: Zircon whiskers were prepared via non-hydrolytic sol-gel process combined with molten salt method, using $Si(OC_2H_5)_4$ (TEOS) and $ZrCl_4$ as raw materials, LiF as mineralizer, and Na_2WO_4 as molten salt. The phase composition, morphology and microstructure of the samples were characterized by X-ray diffraction analysis (XRD), field emission scanning electron microscopy (FE-SEM) and transmission electron microscopy (TEM). The influence of introducing molten salt and calcination temperature on the synthesis and morphology of zircon crystals was investigated. The results show that the introduction of Na_2WO_4 contributes to the one-dimensional preferential growth of zircon. Zircon whiskers elongated along the c-axis, with diameter of ~100nm and aspect ratio of more than 15, are achieved at the temperature of 850 ^oC, and neither over low nor over high calcination temperature is conducive to the growth of zircon whiskers.

Introduction

Whisker is fiber-like single crystal, with aspect ratio of more than 10 [1]. It has well-ordered atomic arrangement and complete structure, which endows the whisker material with high strength [2]. And because its strength is close to the theoretical value of crystal, whisker is used as reinforcing phase in composite materials [3].

Zircon ($ZrSiO_4$) is a kind of structure ceramic material with excellent properties, such as high melt point, low thermal conductivity, low thermal expansion coefficient, high index of refraction, ultimate chemical durability and phase stability [2,4,5]. In addition, the zircon has higher thermal shock resistance than that of mullite and alumina [6]. Due to these advantages, zircon is widely used in refractory, opacifying glaze, high temperature structural ceramics, and so on. As a new type of composite material reinforcement, zircon whisker owning the properties of both zircon and whisker has vast potential applications.

Non-hydrolytic sol-gel (NHSG) process is a very effective method for low-temperature synthesis of composite oxide [7], and molten salt method can provide a liquid state environment for the anisotropic growth of crystal [8]. Therefore, in this paper, zircon whiskers were prepared via NHSG process combined with molten salt method. The influence of introducing molten salt and calcination temperature on the synthesis and morphology of zircon crystal was researched.

Experimental Procedures

With the Si/Zr and Li/Zr molar ratio being 1.2 and 0.36 [9], respectively, 8 mL TEOS was mixed with $ZrCl_4$ and LiF. 30 mL ethanol was added into the above mixture with stirring, and then transparent solution was obtained. After reflux and drying, the dried gel was formed. The gel was pre-calcined at 400 ^oC for 30 min, then muddled uniformly with Na_2WO_4 molten salt and calcined at different temperatures. Finally, the samples were achieved by washing with dilute HF acid and distilled water for several times.

The phase composition of samples was analyzed by X-ray diffraction (XRD, D8 Advance, Bruker AXS Co. Ltd.) and CuKα radiation (λ = 0.154 nm), with scanning range of 5 °~70 ° 2θ. The morphologic information of samples was obtained by field emission scanning electron microscopy (SEM, JSM-6700F, JEOL) and transmission electron microscopy (TEM, JEM-2010, JEOL). And TEM was also used to characterize and analyze the microstructure and growth direction of whisker.

Results and Discussion

In order to investigate the effect of molten salt added on the one-dimensional preferential growth of zircon, the phase composition and morphology of the samples calcined at 800 °C were analyzed by XRD and SEM as shown in Fig. 1 and Fig. 2, respectively.

It can be seen that the samples with or without molten salt are all composed of single $ZrSiO_4$ crystal phase (Fig. 1), indicating that the addition of Na_2WO_4 molten salt doesn't hinder the synthesis of zircon. As can be seen from Fig. 2, the sample with molten salt mainly consists of rod-like $ZrSiO_4$ whiskers, while the sample without molten salt entirely composed of zircon grains.

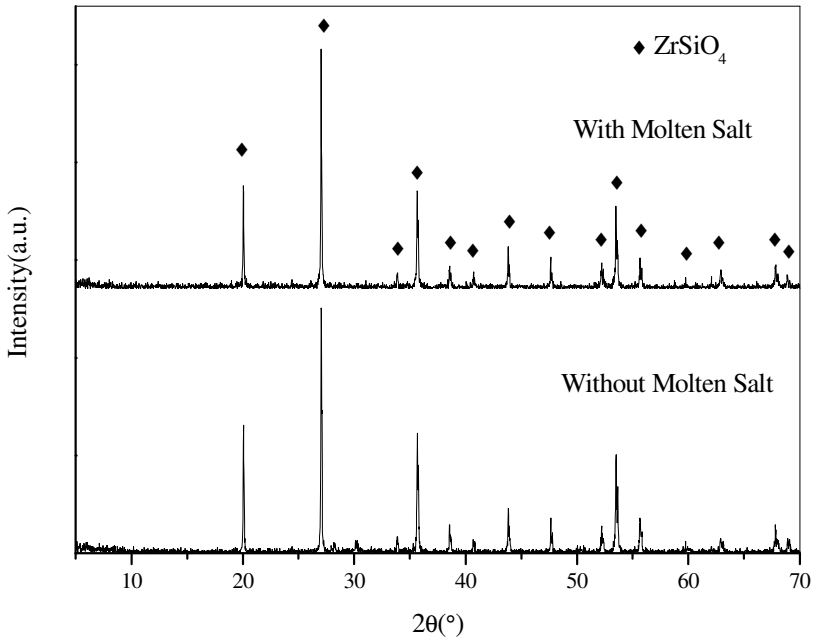

Fig. 1 XRD patterns of samples without or with molten salt

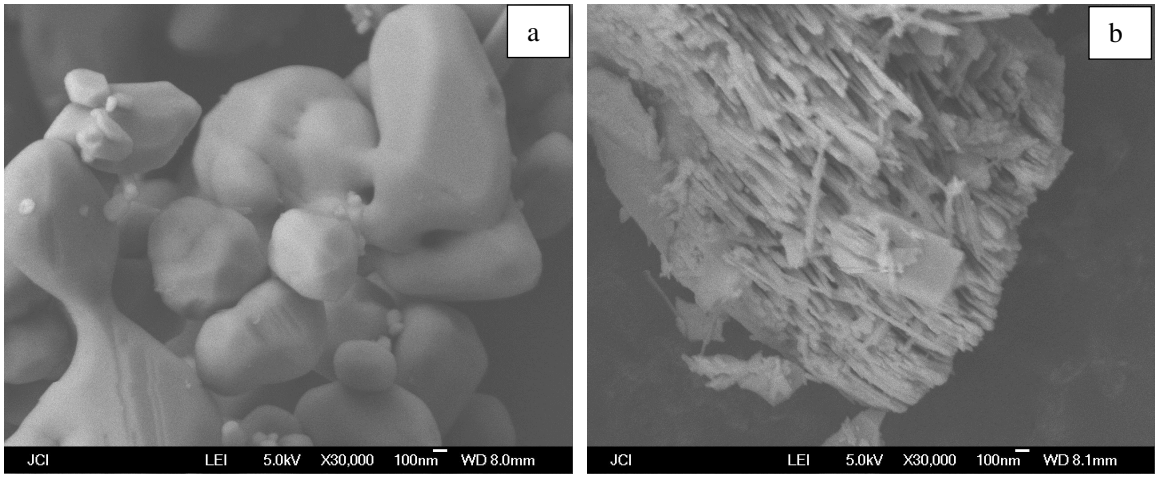

Fig. 2 FE-SEM micrographs of samples (a) without molten salt; (b) with molten salt

The XRD patterns of samples with Na_2WO_4 molten salt calcined at different temperatures are shown in Fig. 3. At 650 °C, the diffraction peaks agree well with $Na_7Zr_6F_{31}$ phase (PDF#10-0177),

and no characteristic diffraction peak corresponding to $ZrSiO_4$ is detected. As the calcination temperature increases to 700 °C, the sample mainly consists of $ZrSiO_4$ crystal phase, as well as a small amount of $Na_7Zr_6F_{31}$ phase. When the temperature rises to 750 °C or higher gradually, $Na_7Zr_6F_{31}$ phase disappears and the samples are entirely composed of $ZrSiO_4$ crystal phase.

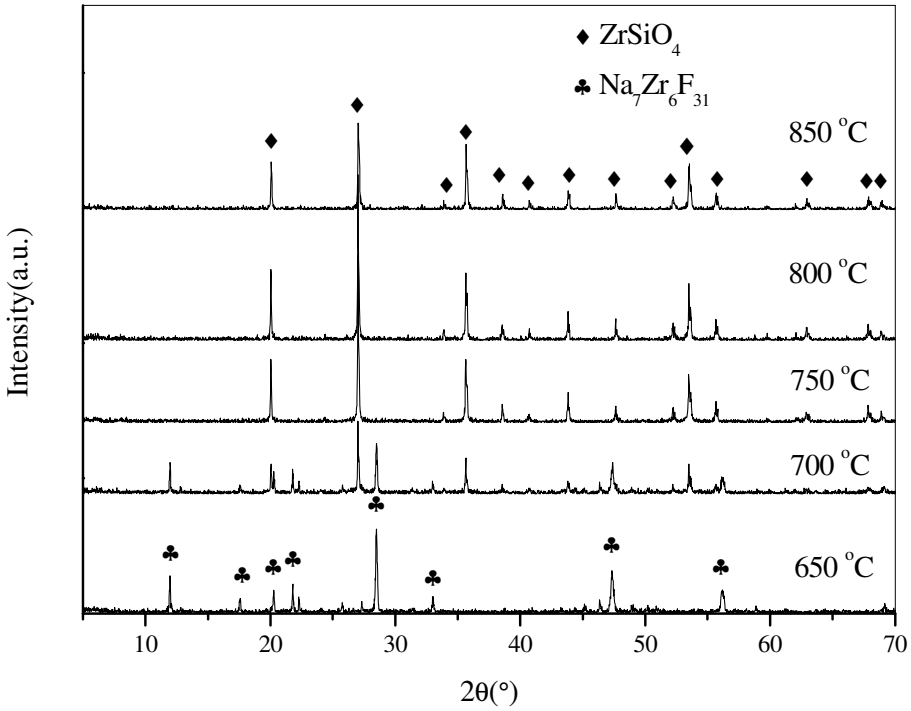

Fig. 3 XRD patterns of samples with molten salt calcined at different temperatures

Based on the analysis above, the forming process of $ZrSiO_4$ whisker can be implied as follows: the dry gel of zircon acts with molten salt to form $Na_7Zr_6F_{31}$ at 650 °C. When Na_2WO_4 molten salt (m.p. 695 °C) melts at 700 °C, zircon crystal phase forms gradually, and the sample is mainly composed of zircon and $Na_7Zr_6F_{31}$ crystal phases. With the temperature further rising, zircon and $Na_7Zr_6F_{31}$ crystal phases are dissolved in liquid molten salt to form supersaturated solution of zircon. Due to the anisotropic characteristics of zircon crystal, and the liquid state environment produced by adding molten salt that is beneficial to the one-dimensional preferential growth of crystal than solid state recation, zircon appears and grows into whisker under the appropriate supersaturated condition.

The FE-SEM micrographs of the samples are shown in Fig. 4 The samples calcined at 750 °C and 800 °C are both composed of massive zircon crystals and whiskers with small diameter and short length. When the temperature rises to 850 °C, the sample mainly consists of well-developed zircon whiskers with average diameter of ~100 nm and aspect ratio of more than 15, accompanied by a small number of zircon grains. With the temperature further increasing to 900 °C, zircon whiskers disappear, and the sample is basically composed of massive zircon crystals. Consequently, it can be concluded that both over low and over high calcination temperatures are not conducive to the growth of zircon whiskers.

Usually, the viscosity of molten salt rapidly decreases with increasing of the calcination temperature. The one-dimensional preferential growth of zircon are destroyed at over low temperature due to the insufficiency of zircon growth dynamic and the high viscosity of molten salt. Thus the massive zircon crystals and zircon whiskers with small diameter and short length coexist in the samples calcined at 750 °C and 800 °C. Nevertheless, the growth rate differences along three-dimensional direction will obviously be reduced at over high temperature, which are also not conducive to the one-dimensional preferential growth of zircon crystals. Only at 850 °C, the combined effect of sufficiency growth dynamic, appropriate viscosity of molt salt, and larger three-dimensional growth rate differences promote the growth and development of zircon whiskers.

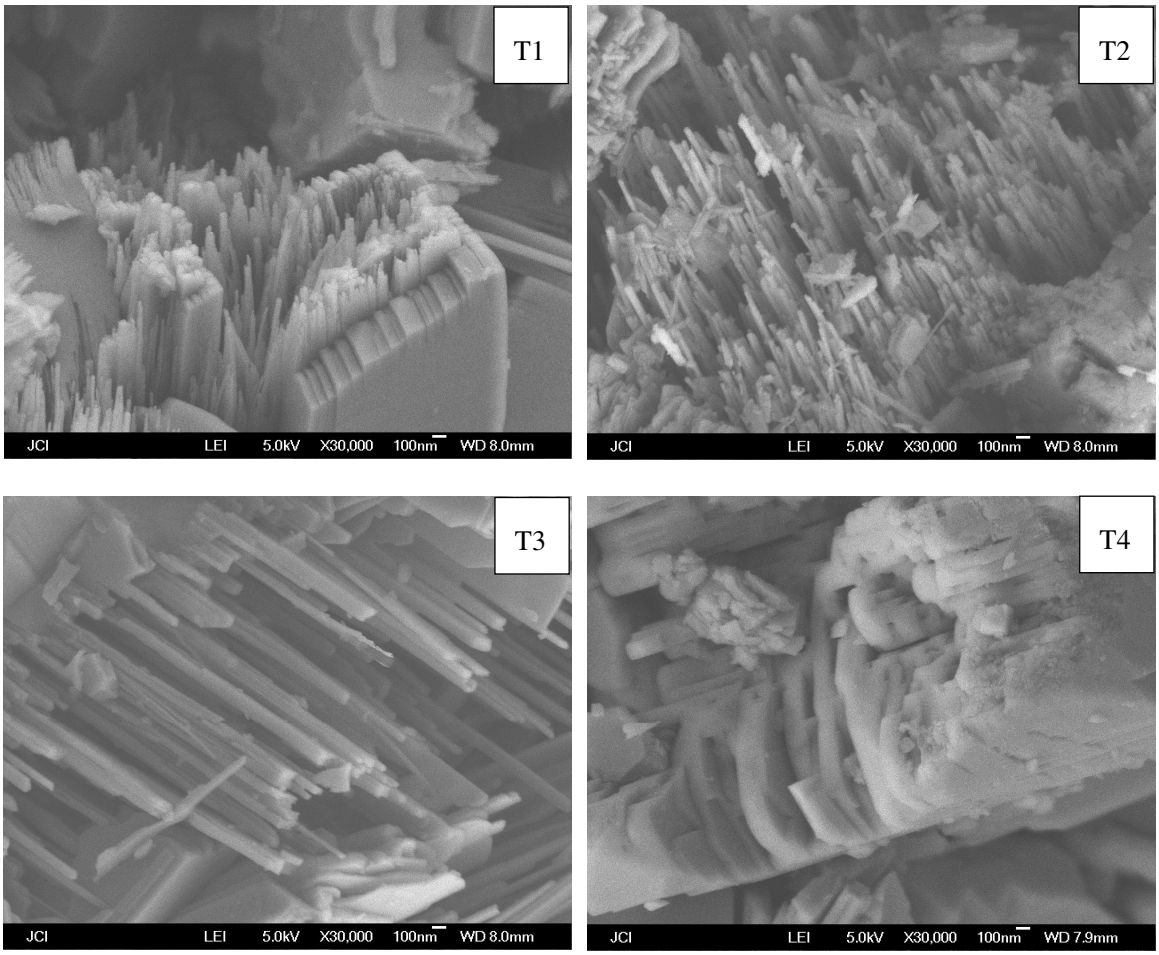

Fig. 4 FE-SEM morphologies of samples calcined at different temperatures
(T1: 750 ^{o}C; T2: 800 ^{o}C; T3: 850 ^{o}C; T4: 900 ^{o}C)

The TEM, SAED and HRTEM micrographs of zircon whisker obtained at 850 ^{o}C are showed in Fig. 5. The unit cell parameters (a = b = 6.686 Å, c = 5.595 Å) are calculated by analyzing the SAED and HRTEM micrographs, which are consistent with standard diffraction card of zircon (PDF#06-0266). Moreover, the single crystal structure of zircon whisker is confirmed by SAED [10]. And the elongated direction of zircon whisker is parallel to c-axis, as shown in HRTEM micrograph.

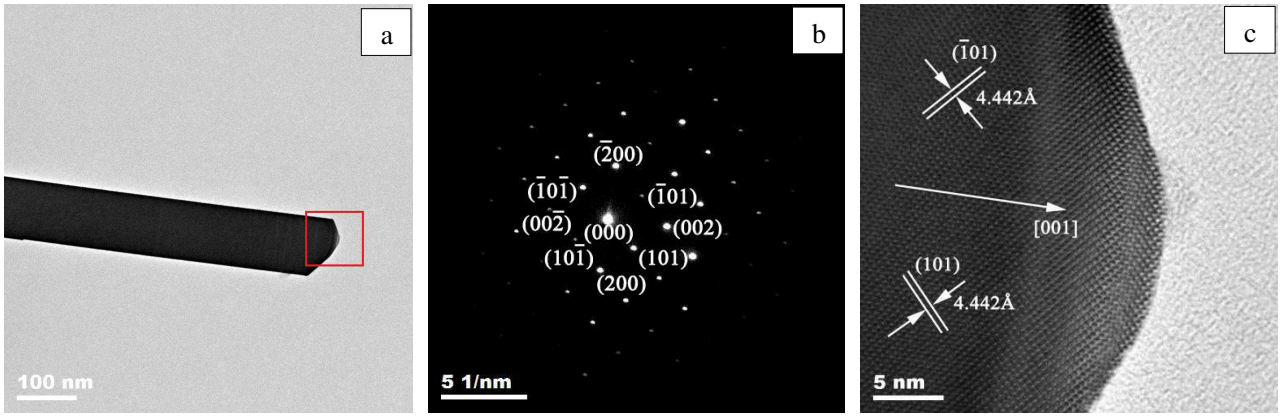

Fig. 5 (a) TEM, (b) SAED and (c) HRTEM of zircon whisker

Conclusions

Zircon whiskers were prepared via NHSG process combined with molten salt method. The addition of Na_2WO_4 molten salt contributes to the one-dimensional growth of zircon crystals significantly. Optimized zircon whiskers, with diameter of ~100 nm, aspect ratio of more than 15, can be obtained at 850 ^oC, and the growth direction of whiskers is along c-axis. Both over low and over high calcination temperatures count against the growth of zircon whiskers. NHSG process could realize the low temperature synthesis of zircon, and Na_2WO_4 molt salt provides a suitable liquid environment, both of which promote the growth of zircon whiskers.

Keywords: mullite whisker, non-hydrolytic sol-gel process, molten salt method, crystal growth

Abstract. Mullite whisker was prepared at low temperature via non-hydrolytic sol-gel (NHSG) process combined with molten salt method. The influence of heat treatment temperature was studied on the morphology and the microstructure of whisker, and its growth mechanism was also described. The results show that the mullite whisker appears at the lowest temperature of 750 ºC, and optimized mullite whisker can be prepared at 850 ºC with the growth direction of [001], whose diameter is in the range of 170~300 nm with the aspect ratio of >30.

Introduction

Mullite is widely used as high temperature engineering material and refractory material because of its excellent high temperature strength and creep resistance, low thermal expansion coefficient and good chemical stability [1-4]. Mullite whisker has attracted much attention due to its serving as a reinforcement phase in high temperature ceramic composites [5-8]. Various processing routes have been reported for the preparation of mullite whisker, such as mineral decomposition method [9], oxide doping method [10], sol–gel process combined with vapour-phase reaction method [11], molten salt method [12], sol-gel process combined with molten salt method [13], non-hydrolytic sol-gel process combined with vapour-phase reaction method [14]. Nevertheless, the above mentioned methods generally require an annealing temperature of above 1000 ºC [13]. Non-hydrolytic sol-gel (NHSG) process simplifies the sol-gel process, and especially makes the sol homogeneous at the atomic level during the sol-gel process, thus greatly reducing the synthesis temperature of multicomponent oxides [15,16]. Meanwhile, molten salt method has been employed to prepare mullite whisker because molten salt provides liquid environment in which the whisker growth is easily accelerated. However, to the best of our knowledge, there is no report on the mullite whisker prepared by NHSG process combined with molybdate molten salt.

In this paper, mullite whisker was prepared by the combination of NHSG process with molten salt method. The influence of heat treatment temperature was studied on the whisker, and its growth mechanism was also discussed.

Experimental

Preparation

Anhydrous aluminum chloride ($AlCl_3$, AR, Shanghai), tetraethoxysilane ($Si(OC_2H_5)_4$, AR, Shanghai) and anhydrous ether (EtOEt, AR, Shanghai) were used as precursors and mixed in a conical flask with the nominal composition of mullite ($3Al_2O_3 \cdot 2SiO_2$). The reaction mixture was continuously heated under reflux at 110 ºC for 24 h to obtain the mullite xerogel via non-hydrolytic sol-gel process. The xerogel was calcined at 910 ºC for 10 min to prepare mullite crystal seed. Then mullite crystal seed and molybdate with the mass ratio of 1:1 were ball-milled for 2 min. The milled mixture was heated to the final temperature and then held for 6 h. The prepared samples were

crushed and washed with 10 vol.% HF solution to remove the molybdate. Finally, white powder was obtained after filtrating, washing and drying. Based on the eutectic composition (at 523 ºC) in the lithia-molybdena phase diagram [17], the molten salt of molybdate was prepared using lithium carbonate and molybdenum oxide as raw materials.

Characterization

Differential thermal analysis (DTA) and thermo gravimetric analysis (TG) were carried out by using NETZSCH STA 449C thermal analyzer. Infrared spectroscopy (IR) studies were performed with Nicolet 5700 infrared spectrometer in the wavenumber range of 4000-400 cm^{-1}. The phase compositions of samples were determine by the Bruker D8 Advance X-ray diffraction (XRD), and their morphology was observed by the JSM-6700F scanning electron microscopy (FE-SEM). Microstructure of the whiskers was investigated by using JEM-2010 transmission electron microscope (TEM).

Results and Discussion

In order to study the phase transition of mullite xerogel during the heat treatment, its DTA–TG test was carried out from room temperature to 1300 °C at the rate of 10 °C/min in nitrogen atmosphere. There is a broad endothermic peak in the DTA curve with the peak temperature of 181 °C, which is due to the volatilization of organic compounds and decomposition of the ethyoxyl groups in the xerogel, and correspondingly there is a 47.48 % weight loss in the TG curve (Fig. 1(a)).

At 905 °C, the DTA curve also shows a sharp exothermic peak attributed to the crystallization of mullite. This can be deduced from the fact that the XRD pattern of the sample prepared at 910 °C has mullite diffraction peaks while its counterpart at 880 °C has no mullite peaks (Fig. 1(b)). It is noteworthy that the background strength in the XRD pattern is relatively high at 910 °C, which suggests that there is a great deal of amorphous phase due to the short holding time of only 10 min. The existing amorphous mullite is easier to dissolve in molybdate melt than the crystalline mullite. At the same time, a small amount of crystalline mullite, as crystal seed, plays an important role in the whisker growth process.

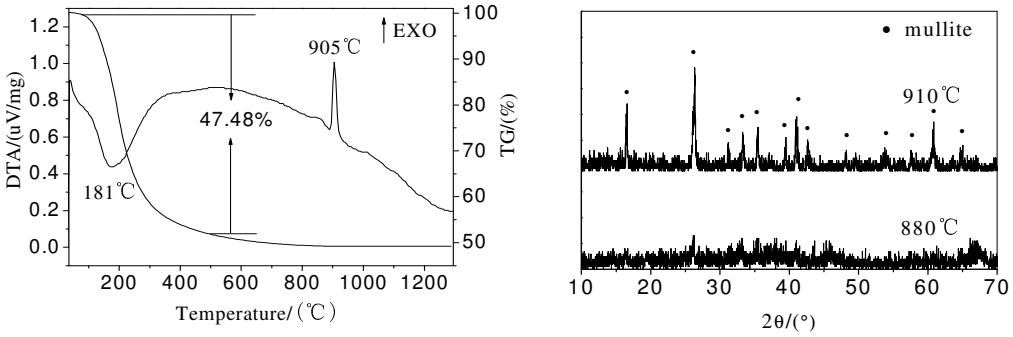

Fig. 1 (a) DTA-TG curves of the xerogel powder, (b) XRD patterns of the samples heat treated at different temperatures.

In order to verify why NHSG method can synthesize mullite at the much lower temperature of 910 ºC than both traditional solid phase method and hydrolytic sol-gel method, FT-IR test was performed to analyse the bonding of mullite xerogel prepared via NHSG method. Two absorption bands at 1090 cm_{-1} and 610 cm_{-1} appeared in the the FT-IR spectrum of mullite xerogel (Fig. 2), which were ascribed to the vibration of Al-O-Si [18,19]. The reaction process can be described as the following formula:

$$Si(OC_2H_5)_4 + AlCl_3 + C_2H_5OC_2H_5 \xrightarrow{NHSG} = Al - O - Si \equiv + C_2H_5Cl \uparrow \quad (1\text{-}1)$$

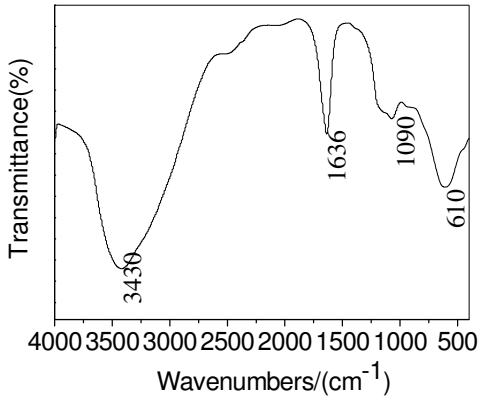

Fig. 2 FT-IR spectrum of mullite xerogel prepared via NHSG method.

According to the formula, the C-Cl absorption peak should have existed in the infrared spectrum. However, it doesn't appear in the spectrum because C_2H_5Cl is gaseous at room temperature [20] and can escape during the exothermic reaction. The key to synthesizing mullite at low temperature lies in the formation of Al-O-Si heterocondensational bond through the non-hydrolytic process.

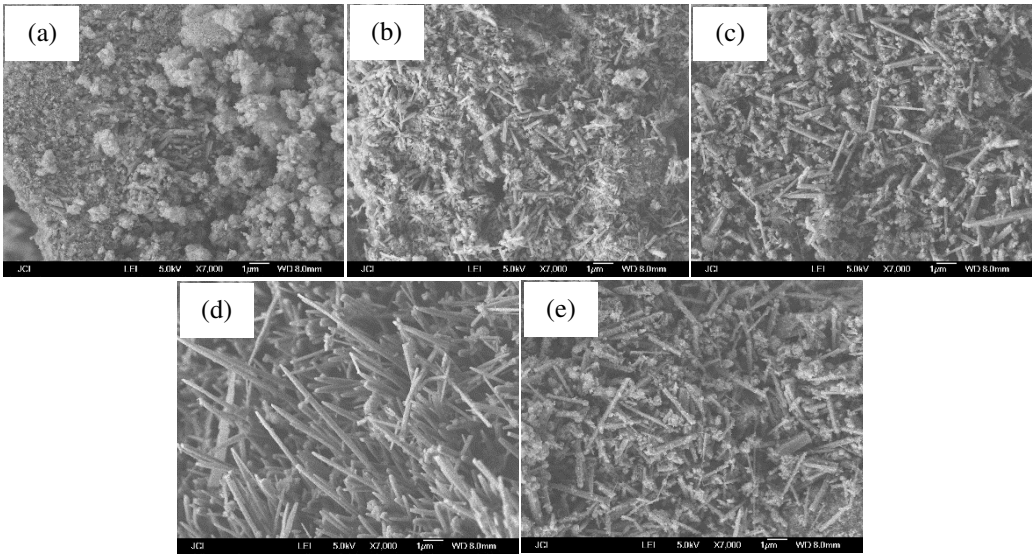

Fig. 3 FE-SEM micrographs of the samples heat treated at different temperatures: (a) 700 °C, (b) 750 °C, (c) 800 °C, (d) 850 °C and (e) 900 °C.

FE-SEM micrographs of the samples heat treated at 700 ºC, 750 ºC, 800 ºC, 850 ºC and 900 ºC are shown in Fig. 3. It can be seen from Fig. 3 that heat treating temperature has great influence on the formation of mullite whisker: there is no mullite whisker present after 700 °C heat treatment, and the short rod-like mullite whisker appears with the aspect ratio of about 12 and with the length of 1~2 μm through 750 °C annealing (Fig. 3(b)); with the increase of heat treating temperature, both dimension and amount of the mullite whisker increase (Fig. 3(b-d)), and the optimized temperature of 850 ºC results in the well-developed mullite whisker with the diameter in the range of 170-300 nm and the aspect ratio of >30 (Fig. 3(d)); when the temperature raises up to 900 °C, the whisker begins to decrease in both length and amount, and what is more, it is mingled with a lot of fine mullite particles and some thick whisker, which is probably due to the fast evaporation of molten salt and the reduction in the three-dimensional growth rate difference with the increase of temperature.

Fig. 4 shows the TEM micrograph of the representative whisker, the selected area electron diffraction (SAED) pattern and the lattice image of the sample heat treated at 850 ℃. The SAED pattern (Fig. 4(b)) as well as the measured lattice spacing confirms that the whisker is single-crystal

of mullite, which is in good agreement with the XRD analysis, and the whisker growth direction can be identified as [001]. The interplanar spacing of (110) can be determined to be 5.39 Å from Fig. 4(c).

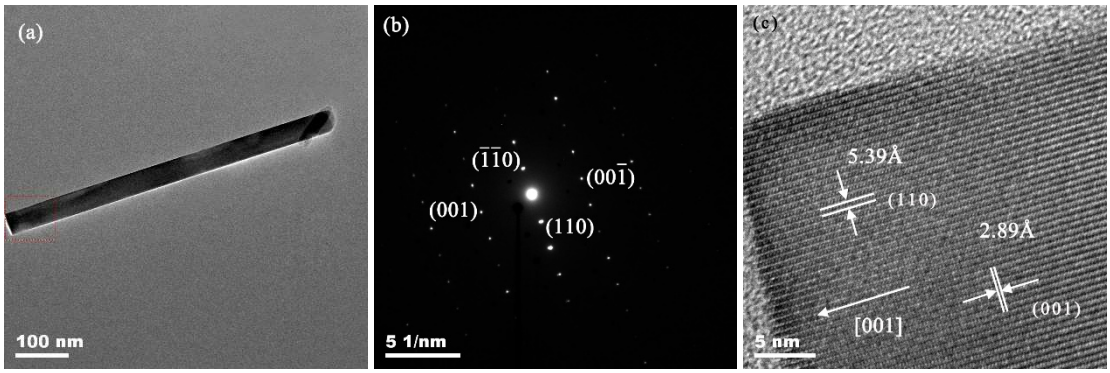

Fig. 4 TEM, SAED and HR-TEM photographs of whisker.

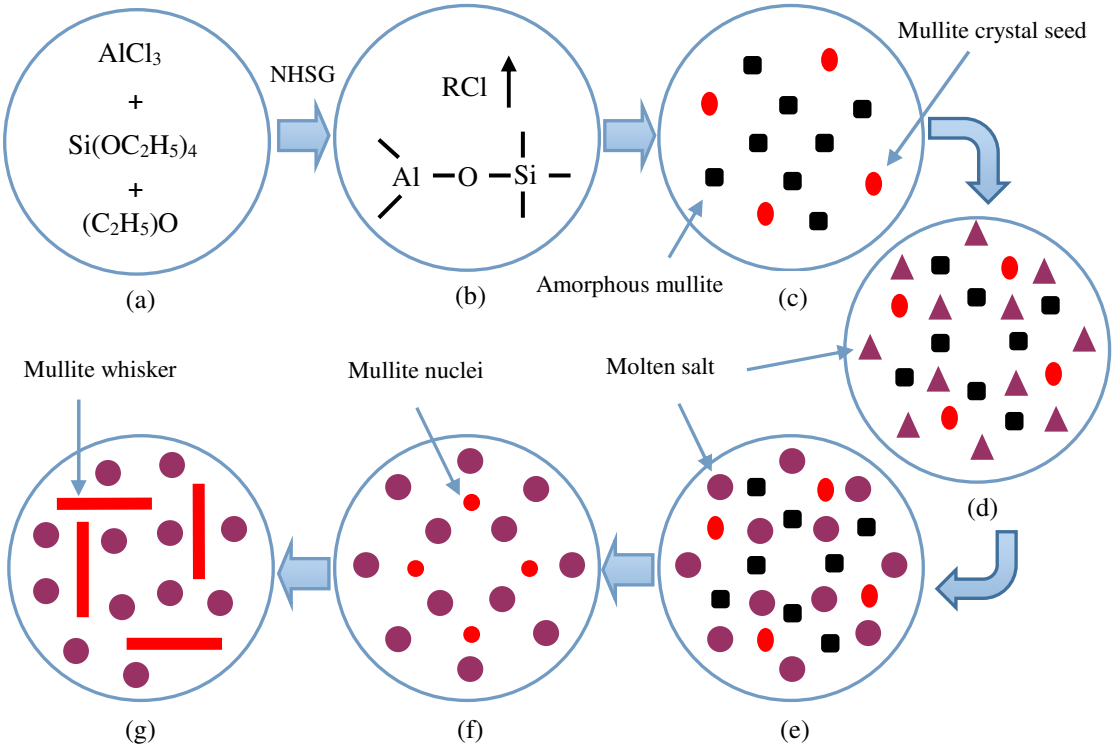

Fig. 5 Schematic of the mullite whisker growth process: (a) precursors, (b) reaction products via NHSG process, (c) mullite crystal seed with its amorphous phase after annealing at 910 °C, (d) mixture of mullite crystal seed, amorphous mullite and molten salt, (e) molten salt melting at over the eutectic temperature, (f) amorphous mullite dissolution in molten salt, (g) whisker growth.

Fig. 5 shows the schematic of the mullite whisker growth process. Firstly, the precursors (Fig. 5(a)) reacted to form mullite xerogel via NHSG process (Fig. 5(b)), and mullite crystal seed came into existence with a great deal of amorphous phase at 910 °C (Fig. 5(c)). The amorphous mullite is easy to dissolve into the molten salt due to its fine particle size and high activity. Then, mullite crystal seed with amorphous phase and molybdate molten salt were mixed at room temperature (Fig. 5(d)), and the molten salt melted at more than 523 °C (Fig. 5(e)). Thirdly, amorphous mullite began to dissolve into the molten salt with the size decrease of the mullite seed (Fig. 5(f)). Finally, from the supersaturated molten salt, mullite crystallizes on the surface of the mullite seed and continues to grow into whisker (Fig. 5(g)).

Conclusions

The formation of Al-O-Si bond in the mullite xerogel via NHSG route plays the key role in the low temperature synthesis of mullite crystal seed. With the aid of the prepared seed and the molybdate molten salt, the mullite whisker can be formed at the lowest temperature of 750 °C, and at 850 °C, the optimized mullite whisker was prepared with the growth direction of [001], the diameters in the range of 170~300 nm and the aspect ratio of >30. Overhigh or overlow annealing temperature is not beneficial to the growth of mullite whisker.

Keywords: Monolith, γ-Alumina Washcoat, Cobalt-Nickel, Active Phase Loading.

Abstract: The preparation conditions to obtain cobalt-nickel monolithic catalyst with high loading and homogeneous distribution are studied. Washcoating of raw monolith with gamma alumina solution was examined and characterized by SEM. A uniform layer of alumina washcoat as a support for active phase was achieved in this process. Also the effect of the molarity of solution and the number of impregnation were studied to obtain different loading of active phase on monolith walls. Catalysts with 38.81, 20.44 and 3.22 wt.% of loading were obtained by four steps of impregnation in active phase solution with 3.33, 1.42, 0.3 of molarity, respectively. It was found that increase in concentration of active phase loading leads to increase in active phase loading but reduces the uniformity of active phase distribution.

Introduction

Monolithic catalysts are one of the most attractive structures that have sensible application in catalytic reaction engineering and industrial catalysis [1-3]. This is due to the commercial success of such well-known environmental catalysis processes as the purification of exhaust gases from automobiles, the abatement of NO_x emitted in the stack gases from power stations by the selective catalytic reduction process, and the catalytic combustion of VOCs. The main reason for focusing research on monoliths was their low pressure drop [2, 4, 5].

The most common material for monolithic structures is cordierite (a ceramic material consisting of magnesia, silica, and alumina ($2MgO.2Al_2O_3.5SiO_2$)). Cordierite has several critical properties such as high mechanical resistance and high thermal shock resistance that are required for many processes in chemical engineering. Generally cordierite monoliths have a low specific surface area, usually less than 1 m^2/g, so it is essential to coat monolith surface with a high surface material to increase the surface area and provide a suitable bed for active phase deposition [6]. Washcoat materials, most often gamma alumina (γ-Al_2O_3), are used to increase the surface area and distribute the catalyst on the surface of the monolith to process a monolith into an active monolithic catalyst. The interior walls of monolith are coated with a layer of a γ-Al_2O_3, called the washcoat. Finally, within the matrix of the washcoat, incorporate the noble metals that catalyze the conversion reactions of the various reactants [7, 8].

Hydrazine (N_2H_4) as a hydrogen rich material has an extensive usage in fuel cells and gas generators. This material can decompose over supported catalysts and produce nitrogen, hydrogen and ammonia. The catalytic decomposition of hydrazine can be occurred as Eq. 1 and 2 [9, 10]:

$$3N_2H_4\ (g) \rightarrow 4NH_3\ (g) + N_2\ (g) \quad \Delta H = -157\ kJ\ mol^{-1} \tag{1}$$

$$2NH_3\ (g) \rightarrow N_2\ (g) + 3H_2\ (g) \qquad \Delta H = 46.2\ kJ\ mol^{-1} \tag{2}$$

Several transition metals, such as Ir, Ni, Co, Pt, Ru, Pd, Ag, Cu, Fe and W, are active catalysts for the decomposition of hydrazine [11, 12]. These catalysts have several advantages and disadvantages that have been discussed in literatures. These catalysts are generally in pellet shapes. This kind of support forms causes several problems like high pressure drop and low strength hydrazine decomposition reactor. It is proposed that using of monoliths as supports in hydrazine decomposition catalysts can improve transporting phenomena properties during the reaction [13].

In this study, the first objective was to develop a simple procedure leading to washcoat of monolith with γ-Al_2O_3 and obtain a washcoat with uniform distribution. This washcoated monolith was used as a support to deposition of cobalt-nickel as a usual bimetallic catalyst in hydrazine decomposition. Then cobalt-nickel active phase as a usual catalyst in hydrazine decomposition was impregnated in washcoated monolith. Effects of molarity of solution on active phase was examined and studied in details. The ultimate goal of the impregnation process is the loading of the monolith with a high amount of active phase in the form of a homogeneous layer on monolith walls.

Experimental

Washcoating of Monolith

The γ-alumina slurry was prepared to coat raw monolith. For the preparation of γ-alumina slurry, a commercial γ-alumina powder (Alfa Aesar, USA, mean particle size: 3μm) was employed. An aqueous slurry of this powder was prepared with addition of γ-Al_2O_3 powder to water solution under mixing to gain a solution with 25 wt.%. HCl and NaOH were employed for setting the pH and stabilization of the slurry.

Subsequently, cubic cordierite samples with 2 cm length (supplied by Iran Delco, Iran) and 600 cells per square inch (CPSI) were used. The cell shape of the monolithic channels is square cross section with channel width 1.08 ± 0.02 mm. As the first step in monolith preparation for washcoat, it is necessary to remove physical impurities on the surface of monolith by washing monoliths with acetone [14]. After washing with acetone, the acid treatment (washing with HNO_3) was done to increase in the specific surface area [6]. Finally raw monoliths were calcinated at 600 ℃ to improve the characteristic specific of surface. Pre-treatment monoliths were then dipped in the gamma alumina slurry prepared by solving gamma alumina in distilled water. The loaded specimens were withdrawn and excess slurry was removed by blowing air (60℃, 10 min) through the monolith channels. Then the samples were dried at 110℃ for 1.5 h and finally calcined at 560℃ for 2 h.

Ni-Co was then co-impregnated with an aqueous solutions of $Ni(NO_3)_2 \cdot 6H_2O$ (Sigma – Aldrich, USA) and $Co(NO_3)_2 \cdot 6H_2O$ (Sigma – Aldrich, USA). Solutions were prepared by solving equal amounts of these salts in different mL of distilled water to obtain solutions with 0.3, 1.42 and 3.33 M (10, 30 and 50 wt.% respectively). Washcoated samples were dipped in these solutions for 4 hours, and then excess slurries were removed by blowing air, dried at 100℃ for 2 hours calcined at 460℃ for 2 hours. Impregnation, drying and calcination was repeated respectively for four steps to achieve desirable loading. Loading percentage was determined from the increase of monolith weight after every impregnation step.

Characterization

Catalysts were characterized by X-ray diffractometer (Philips model: D6792) using a copper target at 40 kV × 100 mA at 25℃. Also the coated monoliths were examined with a scanning electron microscope SEM in a Philips XL30 ESEM microscope. The SEM images were collected to identify the average thickness of washcoat layer and study the homogeneity of washcoat.

Results and Discussion

SEM Analysis

SEM analyses of washcoated monolith are shown in Fig 1. SEM images represent suitable quality of washcoat on monolith surface. The coat layer is deposited on the channel walls of the support. It is clear that washcoat layer of γ-alumina shows no cracks or peels on monolith surface. The thickness of the alumina washcoat is about 50 microns in the middle of a channel (flat part) up to 100 micron in the corners. The γ-Al_2O_3 layer penetrated the surface open macro-pores of the cordierite, which represents a good anchoring onto the support.

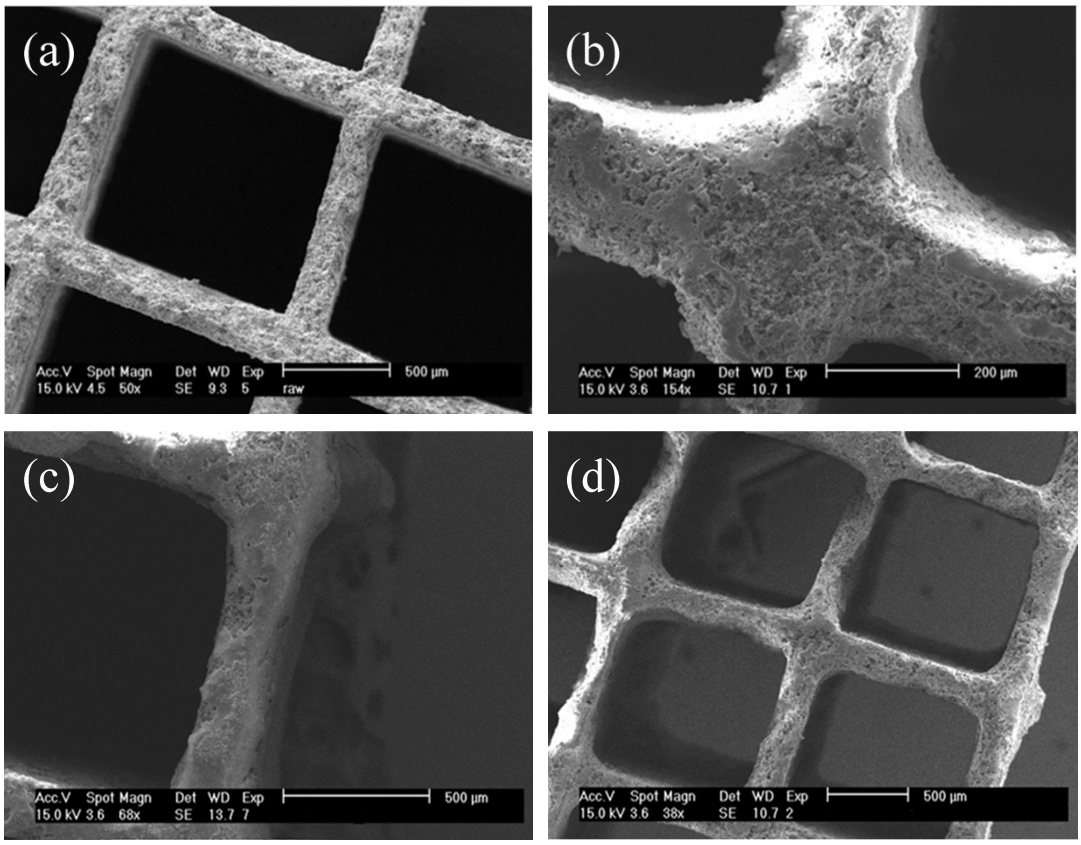

Fig 1. SEM of raw and coated monolith with γ-Al_2O_3; (a): raw monolith; (b), (c) and (d): Coated monolith with γ-Al_2O_3.

XRD analysis

The result of X-ray diffraction corresponding to the monolithic catalysts is presented in Fig. 2. This diffractogram shows the characteristic peaks of the cordierite, gamma alumina, cobalt oxide (Co_3O_4) and nickel oxide (NiO). The presence of bulk $NiAl_2O_4$ could not be confirmed by this technique.

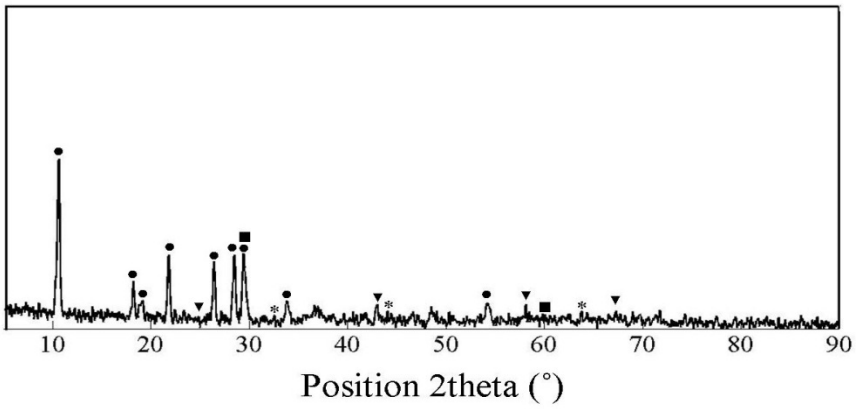

Fig 2. X-ray diffraction pattern of the Ni-Co bimetal monolithic catalyst: cordierite: ●; γ-Al_2O_3: ♥ ; Co_3O_4: ■ ; NiO: ★.

Co-Ni Loading

The required loading of the active phase on washcoated monolith is a key factor in heterogeneous catalysts synthesizing especially hydrazine decomposition catalysts. This loading was achieved with successive impregnation until the total amount of active phase loading is deposited upon the washcoated monolith. Percentage loading of active phase per number of impregnation in different solution is shown in Fig 3. The amount of loading increased with increasing in steps of impregnation. The cobalt-nickel content of the catalysts, was 3.22, 20.44 and 38.81 wt.% respectively, after four steps of impregnation with a 0.3, 1.42, 3.33 M of cobalt-nickel

active phase solution. Increase in active phase concentration leads to increase in solution viscosity and then increase in loading.

It is important to synthesize monolithic catalysts with suitable distribution and dispersion of the active phase loading. Besides, it is a key factor to achieve high loading of active phase in production of hydrazine decomposition catalysts. So it is essential to obtain a high loading, a high dispersion, and a uniform of cobalt-nickel distribution over the surface area of the washcoated monolith. Increasing in molarity of active phase loading leads to the increasing in active phase loading on monolith surface, but causes non-uniformity of active phase deposition. In other hands, increasing cobalt-nickel concentration in the impregnation solution caused in increasing the region in which cobalt-nickel accumulates. This phenomenon can be observed obviously in monolith impregnated with solution of 3.33 molarity.

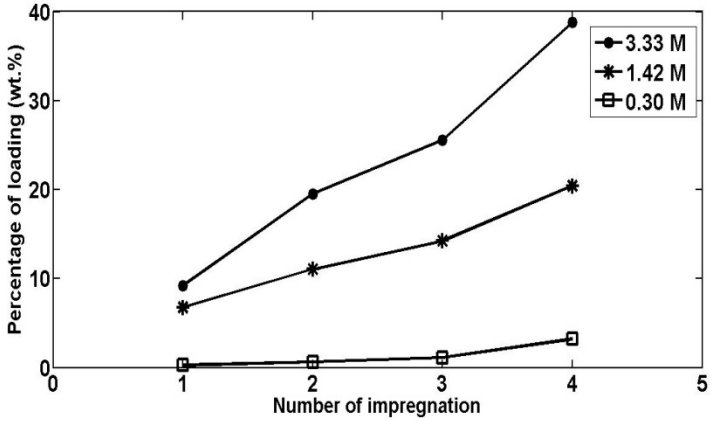

Fig 3. Percentage loading of active phase per number of impregnation in different solution with 3.33, 1.42 and 0.3 of molarity

Calcination immediately after drying is an important factor that was considered. This process prevents dissolving of previous layers of coated layer in active phase solution in every steps of impregnation. So a high loading of active phase on washcoated monolith was achieved.

Summary

Synthesize of cobalt-nickel monolithic catalyst used in hydrazine decomposition studied. A uniform layer of gamma alumina washcoat was prepared on raw monolith surface. In this way, SEM images were employed to show the morphology of coated monolith. Also XRD pattern showed cordierite, alumina, cobalt oxide and nickel oxide characteristic picks as the main compounds in synthesized catalyst. It observed that the molarity of active phase solution has high influence on loading of active phase. Increase in concentration of solution increased the percentage loading but caused uniformity of active phase distribution.

Key words: bittern; magnesium oxysulfate hydrate; morphology control; dislocation

Abstract: A low-cost raw material, bittern obtained from the production process of sea salt, was used to prepare magnesium oxysulfate hydrate ($MgSO_4 \cdot 5Mg(OH)_2 \cdot 2H_2O$, abbreviated as 152MOS) whiskers via hydrothermal synthesis with ammonia and magnesium sulfate as the other starting raw materials. The bittern was firstly filtered and then used directly without de-coloring. X-ray powder diffraction (XRD), transmission electron microscope (TEM), selected area electron diffraction (SAED), energy dispersive X-ray spectroscopy (EDX) and scanning electron microscope (SEM) were employed to investigate the composition and morphology of the products. It was found that the 152MOS whiskers synthesized from bittern at 190℃ for 3 hours exhibited fanlike morphology. The formation of the fanlike whiskers was inhibited and most of the whiskers presented as single fibers when ethanol was used as crystal control agent in the hydrothermal process. From the two-dimensional steps observed at tips of the whiskers, a possible growth mechanism was speculated that it was the extension of dislocations that made the growth of the whiskers.

Introduction

It is a well known technique to add inorganic whiskers, such as silicon carbide, calcium carbonate, magnesium hydroxide and potassium titanate, to polymers with the aim of enhancing the latter's mechanical properties and thermal stability [1–4]. As one-dimensional functional materials, whiskers have attracted great attention because of their curious structure and various remarkable physical, chemical and mechanical properties which are distinctive from those of conventional bulk materials [5]. Among the various whiskers, magnesium oxysulfate hydrate (MOS) whiskers, being proved to be well-suited as an additive for polymers and plastics [6,7], have been paid much attention since they are economically attractive and environmentally benign.

Magnesium oxysulfate hydrate can also be called basic magnesium sulfate or a solid solution in the xMgSO4·yMg(OH)2·zH2O system. By varying the ratio of these three moieties, the family of MOS comprises no less than 20 members [8]. Although previous papers had reported preparation, characterization and potential applications of the whiskers [9-13], almost all work in the literature used magnesium chloride or magnesium hydroxide as raw materials to synthesize MOS. Herein, the MgSO4·5Mg(OH)2·2H2O whiskers were prepared using bittern as raw material directly by hydrothermal synthesis without de-coloring process. It was of great interest for cost reduction, and also a new way for bittern utilization. In order to inhibit the aggregation of single whisker and enhance its application performance, several chemical additives were added, and morphology of the whisker was effectively regulated and controlled.

Experimental

Hydrothermal synthesis of MOS whiskers

The MOS whiskers were synthesized by a hydrothermal procedure in autoclave without additional template [14]. Briefly, ammonia solution was added dropwise into concentrated bittern [15] at room temperature. The slurry was filtrated, the solid filtrate was transferred to autoclave, and then magnesium sulfate was added. The autoclave was heated gradually to 190℃ and kept stirred (400 rpm) for 3 hours. A white precipitate was obtained after the autoclave was cooled down to room temperature. After filtration, the precipitate was washed with distilled water several times and dried in a vacuum oven at 100℃ for 3 hours. Then the product was obtained.

Experimental procedures and characterizations

X-ray powder diffraction (XRD) patterns were obtained with a Rigaku D/max-rA X-ray diffractometer with graphite monochromatized Cu *K*α radiation ($\lambda = 1.542$ Å), with a scanning rate of $4°\cdot min^{-1}$. The operation voltage and current were maintained at 40 kV and 50 mA, respectively.

The morphology of the products was observed on both TEM (JEM-1200EX, JEOL, Japan) at an accelerating voltage of 160 kV and SEM (JSM-6700F, JEOL, Japan) at an accelerating voltage of 12 kV. The structure was also elucidated based on both SAED on TEM and EDX on SEM.

Results and Discussion

Influence of reactants on the formation of the whiskers

Fig. 1 showed the influence of the starting raw material on morphology and composition of the hydrothermal products. Whiskers in Fig. 1a and Fig. 1b were synthesized at 190℃ for 3 hours using $MgCl_2$ and bittern as one of the starting raw materials, respectively. As could be observed the products prepared from $MgCl_2$, ammonia and magnesium sulfate exhibited a randomly arranged, long straight needle-like morphology with an average diameter of 20-40 nm and aspect ratios between 50 and 200 (Fig. 1a). While the products from bittern in replacement of $MgCl_2$ grew to fanlike whiskers, and many whiskers reunited in the same point as shown in Fig. 1b. The corresponding EDX patterns of fanlike whiskers were presented in Fig. $1b_1$ and Fig. $1b_2$. It was shown from the EDX analysis that the elementary composition at the intersection point (Fig. $1b_1$) was consistent with that in the main body (Fig. $1b_2$). The elements of O, Mg and S were observed in both cases. It meant that in the hydrothermal process, bittern could be used as one of the raw materials instead of $MgCl_2$ without de-colouring, which was of great interest for cost reduction. But except for Mg^{2+} and SO_4^{2-} it also contains many other kinds of inorganic ions such as borate ion, K^+, Cl^- and Li^+ in bittern. The crystal nucleation and growth may be influenced by the impurity ions which led to the occurrence of aggregation.

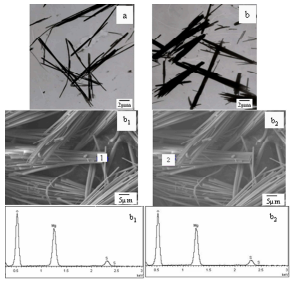

Fig. 1 Influence of starting raw materials on the morphology and composition of the whisker products. (a) and (b) are TEM images of the products with $MgCl_2$ and bittern as the staring materials, respectively. (b1) and（b2）are SEM images and the corresponding EDX spectra at the intersection point (b1) and the main body (b2) of the fanlike whiskers in Fig b

Morphology control of the whiskers

As one-dimensional functional materials, magnesium oxysulfate hydrate whiskers have been proved to be well suited as additives for polymers such as resins and plastics, acting as fillers or reinforcers with the aim of enhancing the polymers' mechanical properties and thermal stability. However, as shown in Fig. 1b, the whiskers synthesized using bittern in replacement of $MgCl_2$ agglomerated and grew to fanlike whiskers. It may be caused by the impurity ions in brine. The dispersed effect of whiskers in polymer matrix will be obviously decreased by the agglomeration which greatly restricts the use of magnesium oxysulfate hydrate whiskers.

As reported in some articles, many inorganic substances and organic compounds can be added as crystal control agents [16-18]. In order to improve the application effect, acetic acid, EDTA and ethanol were added respectively in the hydrothermal process and the morphology of whiskers was effectively controlled. It can be seen from Fig. 2 that when using acetic acid (Fig. 2b) and EDTA (Fig. 2c) as crystal control agents, the whiskers aggregated more severely with increased aspect ratios. It indicated that the presence of organic acids was favorable for the crystallization and growth of 1D $MgSO_4 \cdot 5Mg(OH)_2 \cdot 2H_2O$ whiskers [19]. While most of the whiskers presented as single fibers (Fig. 2d) with less aggregation and better dispersion when ethanol was added. The hydroxyl group in ethanol can form hydrogen bond with -OH group contained in $MgSO_4 \cdot 5Mg(OH)_2 \cdot 2H_2O$. Therefore, the surface energy of crystal nucleus was reduced and the aggregation was prevented.

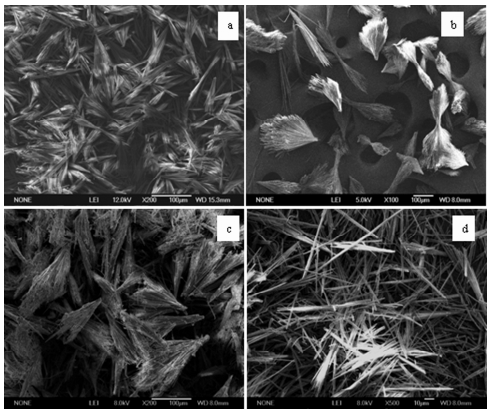

Fig. 2 Effect of additive on morphology of the products: (a) no additive，(b) acetic acid，(c) EDTA , (d) ethanol

Influence of reaction time on the formation of the whiskers

It was found that reaction time had a strong effect on the formation of 152MOS whiskers. Fig. 3 showed the TEM images of the products obtained from hydrothermal reaction of $MgCl_2$, ammonia and $MgSO_4$ at 190℃ with different reaction time and the high-magnification SEM image of the whiskers synthesized at 190℃ for 3h. As can be seen from Fig. 3a, there were some needle-like whiskers coexisted with plate particles when the reaction was maintained for 1h. The XRD pattern in Fig. 4a indicated that the products were mixture of $Mg(OH)_2$ particles and MOS whiskers when the reaction was 1h. The SAED pattern of the plate particles (shown in the inset of Fig. 3a) indicated that the particles were typical polycrystalline $Mg(OH)_2$. With hydrothermal time prolonged, the plate particles disappeared and all the products presented needle-like morphology with aspect ratios between 50 and 200. The SAED pattern of the whiskers shown in the inset of Fig. 3b suggested that the 152MOS whiskers were typical single crystal structure.

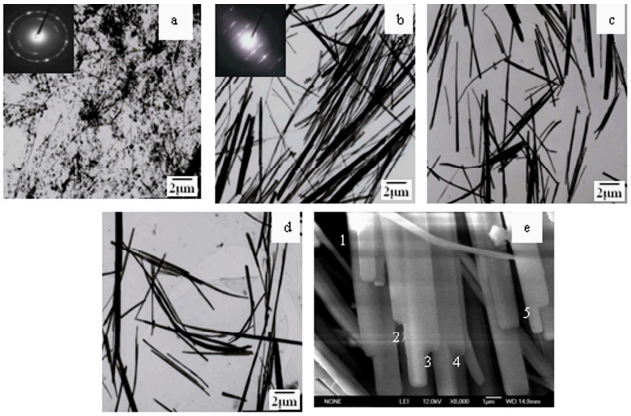

Fig.3 TEM images of the hydrothermal products synthesized at 190℃ for (a) 1h, (b) 3h, (c) 5h and (d) 20h, respectively. (e) is the high-magnification SEM image of the product shown in Fig 3b. The insets in Fig 3a and 3b are the corresponding SAED patterns of the plate particles and the whiskers, respectively

From the XRD patterns shown in Fig. 4a it could be found that the products were high purity MOS whiskers when the hydrothermal time was more than 3 hours. The 2θ values of the major peaks correspond to crystal faces of (201), (202), (203), (111), (114) and (513), respectively. The intensive XRD peaks suggested that the MOS whiskers were structurally highly ordered with high crystallinity.

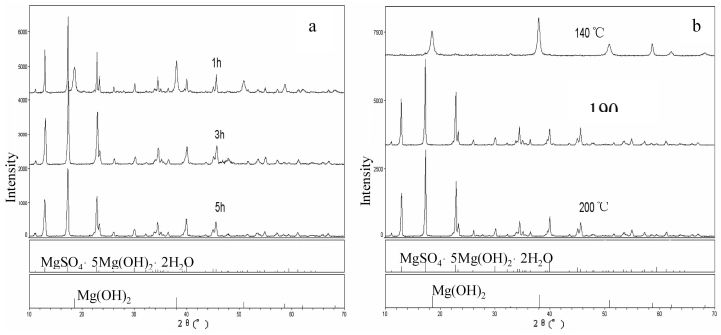

Fig. 4 XRD patterns of the hydrothermal products formed (a) at 190℃ for various reaction times, and (b) at different temperatures for 3h. The bottom bars in the figures are the major diffraction peaks of MgSO4⊙5Mg(OH)2⊙2H2O and Mg(OH)2 standards, respectively, as references

It was also seen that once all the plate $Mg(OH)_2$ particles were converted to needle-like MOS whiskers, the reaction time had no obvious effect on the morphology of the whiskers as shown in Fig. 3c and 3d, which was also in consistent with the XRD patterns in Fig. 4a.

Fig. 3e showed a part of the enlarged view of Fig. 3b, in which many two-dimensional steps can be observed. It was speculated that these steps were formed during crystal growing process as a result of crystal dislocations. Whiskers were preferentially grown crystals, and the formation includes supersaturation of the medium, crystal nucleation, dislocation nucleation and dislocation extension (crystal growth). It was exactly the extension of dislocations that made the growth of the whiskers [20]. Therefore, it was speculated that the growth of 152MOS whiskers was a result of dislocation extension.

Conclusions

152MOS whiskers were hydrothermally prepared using bittern, ammonia and magnesium sulfate as raw materials. The best hydrothermal condition was at 190℃ for 3 hours. The whiskers were preferentially grown single crystal structure and the growth mechanism was ascribed to the result of dislocation extension. The products prepared from bittern without de-coloring aggregated, reunited

in the same point and grew to fan-like whiskers. The whiskers morphology was effectively controlled and its dispersity was correspondingly improved by adding ethanol as crystal control agent. Using the magnesium resources in bittern to prepare magnesium oxysulfate hydrate whiskers is an effective way for cost reduction, and also a newly-proposed way for bittern utilization.

Keywords: SSOS, degree of substitution, surface sizing

Abstract: The preparation of Starch sodium octenyl Succinate(SSOS) and its application as a surface sizing agent in papermaking was studied in this paper. The effect of different reaction conditions on esterification of starch was firstly discussed. Based on which, SSOS with different degree of substitution (DS) was obtained and its surface sizing performance was researched. The results showed that the optimal esterification conditions were as follows: When pH is 8.5, reaction emperature is 35°C, reaction time is 3h, the maximum reaction efficiency can be achieved. The study of surface sizing performance of SSOS showed that when solid content of SSOS was 0.8613 and its DS was 0.0381, the picking speed of paper was up to a maximum value. SSOS showed a good film-forming property when its concentration was 3%.

Introductions

SSOS is an effective modified starch, which is widely used in industry such as food and paper making. Research on properties and applications of SSOS has aroused increasingly more attention [1,2]. Due to limitations of raw materials and different pulps in paper making industry of our country, the surface-strength of paper isn't high, which lead to farina or fibrilla desquamation from the paper during the printing process. Thus it is necessary to increase the strength of paper by some way. Because the special structure of SSOS, its good biodegradability and non-toxicity, it can be used as surface sizing agent in papermaking [3].In this paper SSOS is synthesized by esterification of starch and its reaction conditions were discussed firstly. Then the produced SSOS was used in surface sizing for papermaking, and its performance was analyzed.

Materials and Methods

Material and Equipment. Corn starch was purchased from Huanglong Food Industry Co. (Changchun, China); Octenyl Succinic Anhydride(OSA) was from Wei-hua Spices Chemical Co. (Hangzhou, China); reed paddle board and printing ink(medium viscosity) were provided by lab of light chemical engineering of our university; All other chemicals such as pure alcohol, solid natrium hydroxide, ammonium thiocyanate, and ferric trichloride were purchased locally and used as received without any further purification.

Methods. Preparation of Starch Sodium Octenyl Succinate. Corn starch was suspended in appropriate amount of deionized water in a beaker, which was then put in a thermostat water-bath to control the reaction temperature at a given value; The PH was adjusted to a given value by 1mol/L sodium hydrate. Then OSA, which dissolved in ethanol, was dropped in for one hour, with constant

stirring. During which 1mol/L sodium hydrate was dropped in to control the pH. At the end of reaction, 1mol/L hydrochloric acid was used to adjust the PH value to 7. Then the product was filtered and washed three times with 40% ethanol, Followed which it was dried at 55ºC overnight, crashed, and sieved.

Paper preparation. The raw materials, reed paddle board, was rived, marinated, and pulped by PFI vertical milling machine (35-39°SR). Then Paper was obtained only by adding filler, CaCO3, without squeezing . Then SSOS with different degree of substitution was cast to the surface of paper and the product was set aside for 24 hours and then tested in a constant temperature, pressure and humidity.

Tests. Determination of the degree of substitution and solid content. 5g SSOS was accurately weight and diluted with tiny amounts of ethanol, then.2.5mol/L hydrochloric acid in ethanol (25ml) was added. The slurry was magnetic stirred for 30 minutes, then added 90% ethanol(100ml) and stirred for 10 minutes. The suspension was filtrated again, and the residue was washed with 90% ethanol until no Cl- could be detected any longer and then moved to 500ml beaker. The SSOS was re-dispersed in 300 mL of distilled water, and then heated in a boiling water for 10 min. The starch solution was titrated with 0.1 M standard NaOH solution, using phenolphthalein as an indicato. According to the following formula to calculate the degree of substitution (DS) [8]:

$$DS = \frac{0.1624A}{1 - 0.210A} \quad . \tag{1}$$

A is the amount of sodium hydroxide consumed (mmol/g SSOS). Solid content(SC) was difference value of quality before painting on the paper, then divided by the area[9].

Surface strength. Surface strength of the paper was tested by printing adaptability instrument. 5 scrip specimens were cut from the paper according to the standard sample size. The sample was put between the paper clips, rotating fan handle which touched the rubber roller, then proper speeds were used to test the picking speed [7]. The sample was quickly got after printing, using a magnifying glass to observe surface condition with the aid of fluorescent, fluff position was recorded if the sample fluffing. The distance from starting point of printing to fluff pares crack point was measured, and then picking speed was got according to the speed curve diagram.

Waterproofness. According to the stockigt measurement [5], 5*5cm pattern was folded into boat. 1% $FeCl_3$ solution was dripped on the inside of paper. The boat was put on the 2% NH_4CNS solution, and at the same time the stopwatch started to time. The time when $FeCl_3$ reacted with NH_4CNS to produce red colour was recorded as the degree of sizing.

$$FeCl_3 + 3NH_4CNS \longrightarrow [Fe(CNS)_3] + 3NH_4Cl. \tag{2}$$

Results and Discussion

Influences of the preparation of SSOS. The DS of SSOS was closely related to the reactions conditions such as PH value, addition of OSA, reaction time, reaction temperature and so on.

Effect of temperature on esterification. Effect of temperature on esterification was shown in Fig 1. The results showed that the optimum temperature of esterification was 35 ºC. The DS was increased with the increase of temperature firstly and then decreased. This was perhaps because that the solubility and diffusion ability of OSA was increased when the temperature raised. But when the temperature is too high, it can lead to a faster decomposition of SSOS than that of lower temperature. Thus the optimal temperature was 35 ºC.

Effect of reaction time on esterification. The effect of reaction time on esterification was shown in Fig 2. The DS of the product was increased firstly and then decreased with the increment of reaction time. The DS was up to the highest at the traction time of 3h. It may be due to that esterification is reversible, which caused the decrease of DS when the reaction time beyond 3h.

Effect of PH on esterification. The effect of pH on esterification was shown in Fig 3. The results showed that when PH was 8.5，the DS of SSOS reached to its maximum value. It was because that with the increase of pH and amount of sodium hydrate, and starch was prone to be gelatinized. Besides, with the increment of the alkaline, much OSA would react with alkali instead of starch, which led to the decrease of DS.

Effect of dosage of the OSA on esterification reaction. To investigate the effect of time on esterification reaction in Fig.4, PH 8.5, 3h, 35 ℃, and the dosage of the starch milk was 0.25mg/L. Seen from Fig.4 , the DS kept increasing with the increase of the OSA, . The different DS was made for the experiment.

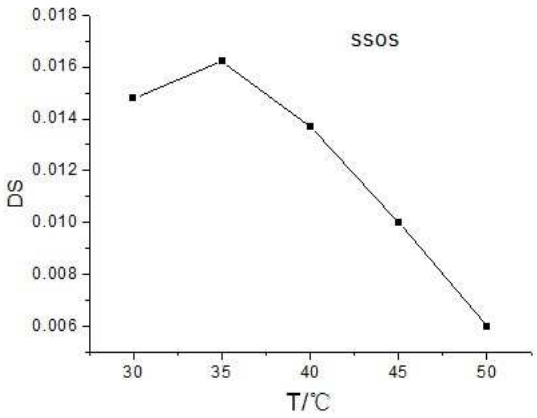

Fig 1 Effect of temperature on esterification

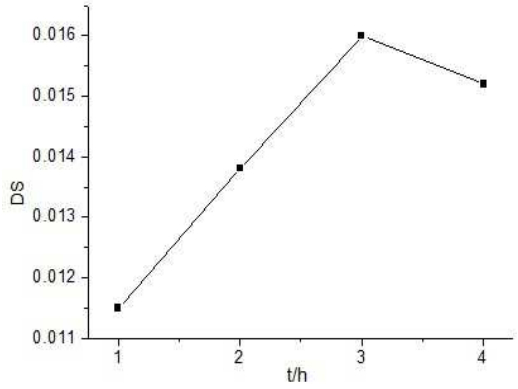

Fig 2 Effect of reaction time on esterification

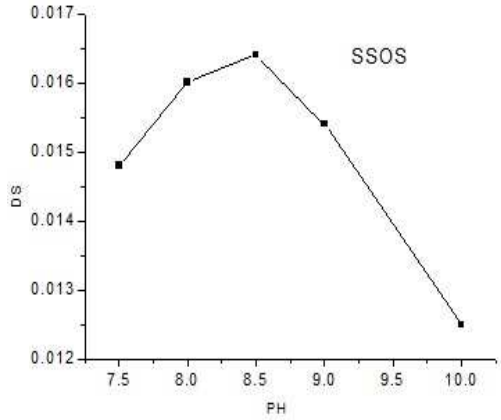

Fig 3 Effect of PH on esterification

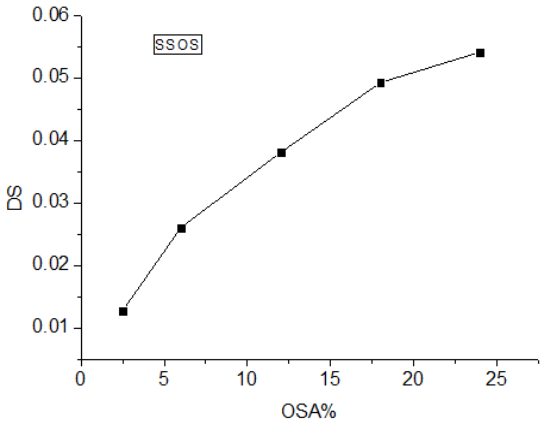

Fig 4 Effect of dosage of the OSA on esterification

Surface sizing performance of SSOS. Strength of the surface of paper was also called anti-dropping anti-blockage, which showed that the resistance ability of off powder and dropping in the printing process. Dropping and off powder was a common phenomenon in paper making industry, which was the paper defects. The mechanism is that when surface tension of the paper was less than external mechanical forces, some stuff like fiber fines, fragment, filler particles, sizing agent, and pigment particle were fell off the edge of paper under the action of mechanical force. SSOS was used to size the paper surface and its ability of resistance of the off power was studied, the sizing effect was measured at the same time.

Effect of DS and solid content on the surface strength of the paper. Printing adaptability test was made to assess SSOS sized paper and the result was shown in fig. 5. Each trend line represented different solid content of SSOS. The results showed that while the solid content was constant, the surface strength of paper increased with the increase of DS of SSOS. Native starch was illiquid, on the contrary, the modified starch, which infiltrated into the paper surface formed hydrogen bonds with the paper fiber, was greatly increased the surface strength of paper. At the same time, the hydrophobic alkenyl was directionally distributed on the fiber surface, which gave water resistence performance of the paper[4,6]. The higher the DS, the more the double bonds combined, which led to increased picking speed of paper. Meanwhile, the sizing effect enhanced with the increase of solid content under the same DS of SSOS. Starch and paper fiber were combined more closely when the solid content of SSOS was increased, thus increased surface strength of the paper obviously.

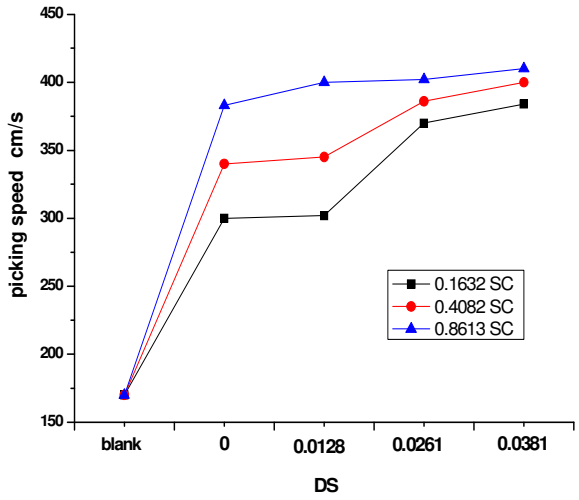

Fig. 5 Effect of DS and solid content on the surface strength

Effect of DS and solid content on water resistance of paper. Stockigt method was adopted to assess sizing effect whether good or not. SSOS with concentration of 1%, 3%, and 5%, respectively, was used as surface sizing agent and the results was shown in Fig. 6. It can be observed that the sizing effect enhanced with the increase of DS, no matter what concentration of the SSOS. It perhaps because that the modified starch which infiltrated into the paper surface formed hydrogen bonds with the paper fiber, while the hydrophobic alkenyl was directionally distributed on the fiber surface, which gave the paper water resistence performance. The more the alkenyl chains, the better the sizing effect. The results also showed that the solution with concentration of 3% had the best surface sizing performance. May be it formed a more impeccable layer than that of lower concentration. Thus its water resistance was better. Solution of 1% has very good liquidity, which led to a thin film, and it is hard to be stripped. When the concentration is more than 5% starch solution had poor liquidity, which cannot form an integrated layer, and its barrier property and water resistance decreased. So the best performance of SSOS was 3% concentration.

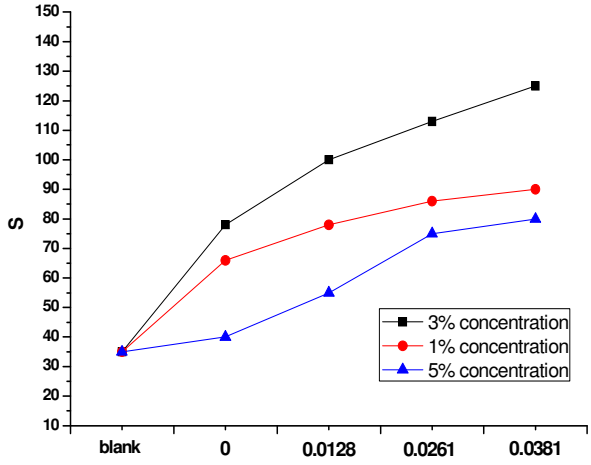

Fig.6 Modified starch of three different solid content starch

Conclusion

SSOS was prepared by using corn starch as the raw materials, and the optimum conditions of esterification were investigated firstly. Then surface sizing performance of SSOS on paper was studied. The influence of DS of SSOS and its solid content on the surface strength and water resistance of paper were discussed. Firstly, the optimal conditions of preparation of SSOS were that temperature of 35 ºC, pH of 8.5, and reaction time of 3h. Picking speed test showed maximum value when the DS was 0.0381 and solid content of SSOS was 0.8613 g/m2. The result indicated that the solid content and the DS of SSOS were two important factors that affect paper surface sizing performance of SSOS.

Keywords: polyacrylonitrile, ionic liquid, dry-jet wet spinning, structure, property

Abstract: In order to study the structure and property development of polyacrylonitrile fiber during spinning process with ionic liquid as solvent, the 13 wt% PAN/[BMIM]Cl solution was prepared by dissolving polyacrylonitrile (PAN) in 1-butyl-3-methylimidazolium chloride ([BMIM]Cl). The dry-jet wet spinning of PAN/[BMIM]Cl was carried out to obtain the samples along spinning line. The mechanical properties, dynamic mechanical properties (DMA) and supramolecular structure of PAN fiber were analyzed. It is found that along spinning line tensile strength of PAN fiber increased significantly; initially, elongation at break increased followed by subsequent decrease. The fiber's glass transition temperature (T_g) drops initially and later becomes constant; however, the fiber's crystallinity and orientation increased.

Introduction

Polyacrylonitrile (PAN) fiber was widely used in costumes, decorations and industrial applications because of its excellent flexibility, fluffy texture, exhibits acid and light sensitivity and other properties. There are some strong dipole interactions resulting from（-C≡N）in the polyacrylonitrile (PAN). It causes that the fiber's melting point to become relatively higher than the decomposition temperature (T_d). Therefore，Polyacrylonitrile was dissolved in some strongly polar solvents such as N, N-dimethylformamide (DMF), N, N-dimethylacetamide (DMAc), dimethyl sulfoxide (DMSO) and aqueous solution of sodium thiocyanate etc.

In 2004, Cheng *et al.* [1] found that the ionic liquid (IL) was good solvent for polymerization and dissolution of acrylonitrile. Then the dissolution and regeneration of polyacrylonitrile in ILs have been investigated [2]. PAN/[BMIM]Cl solution has a higher apparent viscosity and significant shear thinning properties. The elastic characteristics of the solution were conducive to spinning and stretching [3, 4]. Wan and Yin *et al*. [5, 6] studied the structure of PAN fibers prepared with ionic liquid as a solvent by dry-jet wet spinning.

Previous studies have shown that polyacrylonitrile with IL as solvent has imparted some different characteristics in dissolution [1, 7, 8], solution properties [3, 4] and spinning [5, 6] compared to conventional solvents. As we all known, solution spinning is a complex process and each procedure has significant impact on the final structure and properties of the fibers. Ji [9] studied the relationship between techniques and properties during PAN fiber formation process and suggested that the crystal structure of the fibers has formed basically during the coagulation stage. Both drawing and removal of solvent can increase the mechanical properties of the fibers. Liang *et al*. [10] discussed the changes in formation and evolution of porosity structure during spinning process and found that porosity structure can affect the fiber's resultant physical properties. However, after-processing,

stretching can reduce fiber pores, thus fiber density, mechanical properties, crystallinity would increase. The study of the relationship between structure evolution and mechanical properties during the spinning process of PAN fiber in the [BMIM]Cl system have yet to be further explored. In this work the macromolecular structure of PAN fiber during the spinning process was evaluated using wide-angle X-ray synchrotron radiation diffraction (WAXD) technique. The relationship between the structure and properties during the spinning process was investigated by combining mechanical testing and dynamic mechanical analysis (DMA).

Experimental

Samples

Materials

The copolymer poly(AN-co-MA) (Acrylonitrile : methyl acrylate = 9:1) was provided by Shanghai Petrochemical Co. Ltd. (Shanghai, China) with a viscosity average molecular (Mv) of 9.0×10^4g/mol. The ionic liquid [BMIM]Cl was synthesized and purified according to the literature[11].

Polyacrylonitrile fibers preparation

The 13 wt% PAN/[BMIM]Cl solutions were prepared by dissolving PAN in [BMIM]Cl by kneading. PAN fibers were prepared by the dry–jet wet spinning process with a lab scaled spinning machine with the following process diagram and conditions, shown in Fig. 1.

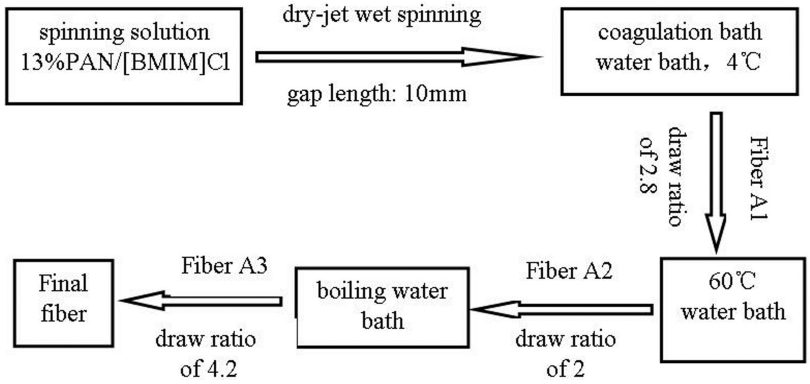

Fig. 1 The flow-process diagram of dry-jet wet spinning process for PAN fibers

Fiber diameter

Fiber diameters were measured by Polarizing microscope WT-MV3100H (Shanghai Science and Technology Development Co., Ltd.). At least 15 measurements were taken as the average value.

Mechanical properties

Samples were washed with hot water to remove residual solvents and dried to constant weight. The stress-strain curves of a single fiber were recorded using a XQ-1A tensile tester with a gauge length of 20 mm and an extension rate of 20 mm/min. At least 20 samples were tested for each samples and the tenacity, elongation at break and initial modulus were calculated averagely.

Fiber birefringence

Fiber's birefringence was measured using Mongolian compensation method by Motic BA300Pol polarizing microscope. The compensation angle θ (^{o}) of fiber was measured using a polarizing microscope. The birefringence was calculated according to Eq. (1).

$$\Delta n = \theta\lambda / 180^o d \tag{1}$$

Where Δn is the birefringence, $\lambda=0.589\times10^{-9}$ m is the wavelength of sodium, θ is compensation angle, d is the fiber's diameter (m).

Wide-angle X-ray diffraction

Wide-angle X-ray diffraction (WAXD) characterizations of fibers were carried out at the Shanghai Synchrotron Radiation Facility (SSRF) on beam line (BL14B). The X-ray wavelength was 1.24Å. The 2θ vs. intensity curves were obtained by integrating using FIT2D software based on fiber's diffraction curves. The content of crystal phase and mesophase, orientation factor and crystallite size were calculated according to the reference[12].

The Dynamic Mechanical Analysis

The dynamic mechanical Analysis (DMA) was carried out by TA Q800 instrument to obtain the loss factor (tanδ). The frequency applied was 1 Hz over a temperature range from 25 °C to 400 °C in the temperature-frequency sweeping mode. Heating rate is 5°C/min and the amplitude is 15μm.

Results and discussion

Mechanical properties of PAN fiber during spinning process

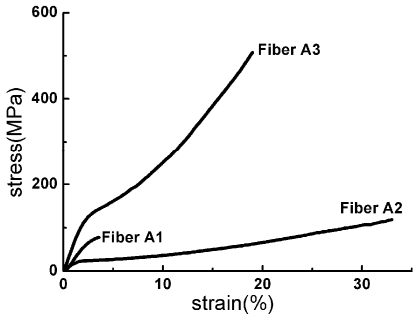

Fig. 2 The stress-strain curves of PAN fiber during spinning process

TABLE 1 MECHANICAL PROPERTIES OF PAN FIBER DURING SPINNING PROCESS

Samples	Diameter [μm]	Tensile strength [MPa]	Elongation at break [%]	Initial modulus [GPa]
Fiber A1	59.26	70.71	3.51	2.99
Fiber A2	51.40	101.85	33.00	2.21
Fiber A3	25.68	500.81	19.01	6.29

The stress-strain curves of the washed and dried PAN fibers obtained from spinning line were shown in Fig.2. It is found that along spinning line the fiber's tensile strength increased significantly while initial modulus and elongation at break showed different regulation. Fiber A1 is brittle and has no apparent yield behavior. However, fiber A2 and fiber A3 got plastic deformation under load and exhibited obvious yield behaviors. Fiber A2 and A3 were in elastic region before the yield point. After the yield point, plastic deformation occurred but no obvious phenomenon of the narrow neck. Then, with the strain increase, the tensile stress continued to increase.

DMA of PAN Fiber During Spinning Process

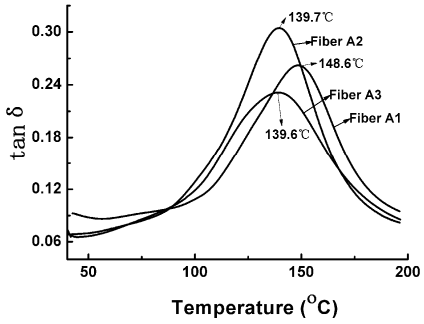

Fig. 3 Curves of tanδ vs. temperature of PAN fibers during spinning process

As shown in Fig. 3, only the glass transition peak was observed in the temperature-tanδ curves. It can be seen from the curves the Tg of Fiber A1 is the largest, which attributes to the entanglement of macromolecular chain in amorphous regions[13]. After the pre-drawing in water bath, the macromolecular chains of amorphous region began to be oriented and the entanglements reduced so the Tg decreases.

Supermolecular structure of PAN fibers during spinning process

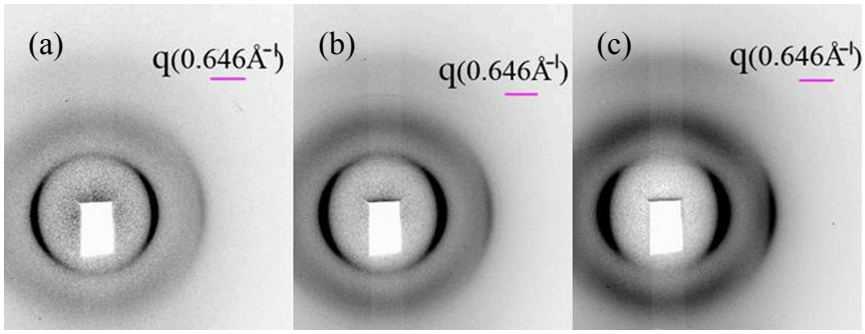

Fig. 4 WAXD patterns of PAN fibers during spinning process, (a) Fiber A1, (b) Fiber A2 and (c) Fiber A3

Table 2 Parameters of supermolecular structure of PAN fibers during spinning process

Samples	Percent of crystal phase[%]	Percent of mesophase [%]	Crystallite size of (100) [nm]	Birefringence [$\Delta n \times 10^2$]	Crystal orientation factor [f_c]
Fiber A1	44.8	30.8	4.44	0.31	0.66
Fiber A2	45.3	31.5	4.09	0.54	0.69
Fiber A3	49.5	31.1	4.36	0.87	0.77

From Fig. 4, the image of dimensional WAXD of fiber A1 showed an obvious long diffraction arc indicated a low orientation in crystal phase. The diffraction arcs of fiber A2 and A3 gradually become short and the strength is increased after the drawing. The $2\theta=16.9°$ and $2\theta=29.5°$ in the equatorial line show apparent reflex arc which belong to hexagonal crystal system [14], corresponding to the (100) plane and the ($2\bar{1}0$) plane.

From the calculation results shown in Table 2, it is clear that the content of crystal phase, the birefringence and crystal orientation factor increased along the spinning line, which caused the increase of tenacity of the fibers. And the change of crystallite size could be the corresponding to the change of initial modulus of the PAN fibers because the larger crystallite often caused larger initial modulus of fiber.

Summary

From the analysis of properties and structure of the PAN fiber during spinning process, it is found the increase of the content of crystal phase and orientation both in crystal phase and non-crystal phase resulted in the increase of tenacity along spinning line. While the different change of initial modulus was resulted from the variation of the crystallite size as the larger crystallite leaded to the larger initial modulus. And the higher Tg was observed in the coagulated PAN fiber (Fiber A1) which was caused by the strong entanglements of the molecular chains in the amorphous phase due to the low orientation of Fiber A1.

Keywords: cellulose diacetate; ionic liquid; plasticization

Abstract: Three ionic liquids, 1-butyl-3-methylimidazolium terafluoroborate ($BMIMBF_4$), 1-butyl-3-methylimidazolium trifluoromethanesulfonate (BMIMOTF) and 1-butyl-3-methylimidazolium hexafluorophosphate($BMIMPF_6$) were applied as the plasticizers of CDA. Among three ILs, $BMIMBF_4$ was considered to be the most effective plasticizer, which was confirmed by TGA and DMA. The interaction between ILs and CDA was also investigated.

Introduction

In recent years, cellulose material has become one of the focuses as a replacement of petroleum-based material in the field of fibers and textiles due to the anxiety about exhaustible resources[1-3]. However, limited by the strong intermolecular interactions of a large number of hydrogen bonds among hydroxyl groups of the anhydroglucose units in cellulose (Fig 1)[4-7], its processing is basically realized by solvation and derivatization to weaken and unlock the intermolecular hydrogen bonds[8-9], which is nongreen and raises a lot of environment problems. Cellulose cannot be melt processed for its higher melting processing temperature (T_m) than decomposition temperature (T_d), resulting from the strong intermolecular interactions. Although acetyl groups substituting the hydroxyl group in Cellulose diacetate (CDA) making it thermoplastic[10], CDA cannot be melt processed either without any modification dut to its melting processing temperature (T_m) close to decomposition temperature (T_d) [11].

To improve the melt processability and facilitate processing of CDA, it is commonly modified by low molecular weight plasticizers like phthalates, glycerine and phosphates because of their low cost and facility of compounding, while a serious problem of plasticizer leaching occurs which is responsible for the lowering of the mechanical properties of molded CDA products[12-13]. To solve this migration problems, some attempts have been made by introducing long chain to CDA, i.e. chemical modification. Polylactic acid (PLA) and caprolactone (CL) are commonly practiced to graft CDA, main role being to destroy the cellulose crystalline structure and lead to a lower glass transition temperature[14-19]. However, chemical modification depends very much on the degree of substitution, and often, external plasticizers and catalysts have been used to assist grafting. Despite of the good modification effect of introduction of side chain, it also causes some problems to be solved such as side chain flow and increased brittleness of products and so on[20].

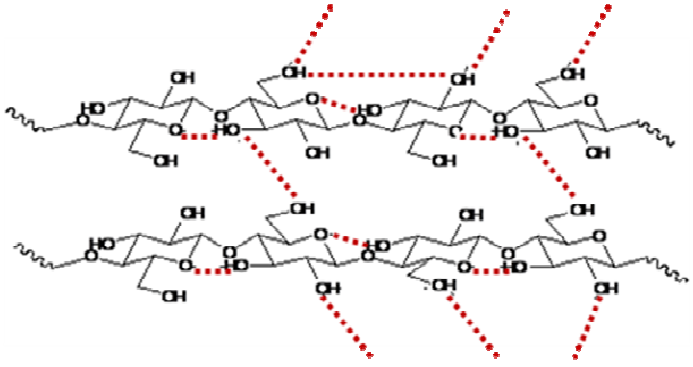

Fig. 1 Schematic Diagram of H-bondings in Cellulose

Ionic liquids (ILs) are low melting point salts being entirely composed of ions. They have been extensively investigated in the last decade due to their many unique properties such as recyclablility, negligible vapor pressure, thermal and chemical stability and non-flammablility[21-23]. It is also reported that ILs containing imidazolium or pyridinium cations are similar to some conventional plasticizers, containing an aromatic core and pendant alkyl groups[24]. Moreover, ILs exhibit many of ideal plasticizer characteristics such as low volatility, low leachability, high and low thermal stability, thermodynamic compatibility with polymers, with performance, reproducibility, and wide thermal range being some of greatest advantages over traditional plasticizing agent, which attract many interest in the studies on the plasticizing effect of ILs as plasticizer of polymer. However, to the best of our knowledge, very little effort has been devoted to the preparation of cellulose material by ILs plasticizing, not to mention the subsequent processing.

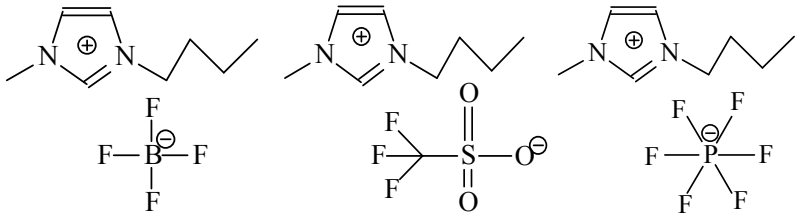

Fig. 2 Chemical Structure of plasticizing agents investigated

In this paper, the plasticization effect of ILs and the interaction between ILs and CDA were investigated. Firstly the solubility of CDA in different ILs were studied, considering that the interaction between ILs and CDA was more easier to observe in solution than in plasticized mass. By comparison, the solubility of cellulose in defferent ILs were also investigated(as shown in table 1). It was found that cellulose could not be solved in 1-butyl-3-methylimidazolium terafluoroborate ($BMIMBF_4$), 1-butyl-3-methylimidazolium trifluoromethanesulfonate (BMIMOTF) and 1-butyl-3-methylimidazolium hexafluorophosphate($BMIMPF_6$), which is in consistent with literature, while CDA exhibited the opposite solubility in these three ILs. In consideration of the difference of structure between cellulose and CDA, we inferred that it was the acetyl groups that played an important role in interaction with those three ILs.

Table 1. The solubility of CDA and cellulose in different ILs at 30°C

	BMIMOTF	$BMIMPF_6$	$BMIMBF_4$	BMIMCOOH
CDA	soluble	soluble	soluble	insoluble
cellulose	insoluble	insoluble	insoluble	soluble

In the further exploration, $BMIMBF_4$, BMIMOTF and $BMIMPF_6$ were used as plasticizer. ILs and CDA with a certain mass ratio were mixed and dissolved in acetone. Colorless and transparent solutions were prepared and then were casted in aluminum foil. Thin plasticizing film samples were recovered after acetone volatilization.

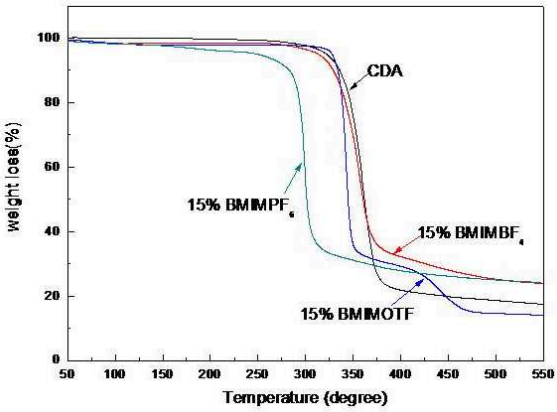

Fig. 3 Thermal stability of CDA and plasticized CDAs by different ILs

The plasticized samples were tested for thermal stability. It was evident from Fig. 3 that CDA sample plasticized with 15 wt% $BMIMBF_4$ had a similar thermal stability with CDA, which was more stable than those plasticized by BMIMOTF and $BMIMPF_6$ (Table 2). The glass transition temperatures of CDA and plasticized CDAs samples were also tested by DMA. As shown in Table 2, T_g of plasticized CDAs were much lower than CDA, while the differences in T_d were not significant, especially in the case of $BMIMBF_4$ as plasticizer. It is indicated that ILs as plasticizer can be effective in broadening the processing temperature by reducing T_g of plasticized CDA, resulting in improving the processability of CDA. Among three ILs, $BMIMBF_4$ was considered to be the most effective plasticizer.

Table 2. T_g and T_d at 5%, 10%, 50% weight loss of CDA and plasticized CDA (15 wt% ILs)

samples	T_g	$T_{d,5\%}$	$T_{d,10\%}$	$T_{d,50\%}$
CDA	231 °C	318.3 °C	333.8 °C	363.2 °C
CDA/$BMIMBF_4$	161 °C	311.8 °C	328.1 °C	360.8 °C
CDA/BMIMOTF	163 °C	327.3 °C	332.9 °C	344.4 °C
CDA/$BMIMPF_6$	176 °C	234.4 °C	282.9 °C	301.1°C

The interaction between $BMIMBF_4$ and CDA in plasticized samples was investigated by FT-IR (Fig.4). It could be noticed that the O-H stretching decreased in intensity and the peak position assigned to C=O in acetyl groups[25] moved to higher wavenumber with the introduction of $BMIMBF_4$, meanwhile, the peak position assigned to C-H in imidazolium ring[26] moved to lower wavenumber, which indicated that the hydrogen-band matrix in CDA was weakened and partly destroyed by the interaction between CDA and $BMIMBF_4$. And it was also indicated that when the ILs serve as solvents, the same interaction occurs in the solvation(as shown in figure 5).

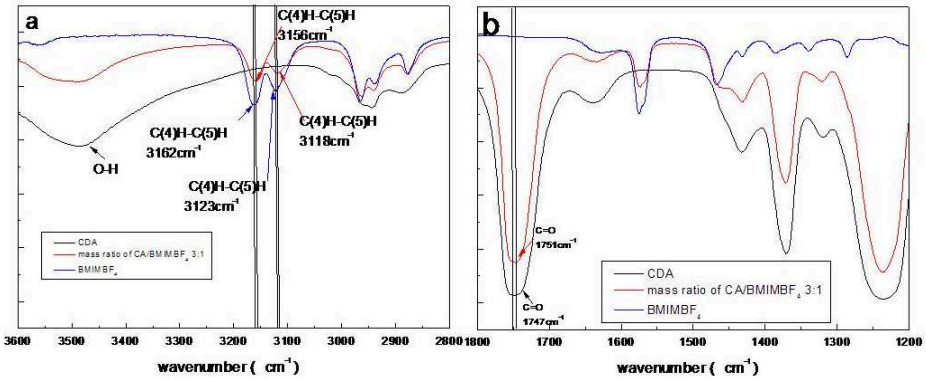

Fig. 4 IR spectra of CDA, $[BMIM]BF_4$ and CDA/25wt%$[BMIM]BF_4$ in the region (a)from 3600 cm^{-1} to 2800 cm^{-1}; (b)from 1800 cm^{-1} to 1200 cm^{-1}

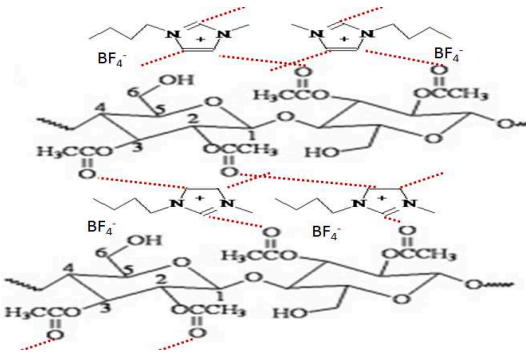

Fig. 5 Proposed schematic diagram for the interactions between repeating monomer units of CDA and [BMIM]BF_4

The application of $BMIMPF_6$, BMIMOTF and $BMIMBF_4$ as plasticizer of CDA is very promising in processing of CDA material allowing CDA to have a wider range of working temperatures. Among these three ILs, $BMIMBF_4$ was regarded as the most effective plasticizer. The interaction between ILs and CDA or the plasticization mechanism will be further investigated in our future work.

Keywords: m-xylylenediamine (MXDA); aniline; vapor-liquid equilibrium; Wilson equation

Abstract: The saturated vapor pressures of m-xylylenediamine (MXDA) were measured with the static method at the temperatures between 150-180℃, and the Antoine parameters of MXDA were regressed. The Vapor-Liquid Equilibrium (VLE) data of aniline-MXDA system at pressure of 4 kPa were determined. The VLE data were tested by the integral method proposed by Herington and showed to meet thermodynamic consistency. Wilson Equation was used to correlate the experimental data and the model parameters were determined. The calculated data from Wilson Equation agreed well with the experimental data of the above binary system.

Introduction

MXDA is an aliphatic diamine having benzene ring produced from isophthalonitrile (IPN).

MXDA is used as an epoxy resin hardener directly and is useful as a chemical intersolvent in the plastic and polymer fields.[1-3] Zhang Peng et al[4] prepared the amorphous Ni-Al alloy thin strip with quenched to make high activity skeleton nickel and the molar yield of MXDA was up to 96%. With Co-Ti/diatomite catalyst, the yield of MXD to 94% was made for UOP Inc.[5] In this hydrogenation reaction, optimum reaction conditions are crucial to produce a high grade of MXDA. The solubility of IPN in several commonly used solvent is compared with each other in literature.[6]

Because the solubility of aniline to IPN is very big and aniline does not participate in this reaction[7], aniline is determined for the reaction solvent in this paper. In the subsequent design of the reaction product separation, the VLE data of aniline-MXDA system are essential which are not reported now. The VLE data of aniline-MXDA system are determined at pressure of 4 kPa with gas-liquid dual-loop method and Wilson Equation is used to correlate the experimental data in this paper.

Experimental

Experimental principle. The VLE data of aniline-MXDA system are determined with the loop method used widely in this paper. When the vapor-liquid equilibrium is reached, in addition to the pressure and the temperature of the two-phase is equal respectively, the chemical potentials of each phase is equal too, that means the fugacity of each phase is equal. When these VLE data are determined at pressure of 4 kPa, the activity coefficients of the different components can be calculated by equation (1), then, Wilson equation is used to correlate the activity coefficients with the compositions of the different components by equation (2). The Wilson parameter— Λij can be changed with the temperature changing and $\ln \Lambda ij$ can be expressed as a function of temperature shown in equation (3). The binary interaction parameters—a_{ij}, b_{ij}, c_{ij}, d_{ij} included in equation (3) can be regressed with the VLE data and the saturated vapor pressures data of the pure component determined in this paper, then, the vapor-liquid equilibrium equation can be got.

$$\gamma_i = \frac{Py_i}{P_i^0 x_i} \quad (1)$$

$$\ln \gamma_i = 1 - \ln(\sum_j \Lambda_{ij} x_1) - \sum_j \frac{\Lambda_{ji} x_j}{\sum_k \Lambda_{jk} x_k} \quad (2)$$

$$\ln \Lambda_{ij} = a_{ij} + b_{ij}/T + c_{ij} \ln T + d_{ij} T \quad (3)$$

Materials. IPN (purity≥99.9%), aniline(purity≥99.5%), methanol (purity≥99.5%)，and the origins of the chemicals is from Sinopharm Chemical Reagent Co., Ltd.

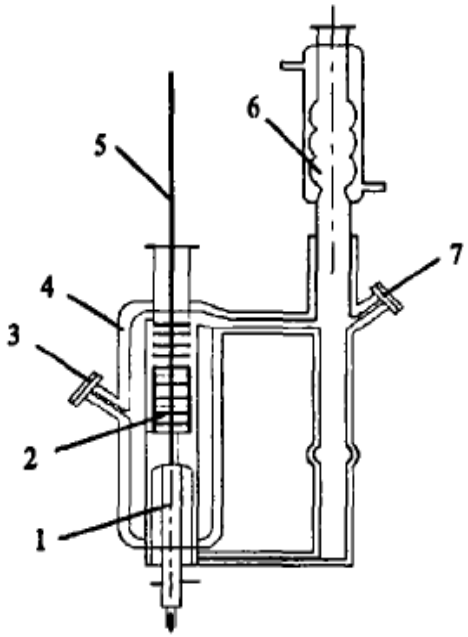

Fig.1 Sketch of EC-2 VLE equipment

5.thermometer 6.condenser 7.vapor phase sample connection

Experimental procedure. This experiment is conducted in the gas-liquid equilibrium kettle shown as Figure 1. First, some tested solution is put into the gas-liquid equilibrium kettle, then, the cooling water is entered and the kettle is heated slowly. When the condensate of the gas phase begins to reflux, this refluxing operation can be stable through controlling the heating. After this refluxing operation has been stabilized for 30min, the gas and liquid samples are taken with the syringe, the compositions of them are analyzed respectively and the equilibrium temperature and pressure are recorded at the same time (thermometer calibration accuracy ±0.01K). The pressure of this system is controlled with a Nessler vacuum pump and is determined with a U-shaped mercury manometer (accuracy±0.067 kPa). In order to examine the device reliability, the vapor-liquid equilibrium data of the binary system of benzene and toluene are determined. The average deviation of the equilibrium temperature is 0.70K and it of the gas and liquid composition is less than 0.008.

Analytical technique. Analytical instruments：Agilent 7890A gas chromatograph with hydrogen flame (FID) detector: Chromatograph column: DB-1(Φ0.25×30m, membrane thickness: 0.25μm). Chromatograph conditions: column temperature box: initiation temperature: 100℃(remaining 3 min), heating rate: 30 K/min, termination of temperature: 250℃(remaining 2 min), vaporizer temperature: 250℃, Detector: 250℃ (hydrogen flow rate: 40 ml/min, air flow rate: 400ml/min,

mixing gas flow rate: 35ml/min）, speed：1.0mL/min, split ratio: 100:1, the injection volume: 0.2μL. The area normalization method is used for the quantitative analysis.

Results and Discussion

Determination and fitting of saturated vapor pressures of MXDA. As section 2.1 described, the activity coefficients of the different components are needed for the correlation of the thermodynamic equation, but the data of saturated vapor pressures of MXDA are not reported completely. The saturated vapor pressures of MXDA are measured with the static method at the temperatures between 150-180℃ and they are regressed with the 5 Parameters Antoine equation shown in equation (4).

$$\ln p = c_1 + c_2/(T + c_3) + c_4 T + c_5 \ln T \tag{4}$$

Where: p is used to express the saturated vapor pressures of MXDA and its unit is kPa; T is used to express the temperature and its unit is ℃; Antoine equation parameters can be expressed with c_1, c_2, c_3, c_4 and c_5.

The data of saturated vapor pressure of MXDA determined in this paper is given in Table 1 which is used to fit the Antoine equation parameters and the Antoine equation for MXDA is described as equation (5).

Table 1 The saturated vapor pressure data of MXDA

T(℃)	150	153	157.5	165	168	170	172.5	178	180
P(kPa)	3.689	3.708	3.823	4.46	4.641	5.174	5.835	7.307	8.480

$$\ln p = 2337.57 - 9786.71/(T - 8.003) + 1.005T - 451.5 \ln T \tag{5}$$

The average relative deviation expressed in equation (6) between the calculated results and the regressed values is 1.24％.

$$ARD = \frac{1}{k}\sum_{i=1}^{k}\left|\frac{x_{\exp} - x_{cal}}{x_{\exp}}\right| \times 100\% \tag{6}$$

Where: x_{exp} is used to express the experimental values, x_{cal} is used to express the calculated results, k is used to express the experimental points.

Thermodynamic consistency test. Whether the VLE data determined in this paper is reliable, the thermodynamic general relationship can be used to test. If the VLE data can be conformed to the thermodynamic relationship, they can be thought having the thermodynamic consistency. The VLE data are tested for the thermodynamic consistency by the Herington area test method which is based on Gibbs-Duhem law, then, the activity coefficients of the two components are calculated by the VLE experimental data and the area of the $\ln(\gamma_1/\gamma_2)$—x_1 of the area test figure is calculated with the area integration method, the values of D and J can be calculated finally. If D<J or D-J<10, The VLE experimental data can be considered to conform the demand of the thermodynamic consistency.

$I = \int_0^1 \ln\frac{\gamma_1}{\gamma_2} dx_1$, $\Sigma = \int_0^1 \left|\ln\frac{\gamma_1}{\gamma_2}\right| dx_1$, $D = \frac{|I|}{\Sigma} \times 100$, $J = \frac{150\theta}{T_m}$, Where: T_m is the lowest boiling point, K； θ is the boiling point difference of aniline－MXDA.

The test results of the thermodynamic consistency are given in Table 2.

Table 2 Results of thermodynamic consistency test

system	D-J
binary equilibrium system at pressure of 4 (kPa)	-8.21
binary equilibrium system at pressure of 6.67 (kPa)	-13.67

As Table 2 shows, the demand of the thermodynamic consistency can be conformed for these VLE experimental data because of D<J for the two systems.

Determination and fitting of the VLE data of aniline-MXDA system. The VLE data of aniline-MXDA system at pressure of 4 kPa are determined and the binary interaction parameters of aniline-MXDA for Wilson equation are regressed through these VLE data, shown in Table 3.

Table 3 Wilson binary interaction parameters

i= Aniline j= MXDA	a_{ij}	a_{ji}	b_{ij}	b_{ji}	c_{ij}	c_{ji}	d_{ij}	d_{ji}
P=4(kPa)	253.302	771.065	47063.48	154491.4	15.813	52.543	0.2935	0.8366

The VLE values of aniline-MXDA system are calculated with Wilson equation and the calculation results and the experimental data are given in Table 4. The data in the tables show, at the pressure of 4 kPa, the average absolute error of the calculation results and the experimental data of the VLE temperature is -0.768K, the average absolute error of the calculation results and the experimental data of the vapor composition of aniline is -0.0867. The above results prove the regressed Wilson equation parameters of aniline-MXDA can be used to calculate the phase equilibrium data of aniline-MXDA system.

Table 4 Experimental and calculated VLE data of the binary system (Aniline(1)- MXDA) at 4 kPa

* AAD is the average absolute error.

Conclusion

The saturated vapor pressures of MXDA are measured at the temperatures between 150-180℃ and the expanding Antoine equation is used to correlate them. The VLE data of aniline-MXDA system at pressure of 4 kPa are determined and Wilson Equation is used to correlate the experimental data and the model parameters are regressed. The regression values are compared with the experimental data and the average relative error is within 5%.

Experimental Studies of Catalytic Hydrogenation of Isophthalonitrile for Meta-Xylenediamine Preparation

Yugang Li

(Research Center for Computer and Chemical Engineering, QingDao University of Science and Technology，QingDao, 266042, Shandong，China)

E-mail: lyg@putech.com.cn

Keywords: meta-xylenediamine（MXDA）; isophthalonitrile（IPN）; hydrogenation; catalyze

Abstract: With Raney nickel catalyst, the process of catalytic hydrogenation of isophthalonitrile for meta-xylenediamine preparation using aniline as the solvent is studied in this paper. The effect of the amount of catalyst, the reaction pressure and temperature is discussed. The results show that: on the conditions of the initial raw materials concentration for 2.0mol/L, the ratio of the catalyst quality and the IPN quality for 1/10, the reaction temperature for 100°C, the reaction pressure for 35bar, the reaction inhibitor NaOH for 0.6g and some additives, the reaction is conducted for 80min and the quality yield of meta-xylenediamine is up to 98.58%.

Introduction

MXDA is a kind of high performance epoxy resin curing agent, and is an important chemical intermediates. The process of ammoxidation of meta-xylene to make IPN is a mature technology, while the technology of catalytic hydrogenation of IPN to prepare MXDA is not yet mature. Therefore, people did a lot of studies for this system and some progress was obtained in recent years.

Zhang Peng et al [1] prepared the amorphous Ni-Al alloy thin strip with quenched to make high activity skeleton nickel and the molar yield of MXDA was up to 96%. With Co-Ti/diatomite catalyst, the yield of MXD to 94% was made for UOP Inc.[2]

When the effects of the reaction conditions is discussed, organic amines, aromatic hydrocarbons, alcohols, ethers, lower aliphatic amide and aromatic monoamines[3,4] can be used as the reaction solvent, and the solubility of IPN in several commonly used solvent is compared with each other in literature.[5] The right choosing of the initial concentration is conducive to the full use of the catalyst active site, then, the utilization rate of the catalyst is improved. Different catalytic hydrogenation reactions need difference optimal pressure and usually 1.5-15MPa is kept. Different catalytic hydrogenation reaction needs difference optimal reaction temperature and the range of 70°C to 130°C is maintained basically.

With the high activity nickel catalyst, the optimum experimental conditions of catalytic hydrogenation of IPN to make MXDA using aniline as the solvent is discussed in this paper.

Experimental

The details of the experimental set-up, experimental procedures and analytical techniques are presented in this section.

Materials

IPN(purity≥99%), methanol(purity≥99.5%), toluene(purity≥99.5%), aniline (purity≥99.5%), hydrogen, deionized water.

Catalyst: high activity Raney nickel catalyst with nickel, aluminum, molybdenum, chromium, iron. The physical properties of this catalyst are shown in Table 1.

TABLE.1 PHYSICAL PROPERTIES OF CATALYST

Physical characteristics	unit	specification	remarks
shape	-	black metal powder	-
particle size	(mu)	400	average particle size
BET-specific surface area	(m^2/g)	⩾100	-
packing density	(kg/L)	1.3	-

Experimental set-up

The experiment of catalytic hydrogenation of IPN to make MXDA is conducted in a 1L büchiglas high-pressure hydrogenation reactor which can provide 100bar pressure safely and the highest temperature is for 250°C. The hydrogenation reactor is made of stainless steel materials and the catalyst can be fully stirred up from the bottom of the reactor by the stirrer which is the type of hydrogen absorbing turbine, then, the gas-liquid-solid three-phase full mixing in this hydrogenation reactor can be achieved. The kettle of the reactor is arranged with the coil pipe and jacket which is used to heat the raw materials in the reaction forepart time and to remove the heat with cooling oil in the reaction process. The structure of this hydrogenation reactor with the complex mixing agitator is shown in Fig.1 and the schematic diagram of the experimental set-up is exhibited in Fig. 2.

Experimental procedure

The raw material (IPN), solvent (aniline), catalyst (high activity Raney nickel catalyst), reaction inhibitor NaOH and some additives are put into the high-pressure reactor from the feed inlet together, then, the reactor is sealed. The mixture in the reactor is heated with the temperature controller while the stirrer is started with 100r/min speed. When the specified reaction temperature is reached, the BPC is opened to enter hydrogen and the stirrer is closed at the same time. When the specified reaction pressure is reached, the stirrer is opened again with 100r/min speed, meanwhile, the hydrogen consumption is recorded with the specific computer software. When the hydrogen consumption is not changed within 30min, the reaction is considered to end, then, the sample can be taken from the high pressure sampler and be analyzed.

Analytical technique

The qualitative analysis of the sample is conducted with GC-MS and the quantitative analysis of the sample is achieved with GC-MS single particle scanning. The internal standard method is used for the quantitative analysis.

Results and discussion

The effect of several chemical and physical parameters which affect the reaction rate and the yield is studied. The amount of catalyst and reaction inhibitor, the reaction temperature and pressure is included mainly.

When the initial raw materials concentration is high, the materials can't be dissolved in the solvent, then, the materials can't be absorbed by the activity site of catalyst fully, thus, it is not conducive to the hydrogenation reaction similarly. Thus, the initial raw material concentration is set to 2.0mol/L in this paper.

Effect of the amount of catalyst

As Figure 3 shows, when the ratio of the catalyst quality and the IPN quality is between 1/8-1/10, the product yield is higher, otherwise, the product yield begins to reduce. Figure 4 indicates the relationship between the ratio of the catalyst quality and the IPN quality and the hydrogen consumption rate. The hydrogen consumption rate is reduced with the reduction of the catalyst/IPN ratio, which means the amount of catalyst is bigger, the reaction speed is faster, as the results, a lot of MXDA is produced in a short time. But some polymerization reactions occur easily within these MXDA molecules at this time and the secondary and tertiary amines can be produced which leads to the reduction of product yield. Comprehensive considering the influence of the product yield, reaction time and economic factors, the ratio of the catalyst quality and the IPN quality is set to 1/10 in this paper.

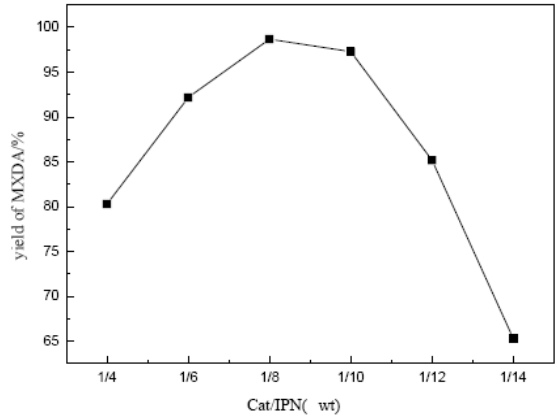

Fig.3 Relationship between catalyst/IPN mass ratio and yield of MXDA

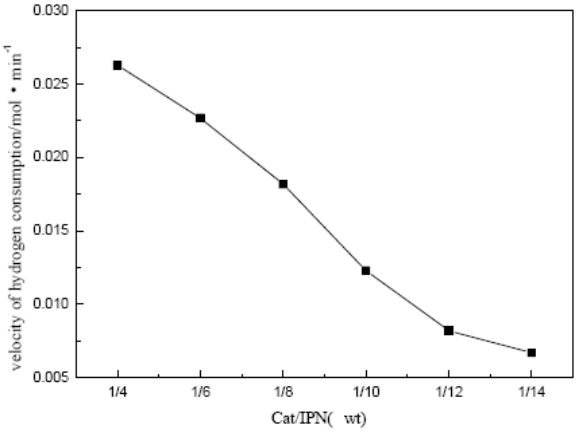

Fig.4 Relationship between catalyst/IPN and velocity of hydrogen consumption

(*reaction condition*: aniline:300ml, IPN:80g, NaOH: 0.6g, water:2ml, temperature:100℃, pressure: 40bar)

Effect of reaction temperature

As Figure 5 shows, the influence of the temperature for the product yield is very significant and there is a peak between 90°Cand 100°C. Because ammonia produced by the side reaction of MXDA deamination can escapes easily at the high temperature which can promote the main equilibrium reaction to the side reaction of MXDA deamination direction. The relationship between the reaction temperature and the reaction time is indicated in Figure 6. Although the product yield at 90°C and it at 100°C is very similar, the reaction time at 100°C is less than it at 90°C for 45min, thus, the optimal reaction temperature is set to 100°C in this paper.

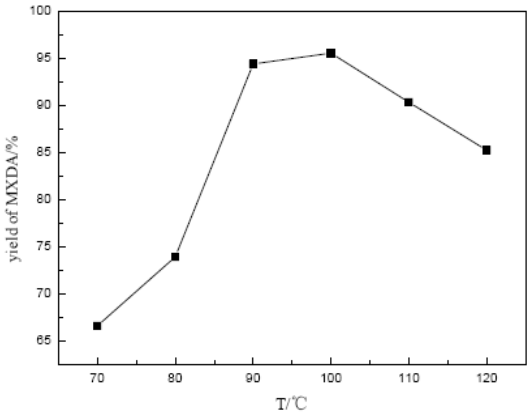

Fig.5 Relationship between temperature MXDA

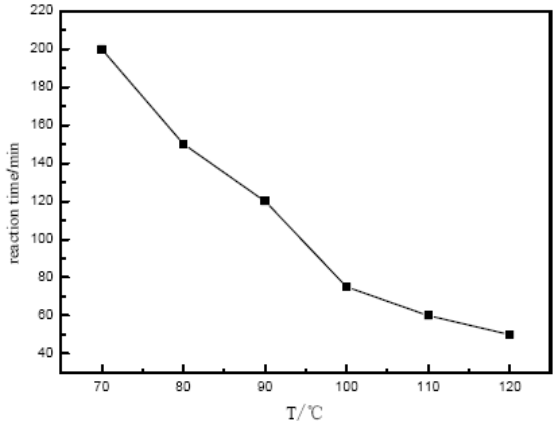

Fig.6 Relationship between temperature and and yield of reaction time

(*reaction condition*: aniline:300ml, IPN: 80g, catalyst: 8g, NaOH: 0.6g, water:2ml, pressure: 40bar)

Effect of reaction pressure

Because the dissolved and adsorbed hydrogen concentration of the reaction system can be improved under the high reaction pressure, the collision probability of IPN and hydrogen with the catalyst activity center is increased, thus, the yield of MXDA and the reaction speed can be improved. As Figure 7 shows, the yield of MXDA is improved with the pressure increasing. When

the pressure reaches 35bar, the product yield is fixed and maintained at a higher level basically.Considering the high producing costs with the higher reaction pressure, the optimal reaction pressure is set to 35bar in this paper.

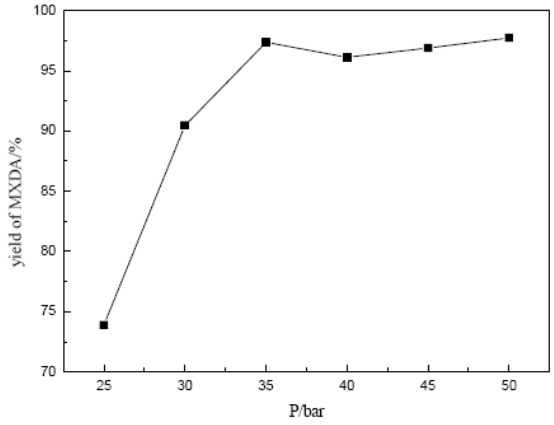

Fig.7 Relationship between pressure and yield of MXDA

(*reaction condition*: aniline:300ml, IPN:80g, catalyst:8g, NaOH:0.6g, water:2ml, temperature: 100℃)

Conclusions

The experimental studies of the catalytic hydrogenation of IPN to make MXDA are conducted in this paper and the optimal reaction conditions are got. With Raney nickel catalyst and aniline solvent, the initial raw material concentration is 2.0mol/L, the ratio of the catalyst quality and the IPN quality is 1/10, the reaction temperature is 100°C, the reaction pressure is 35bar. With above optimal reaction conditions, MXDA quality yield reaches 98.58%. These results can provide the accurate basis for the industrialization of this reaction.

Keywords: montmorillonite, modification, THPC, influencing factors

Abstract. Na-MMT was modified with quaternary phosphonium salts, tetramethylolphosphonium chloride (THPC), via ion-exchange reactions, in acid conditions. Different factors such as reaction time , reaction temperature, the types of solvent, and CEC ratios, were investigated using orthogonal test. Results showed that the best combination of these four factors were $A_1B_3C_1D_1$, that is, the type of the solvent was acetone and water (1:1), reaction time was 3h, CEC ratio was 1:1, and the reaction temperature was 80°C.

Introduction

Montmorillonite (MMT) has now been receiving special attention in the field of reinforcement because of its submicroparticle size and intercalation properties. Composites containing intercalated organic montmorillonite (OMMT) particles exhibit improved moduli, decreased gas permeability, and enhanced thermal stabilities [1,2].

In practice, the use of organoclays prepared by alkyl ammonium salts to manufacture polymer-clay nanocomposites is limited by the clay properties. For instance, the alkyl ammonium salts decompose about 170-180°C and are not suitable for high temperature melt processing techniques. The decomposition products impart an undesirable color, odor, and taste.

Efforts have been made to synthesize thermally stable organo-clays based on stibonium [3], phosphonium [4], or imidazolium surfactants [5]. The montmorillonites modified with such thermally stable cations had higher onset temperature of thermal degradation as well as peak degradation temperature values, thus, allowing them to retain their structural integrity during compounding. We have prepared tetramethylolphosphonium chloride (THPC) modified organoclays in different pH values [6]. Results revealed that the use of acid conditions can increase the d-spacing and thermal stability of the organic silicate layers.

However, different factors have different effect on the preparation and characteristics of this THPC-OMMT even in acid conditions. In the present work, we investigated the factors such as reaction time, reaction temperature, the types of solvent, and CEC ratios on the silicate spacing of this organo-clays.

Design of orthogonal test

The reaction time, reaction temperature, the types of solvent, and CEC ratios were combined with different amounts. For different combining ratio had different effect on the silicate spacing of OMMT, following orthogonal test was used to find out the most effective combination of above four factors. In this test, silicate spacing was used to evaluate the effect of this intercalation performance. Conditions and results were shown in Table 1 and 2.

Table 1. Orthogonal parameters of intercalation and their levels.

Factors / Levels	Reaction time (h)	Reaction temperature (°C)	Types of solvent*	CEC ratios**
Level-1	3	40	acetone：water (1:1)	1.5
Level-2	5	60	methanol：water (1:1)	2
Level-3	7	80	water	1

*The ratio of acetone with methanol and water referred to volume ratio.
** The CEC ratio was the ration of the molar values of cations in THPC and the cations in MMT.

Table 2. Design of orthogonal test for Na-MMT modification.

Factors / Experiments	Reaction time (h)	Reaction temperature (°C)	Types of solvent	CEC ratios
1	3	40	acetone：water(1:1)	1.5

8	7	60	acetone：water(1:1)	1
9	7	80	acetone：water(1:1)	1.5

Results of orthogonal test

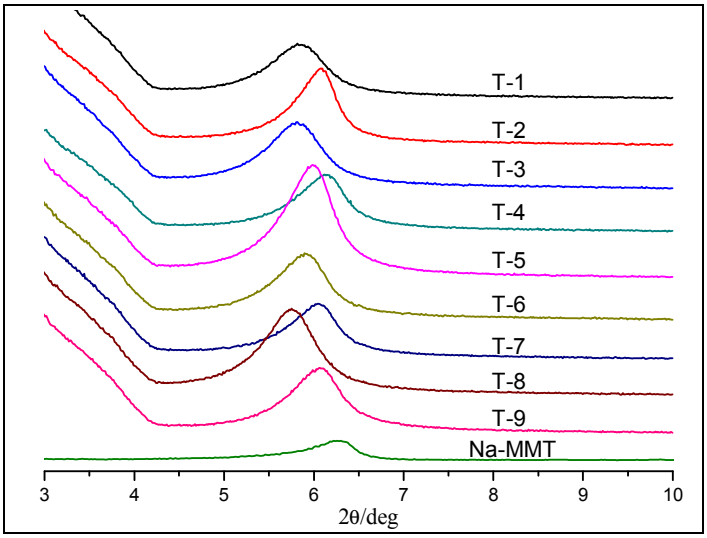

Figure 1. X-ray diffraction (XRD) patterns of different types of OMMT.

Figure 1 compared XRD patterns of OMMT prepared under different environmental conditions. Their d-spacing data were calculated by Bragg formula: $2d\sin\theta=n\lambda$. In curve a, only one peak appeared in the XRD spectrum, indicating only one interlayer space existing in Na-MMT. The XRD of the MMT sample showed a peak at the same position as for the neat silicate that corresponded to a gallery spacing of 1.43 nm. The large full width at half maximum of the as-received clay represented a large inhomogeneity of the intergallery spacings, which were a result of the poorly crystalline nature and the turbostratic packing of smectite minerals.

From Figure 1, we can see that the interlayer spacing of these OMMTs was changed due to the different environmental conditions during the intercalation process. The d-spacing depends on the organic modifier's packing status and the amount readily adsorbed inside the clay galleries. Since none of the clay modifiers was adsorbed to the same extent, relative to each other, no conclusions could be drawn in terms of their respective types of packing or interaction within the clay galleries.

Table 3. Orthogonal test results of different types of OMMT.

Factors / Experiments	A*	B*	C*	D*	Silicate spacing /nm
1	1	1	1	1	1.52
2	1	2	2	2	1.45
3	1	3	3	3	1.52
4	2	1	2	3	1.44
5	2	2	3	1	1.47
6	2	3	1	2	1.50
7	3	1	3	2	1.46
8	3	2	1	3	1.53
9	3	3	2	1	1.46
Average value K_1	1.497	1.473	1.517	1.483	
Average value K_2	1.470	1.483	1.450	1.470	
Average value K_3	1.483	1.493	1.483	1.497	
Range, R	0.027	0.020	0.067	0.027	

*: A=reaction time（h），B=reaction temperature（°C），C=Types of solvent，D=CEC ratios.

From the calculated results and the range values listed in Table 3, it was clear that the types of solvent was the main factor that influenced the silicate spacing of OMMT. The reaction time and CEC ratio were less important but more important than that of reaction temperature.

The influencing behavior of above four factors were summarized in Figure 2. The types of solvent had an important influence on the intercalation of OMMT. Its mechanism depended on the polarity of MMT and the solvent, which strongly influenced the hydrogen bonds developed during preparation process. When water was used as the solvent in the preparation process of OMMT, many hydrogen bonds may be produced and this may hinder the THPC molecules to be intercalated into the interlayer sapcing of MMT. The mixture of methanol and water also had this problem due to the increasing amount of hydrogen bonds produced by methanol. However, when acetone was mixed with water, the hydrogen bonds may decrease and this was beneficial for the intercalation process. Thus, MMT modified by THPC in this environment had larger d-spacing value.

The effect of reaction time on the interlayer spacing of OMMT was such an extent that a shorter reaction time yielded a larger d-spacing. This was due to the intercalation process may be already finished during 3 hours of the intercalation process. When more reaction time was given, the interlayer spacing was not larger. This may be due to other environmental conditions which can decrease the interlayers spacing.

To investigate the effect of CEC ratio on the interlayer spacing of OMMT, the ratio was varied from 1:1 to 2:1. At lower CEC ratio, the intercalation process may be successfully accomplished and a larger d-spacing was obtained. When CEC ratio was increased, more THPC molecules were not easily intercalated and smaller d-spacing was thus obtained.

The effect of reaction temperature had different influence on the silicate spacing of OMMT. With the increase of reaction temperature, the interlayer spacing was increased. It was concluded that more energy was useful for the intercalation process and was beneficial for the enlarging of the interlayer spacing of OMMT.

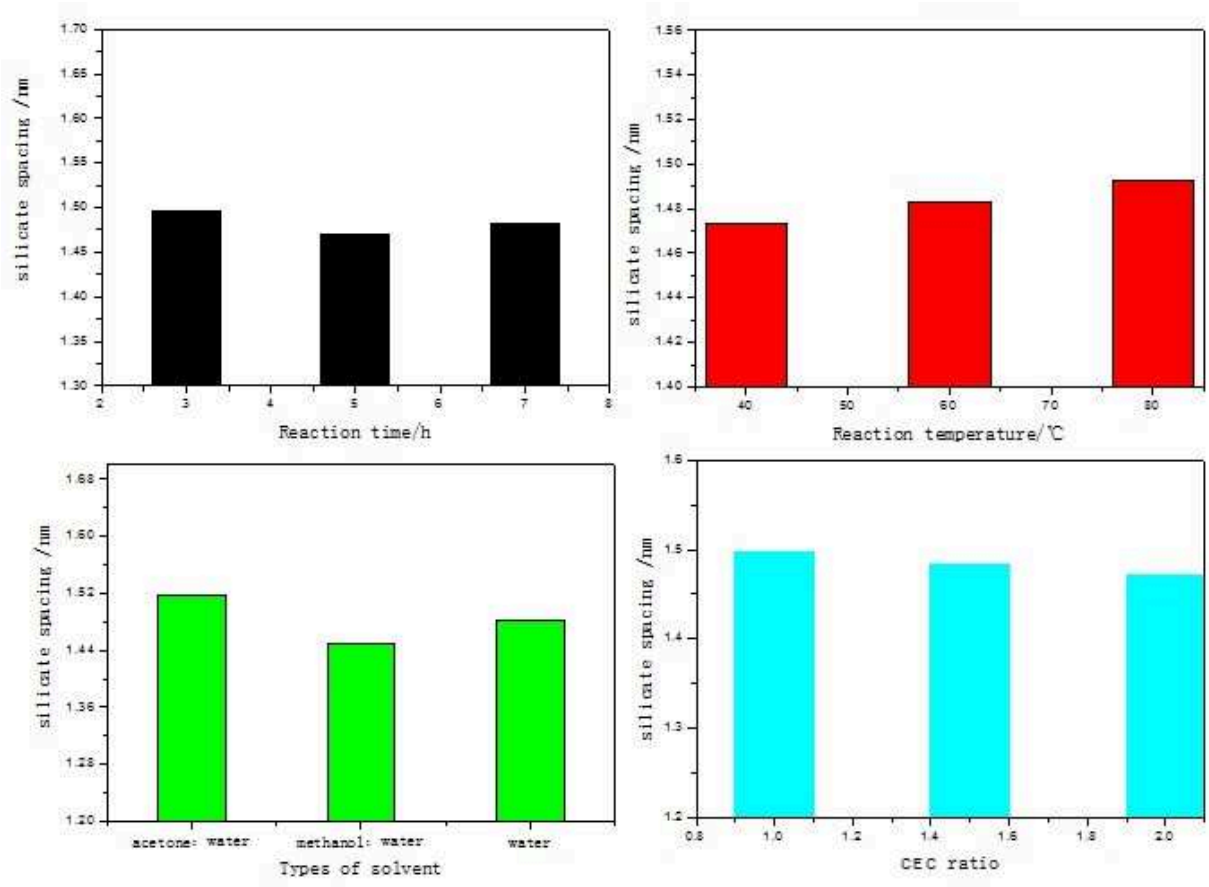

Figure 2. Influencing behavior of interlayer spacing by different factors.

Conclusion

The effect of influencing factors on the modification of MMT by THPC in acid conditions was analyzed by orthogonal test. The levels were chosen according to the preparation process. Results showed that the most satisfactory combination of the four factors was $A_1B_3C_1D_1$, that is, the type of the solvent was acetone and water (1:1), reaction time was 3h, CEC ratio was 1:1, and the reaction temperature was 80°C.

Keywords: Brush plating, PTFE, Structure, Performance

Abstract. Polytetrafluoroethylene (PTFE) is known as a solid material with high lubricating property and low friction coefficient. The application of PTFE is significant to improve the tribological properties of coating. In this paper, Scanning electron microscopy (SEM), Energy Dispersive Spectrometer (EDS), X-ray diffractometry (XRD), Microhardness test and friction and wear experiment are adopted to study the effects of PTFE content on the structure, morphology and properties of coating. The results show that the addition of PTFE particles can reduce spherical particle size and increase the hardness and friction properties of coating when typical cauliflower shaped druse and excellent interface binding characteristics are maintained. If the content of PTFE is too much, some area of coating is prone to powder hoarding which may lead to the decrease of coating density, hardness, and friction coefficient stability.

Introduction

Wear is one of the major failure forms of mechanical parts and engineering components [1-3]. According to the importance of Engineering, adopt reasonable surface protective measures to control surface damage and material loss without influencing the functions of parts [4-8]. Brush plating offers a possible, flexible and high quality deposit technology, which occupies a very important position in surface engineering [9-11]. It is found that in a large number of engineering applications, single metal and alloy brush plating do not present ideal tribological properties [12-15]. The application of PTFE can improve tribological performance of coatings due to its higher lubricity and the lowest friction coefficient [14-16].

Current studies on brush plating are not as many as those on chemical deposit. There are large differences between them, therefore, it is significant to study the effects of PTFE on the structure, morphology and performance of brush plating coating, so as to improve the comprehensive performance of brush plating, enrich connotation of PTFE tribology and perfect brush plating process category. Based on the studies both home and abroad, Ni/PTFE suspensions with different content of PTFE will be prepared by optimized PTFE dispersion process. This paper will analyze the effects of composite coatings with different content of PTFE prepared by brush plating on coatings' structure, morphology and performance.

Experimental Materials and Methods

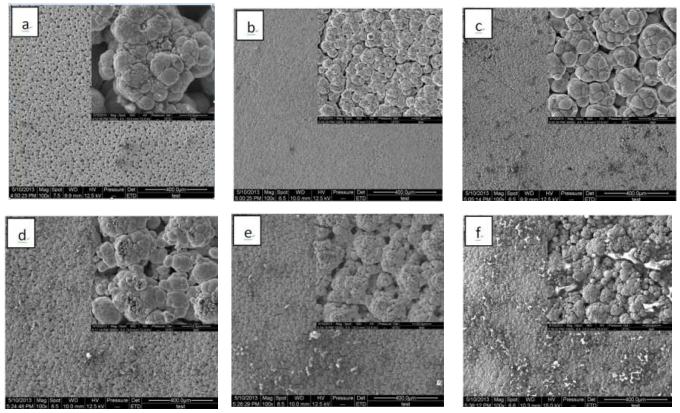
Materials and Preparation. Matrix material is FV520(B) steel, grinded by 240#, 320#, 600#, 800# emery papers respectively and then dropped into alcohol for ultrasonic cleaning for 10 min. Then wipe it by degreasing cotton with alcohol, dry and put it into drying vessel.

Fast speed nickel plating solution is chosen as matrix solution, and PTFE powder of 5μm as a composite. Suspension ensures uniform and qualified coating, so sixteen alkyl three-methy bromide and OP-10 emulsifier are selected as activating agent through process optimization, which is helpful to uniform dispersal of PTFE in the solution.

Brush plating adopts DSD-30-QA DC power supply and ZDB-1 plating pen. Plating rate is 8~12m/min and plating time lasts 10min. After brush plating, the pen should be rinsed with distilled water and dried with a hairdryer stand-by.

Characterization and Testing

The Analysis of Structure, Morphology and Component. Scanning electron microscopy (Quanta 200 SEM) is used to scrutinize the morphology of coatings. Energy Dispersive Spectrometer EDS (genesis xm-2) is used to analyze the components of coatings. X-ray diffraction (XRD) is adopted to confirm the phase structure of coatings, Cu as radiation source. Scanning angles range from 20°to 80° in steps of 0.05°. Kaλ is 1.54056 Å, voltage 45 kV, current 100 mA and scanning speed $4^{o}min^{-1}$.



Performance Testing

Digital micro hardness tester HVS-1000 is adopted in the testing. The load is 100g, and load time is 10s. The average value of five points is taken as microhardness. In the process of measurement, hardness is measured gradually by taking points from the border to the center of coatings. Abandon the obvious deviation data and analyze the hardness of coatings based on the acquired data.

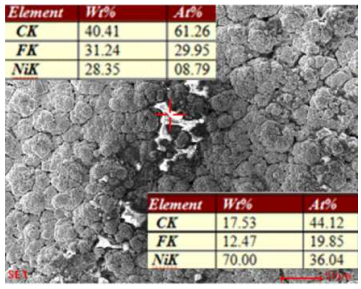
The samples cleaned at room temperature are placed in the friction and wear tester, loading weight 200g. Analyze the friction and wear properties based on friction coefficient curves obtained after data processing. Each set of samples before and after the experiment is weighed by electronic weighing scales, and compare the different values to get the amount of wear and measure the abrasion resistance of coatings.

Results and Discussion

The Effect of PTFE Content on Coating Morphology. Fig. 1 shows that PTFE particles help reduce spherical particle size and increase coating compactness, but they do not change the micromorphology of coatings-typical cauliflower shaped druse. The agglomerated particles become smaller and the coatings become more compact when the content of PTFE ranges from 5 g/L to 20 g/L. But when the content of PTFE is between 20g/L and 40g/L, the particles become larger and the coatings become looser. In the meantime, with the increase of PTFE content, more and more white accumulation appears on coatings' surfaces. The coating with PTFE content of 40g/L is analyzed by energy spectrum in order to know the components of the white precipitate. The results are shown in Fig. 2. It mainly consists of PTFE and nickel. Therefore, with the increase of PTFE, some of the powder is agglomerated on the coating surface and then enwrapped by the deposition of nickel due to difficult dispersal and easy aggregation.

(a) 0g/L, (b) 10g/L, (c) 15g/L, (d) 20g/L, (e) 30g/L, (f) 40g/L

Fig. 1 Surface morphologies of coatings with different PTFE contents



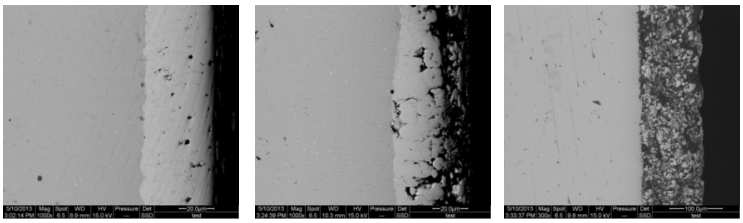


Fig. 2 Spectrum of the coating with PTFE content of 40g/L

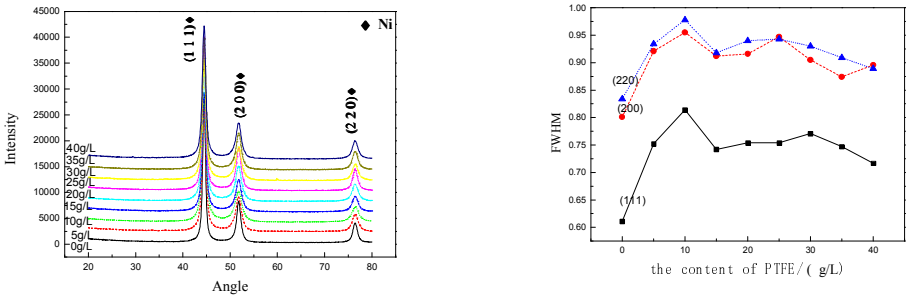
Fig. 3 is cross-sectional morphology of the coatings with different PTFE contents. By comparison, interface morphology changes significantly, but the combination of coatings and substrate are not affected.

According to Fig. 3a, b, c, the cross-sectional morphology of these coatings presents accumulation of particle aggregates, which is different from that of nickel coating. When powder content increases, PTFE embedded in the gap between particles will increase. But too large powder content will lead to unevenly dispersal and powder accumulation (Fig. 3c). Thus, it can be concluded that nickel ions are continuously deoxidized to metallic Ni and deposit on the substrate surface together with PTFE in the solution.



(a) 0g/L (b) 10g/L (c) 30g/L

Fig. 3 Cross-sectional morphology of coatings with different PTFE contents

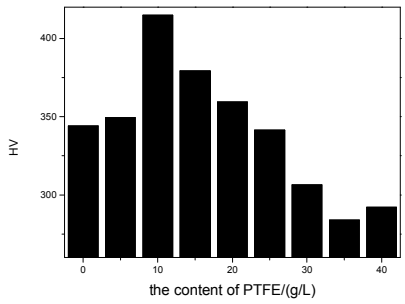
The Effect of PTFE Content on Coating Structure. Fig. 4a shows XRD results of Nickel coatings with different PTFE contents. The analysis by Jade software marks out just crystal indice of Ni and its three strong peaks. There is no diffraction peaks of element F and C. Fig. 4b indicates that the height of three strong peaks of PTFE coatings is significantly lower than that of coatings without PTFE. But the half-width of PTFE coatings is obviously higher. The narrower the peak is, the larger the grains are. The addition of PTFE can remarkably refine coating grains. Diffraction curves of PTFE coatings do not change much in height and width. But the coating with PTFE

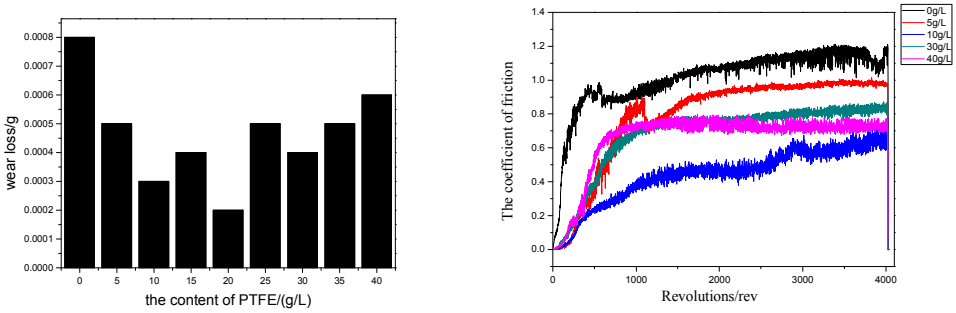
content of 10 g/L stands out with obviously lower peak height and higher peak width, which means the finest grains. Therefore, the solution with PTFE of 10 g/L has the best refining effect.

(a) XRD patterns of coatings (b) FWHM of three strong peaks

Fig. 4 XRD analysis of coatings with different PTFE contents

The Effect of PTFE Content on Coating Properties. Fig. 5 shows the microhardness of coatings with different PTFE contents. The results show that in the initial stage, microhardness is in proportion to PTFE content. When PTFE content reaches 10g/L, coatings achieve the maximum microhardness. With the gradual increase of PTFE, microhardness begins to decrease and when PTFE content is more than 25g/L, microhardness becomes smaller than that of coatings without PTFE. When PTFE content is larger than 30g/L, microhardness remains stable with tiny changes. Too much PTFE results in saturation, therefore, under the same plating process, microhardness does not change too much and PTFE are soft particles, high PTFE content will reduce microhardness of coatings.





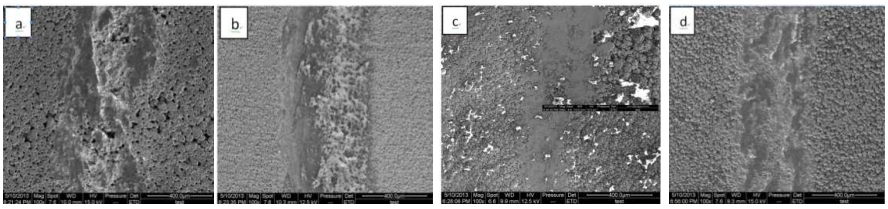


Fig. 5 Microhardness of coatings with different PTFE contents

Fig. 6 and Fig. 7 show the result of Friction and wear experiments. As is seen in Fig. 6a, the wear loss of 20g/L coating is less than other PTFE groups by comparison. Fig.6b is the comparison among dry friction coefficients. When PTFE content is 20g/L, the friction coefficient of coating is minimum and steady. When it is less than 20g/L, the friction coefficient is in inverse proportion to PTFE content. When the PTFE content is more than 20g/L, the friction coefficient increases with the increase of PTFE content. When PTFE content reaches 35g/L, the friction coefficient becomes unstable. The friction coefficient of 20g/L coating has been around 0.09 and the sliding friction coefficient of coating without PTFE is about 0.85. It can be found that the 20g/L coating has better uniformity and self lubricity. Its sliding friction coefficient is only 1/10 of that of a single metal Nickel coating, which can effectively improve the wear resistance of coating. So too much PTFE will have negative effects on the stability of sliding friction coefficient and wear resistance of coatings due to uneven powder distribution. On the contrary, low content of PTFE contributes to more uniform coatings, more stable sliding friction coefficient and better wear resistance.

(a) wear loss (b) friction coefficient

Fig. 6 Wear loss and friction coefficient of coatings with different PTFE contents

(a) 0g/L (b) 10g/L (c) 20g/L (d) 30g/L

Fig. 7 Wear morphology of coatings with different PTFE contents

Fig. 7 shows SEM images of coatings after wear tests. The coating without the addition of PTFE is worn out by pressure head. Its trajectory is not continuous, but wears tracks of other coatings present good continuity. Coatings significantly become soft, and friction coefficients are effectively reduced and wear resistance is increased. Fig. 7b indicates that wear tracks of coatings are visible with low content of PTFE due to insufficient PTFE powder for lubrication, and the stability of sliding friction coefficient is also influenced. The solution is hard to scatter with high PTFE content, which easily causes uneven distribution of powder in coatings. So wear tracks are also uneven and incoherent, obviously in some places and no signs in other places. Friction coefficient is not stable as well and wear resistance is affected. Fig. 8c shows that PTFE powder hoards a little and disperses unevenly in the 20g/L coating, which can significantly reduce sliding friction coefficient and increase wear resistance. The wear track is smooth and continuous in the right corner of enlargement, so the wear resistance of the 20g/L coating is superior.

Conclusion

Grains are refined significantly in PTFE coatings. The 10g/L PTFE coating has the minimum grains and the maximum microhardness. PTFE content in solution greatly affects grain size and coating compactness. The 20g/L PTFE coating gets smaller clusters and higher compactness. Deposition rate is in proportion to PTFE content and reaches the maximum when PTFE content is 25g/L. Then it experiences up and down and gradually tends toward stability. Therefore, the 20g/L PTFE coating possesses the smallest sliding friction coefficient, good self-lubrication and good wear resistance.

Keywords: ZnO: (Al, In), coated fabric, infrared emissivity, infrared stealth.

Abstract. In this paper, we report a study on the infrared stealth properties of cotton fabrics with ZnO: (Al,In) coating. Al, In doped ZnO samples were prepared through sol-gel method. The crystalline phase of the ZnO: (Al, In) solids were determined by XRD. IR-2 Dual-Band Infrared Emissivity Measuring Instrument was used to test the infrared emissivity of the coated fabric. Infrared stealth effect of ZnO: (Al, In) coated fabric was measured using thermal infrared photospectrometry instrument. It was found that the ZnO: (Al, In) thin film has a low infrared emission in the range of 8 ~ 14μm wavelengths, and the addition of Al and In leaded to a better infrared stealth effect.

Introduction

Doped ZnO as filler material could be used to make low infrared emissivity coatings on the target objects, such as thermal camouflage coatings [1], thermal deformation camouflage screen (thermal camouflage net) [2], infrared smoke screen [3] and infrared decoys [4], etc.

In this paper, the sol-gel process was adapted to prepare Al, In doped ZnO. The prepared Al, In doped ZnO solids were coated on cotton fabrics to prepare infrared stealth material. The influence of doped concentration of In on emissivity property and the microstructure were discussed in detail.

Experimental section

ZnO: (Al, In) coated fabric

Al, In doped ZnO was prepared by sol-gel process. Zinc nitrate dihydrate, isopropanol, monoethanolamine were mixed in a flask equipped with a thermometer placed in a constant temperature oil bath pot at 75-85°C and stirred for 1h. Then aluminum chloride hexahydrate and Indiumnitrate were added into the mixture until dissolved. The concentrations of In were 1wt%, 2wt%, 3wt%, 4wt%, 5wt% and 6wt% respectively for six ZnO: (Al, In) sol samples (the concentrations of Al were maintained 2 wt%). The prepared ZnO: (Al, In) gel was heated in a muffle furnace at 400°C for 4h, and calcined at 1100℃ at a heating rate of 2 °C / min when the organic solvent was removed in order to get the ZnO: (Al, In) solids.

The ZnO: (Al, In) solids with 3% molar ratio of In and 2% molar ratio of Al were mixed with zirconia beads, sodium hexametaphosphate (a kind of dispersant), and ethanol, at a weight ratio of 1:50:0.1:10 in a milling instrument dispersion at a rotational speed of 800r/min for5h,10h,15h,20h,25h,30h and 40h. Then the ZnO: (Al, In) suspension was carefully added to the polyvinyl acetate emulsion adhesive and stirred for 30 minutes. The above solution was deposited on the cotton fabric fixed on the glass plate, and uniformly scratched with a stainless steel rod. Then the obtained ZnO: (Al, In) coated fabric was dried at 180°C for 1-2 minutes with a shaping machine.

Characterization

The crystalline phase of the ZnO: (Al, In) films were determined using X-ray diffraction (XRD) diffractometer (D/Max-2550 PC). IR-2 Dual-Band Infrared Emissivity Measuring Instrument was used to test the infrared emissivity of the coated fabric. Infrared stealth effect of ZnO: (Al, In) film was measured using thermal infrared photospectrometry instrument. The granularity of milled ZnO: (Al, In) were analyzed using Nano-ZS English Malvern Instruments.

Results and Discussion

Characterization of ZnO: (Al, In) Film

Figure 1 showed X-ray diffraction pattern of the pure ZnO and ZnO: (Al, In) solids with different In doped molar ratio from 1% to 6%. All the diffraction peaks were indexed according to ZnO standard [PDF#05-0664] indicating that both pure ZnO and (Al,In) doped ZnO have hexagonal wurtzite structure. It meant that Al and In dope effectively.

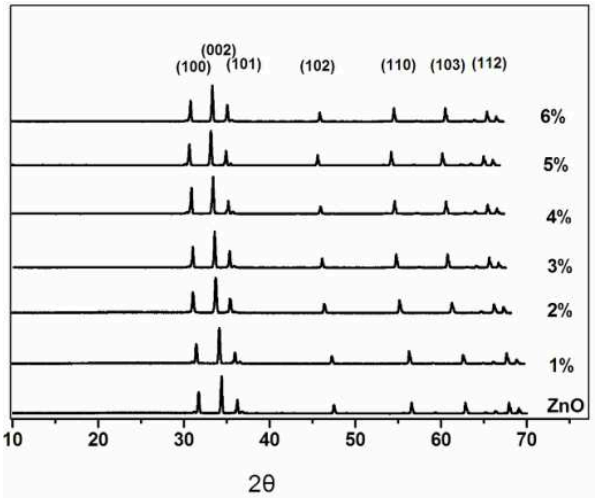

Fig.1. X ray diffraction pattern of pure ZnO and ZnO: (Al, In) with different doping contents of In(Al, 2%)

Effect of Particle Size on the Infrared Emissivity of Coated Fabrics

As shown in table 1, the average particle sizes of ZnO: (Al, In) particles decreased with the increase of milling time. The average particle size is samllest after 30 hrs milling, when the welding and fracture mechanisms come into a balance.

Table 1 Milling time effect on average particle size of ZnO: (Al, In) particles (2% Al and 3% In doping contents)

Milling time/h	5	10	15	20	25	30	40
Average particle size/nm	359	275	233	210	198	180	185

ZnO: (Al, In) particles through different wet-grinding time (5h, 10h, 15h, 20h, 30h,40h) was coated on cotton fabrics with polyvinyl acetate emulsion adhesive. As shown in figure 2, the infrared emissivity of the ZnO: (Al, In) decreased with the average particle size decreasing. The optical infrared emissivity could reach 0.715 at a minimum for sample: ZnO: (Al, In) with 2% Al and 3% In doping contents, 80% ZnO: (Al La) and 20% polyvinyl acetate, particle size was 180nm milled at 30 hrs. The softy of this coated fabric was satisfied at this time. So 30 hrs was better wet-milling time.

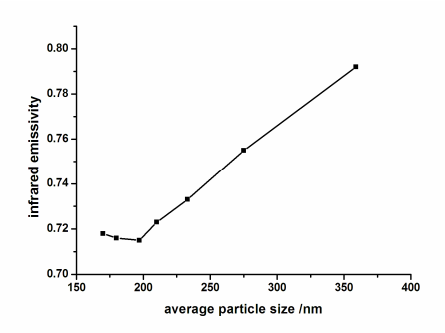

Fig. 2 Effect of particle size on infrared emissivity ZnO: (Al, In) coated fabrics.

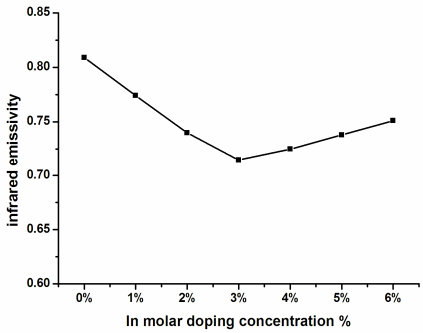
Effect of doping In content on infrared emissivity of coated fabrics

The Effect of In doping content on infrared emissivity of ZnO: (Al, In) film with AL molar ratio of 2% was shown in Figure 3. The infrared emissivity of the pure ZnO in the band of 8-14 μm is 0.832, but the infrared emissivity of ZnO: (Al, In) coated fabrics significantly decreased with an increasing of In doping contents from 1% to 3% and the lowest infrared emissivity was 0.715 at 3% In molar concentration. However, the infrared emissivity rose when In concentration continued improving to 4%.This is because the addition of Al and In is favorable for providing more free electrons and improving scattering of infrared photon. Furthermore, increase amount of Al and In could bring new gap as infrared photon scattering centers and reduced the adsorption of infrared ray.

Thermography

The thermal infrared image of ZnO: (Al, In) coated fabrics, with 2% Al and 3% In doping contents was shown in Figure 4. It illustrated that the samples infrared stealth effect were obviously improved with 2% Al and 3% In doping contents.



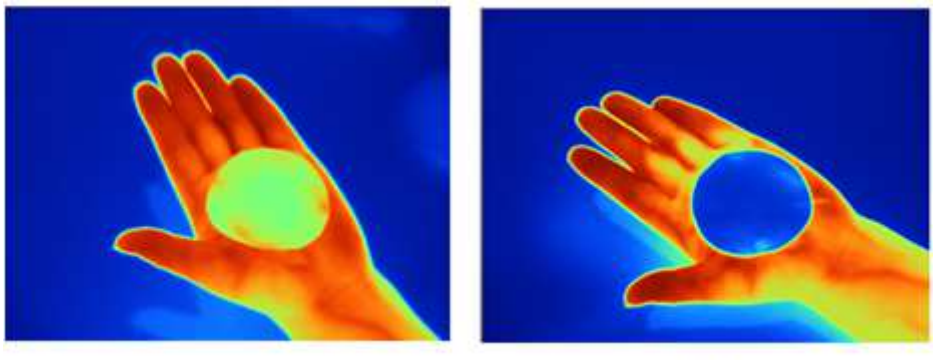


Fig. 3. The infrared emissivity of ZnO: (Al, In) coated fabrics with different In doping contents

(a) (b)

Fig. 4. Thermographies of pure ZnO (a) and ZnO: (Al, In) coated fabrics with 3% In molar ratio (Al , 2%)

Conclusion

ZnO: (Al, In) was synthesized by the sol-gel method and coated on cotton fabric, forming a thin film to reduce infrared emissivity of the fabric.

The addition of Al and In leaded to a better infrared stealth effect. The optimum coated fabric was soft and its infrared emissivity was 0.718, when the mass percentage of adhesive was80%, with 2% Al and 3% In doping contents.

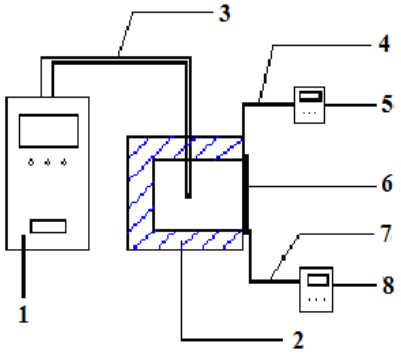
Keywords: Adiabatic coating, Hollow tiny bead, Agglutinating reagent, Thickener

Abstract: Microcosmic features of adiabatic coating was observed, influencing factors of adiabatic coating performance were studied by 4 types of agglutinating reagents when the size of hollow tiny bead was 2.5-60 μm. Next, carboxymethyl cellulose was introduced, 2.6 μm hollow tiny bead was selected to testify antifatigue performance of coating, transmission principle was applied to build one-dimensional mathematic model of adiabatic coating for testifying experimental value, industry test was conducted to check performance of coating in 30 t ladle.



Introduction

Adiabatic materials have heat resistance performance. Adiabatic level is R-33.3, heat reflectivity is 89%, heat conductivity is 0.03 W/(m·°C). 0.3-0.5 mm coating is painted on object surface with some virtues, such as heat insulation, anticorrosion and waterproof. Technical ideas of foreign related products were brought, adiabatic coatings formed integrated development trend, such as high efficiency, thin layer, energy saving, waterproof. Nowadays, little reports are about the application of adiabatic coatings, especially for metallurgical energy saving[1].

New adiabatic coatings must be developed, adiabatic performances were studied from some aspects, such as the size of hollow tiny bead, agglutinating reagent, coating thickness, antifatigue performance. One-dimensional mathematic model was made to testify experimental data by theory calculation. Industry test was conducted to check adiabatic performance in 30 t ladle. Research on adiabatic performance is significant to metallurgical energy saving.

Experiments

The size of steel plate is 1.5×280×300 mm, adiabatic coating was painted on one side of steel plate, formula design was shown in table.1. After dried, coatings were heated by muffle furnace to detect temperature difference on two sides of steel plate, temperature differences were detected by 2 thermocouples, temperature value was recorded from 150°C. Fig.1 expressed experimental equipments[2].

Raw materials:

Hollow tiny bead (main ingredients are SiO_2 and Al_2O_3), silicone (agglutinating reagent, XR-500), Na_2SiO_3 (hydrophilic adhesion agent), sodium alginate (thickener, $(C_6H_7NaO_6)_x$), silicone resin and E 800-800^oC hydrophilic inorganic heat-resistant resin (thickener), A3 steel plate (1.5×280×300 mm).

Ingredients:

Adiabatic performance and microstructure are tightly related to the ingredients, table.1 was the experimental ingredients of adiabatic coatings[3].

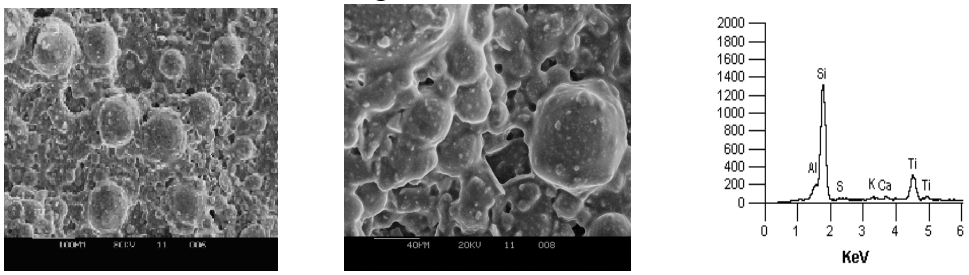

TABLE.1 EXPERIMENTAL INGREDIENTS OF ADIABATIC COATINGS

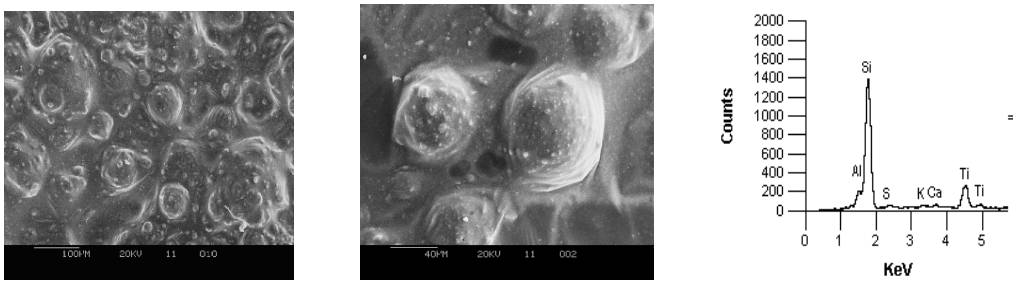
Number	Agglutinating reagent	Thickener	Bead size(μm)	Coating thickness (mm)			
1#	Silicone	$(C_6H_7NaO_6)_x$	58	0.5			
2#	Silicone	None	58	0.5		0.9	
3#	Na_2SiO_3	$(C_6H_7NaO_6)_x$	58	0.5		0.9	
4#	None	Silicone resin	10	0.45			
5#	None	Hydrophilic inorganic heat-resistant resin	15	0.23	0.45	0.59	0.80
			10	0.21	0.41	0.60	0.76
			2.6	0.23	0.45	0.59	0.80

Result and Analysis



Microstructure and ingredients of No.1-No.3 coatings were analyzed by SEM. the size, the particle distribution and the ingredients were displayed in Fig.2-Fig.4. The size of hollow tiny dead is 50-130 μm, pelleting ability brought about good anti-radiation performance. Microporous structure led to low heat conductivity, air molecules can't form convection and Brownian motion, so favorable adiabatic performances were got.

Fig.2 showed that thickener caused porosity structure, but no porosity structure was expressed in Fig.3. Morphology in Fig.4 was different from that in Fig.2 and Fig.3. Coating itself had more air porosity in Fig.4, agglutinating reagent was Na_2SiO_3. The ingredients of agglutinating reagent in No.3 coating were different from that in No.1 and No.2 coatings. No.3 coating had lower Si content and more Al, Si and K content than other coatings, furthermore, it had Zn and Fe, but no Ti and S.

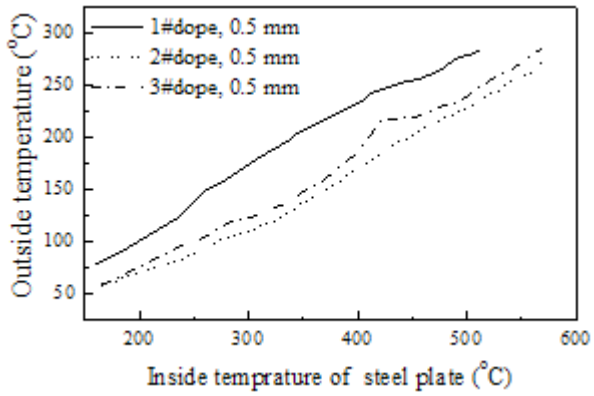

Fig.3 SEM morphological observation and energy spectrum analysis of No.2 coating

(a) Morphology magnified 200 times (b) Morphology magnified 500 times (c) Energy spectrum

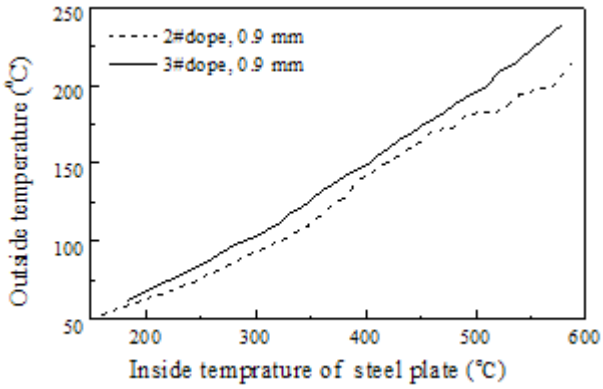

Fig.4 SEM morphological observation and energy spectrum analysis of No.3 coating

To study effect of base material on performance of adiabatic coating, No.1-3 coatings were used, same size of hollow tiny bead, same coating thickness, different base material, see Fig.5-Fig.7. In Fig.5, same 0.5 mm coating and inside temperature of steel plate, highest outside temperature of steel plate appeared in No.1 coating, outside temperature of No.2 coating was close to that of No.3 coating. So No.1 coating had worst adiabatic performance. Fig.6 expressed temperature difference of steel plates with 0.9 mm coating. Combined with Fig.5 and Fig.6, No.3 coating had best adiabatic performance.

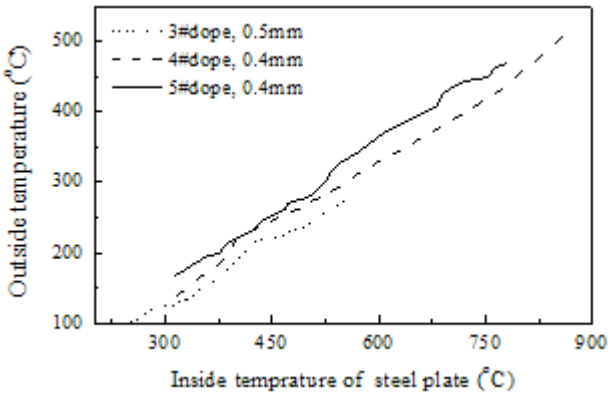
(a)

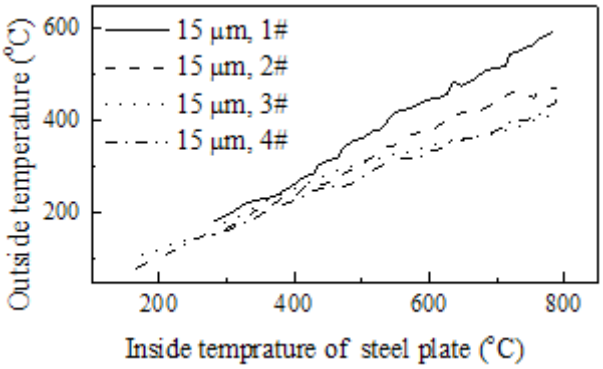
Fig.5 Experimental chart with 0.5mm coating

(b)

Fig.6 Experimental chart with 0.9mm coating

Next, experimental datum of No.3- No.5 coatings were showed in Fig.7. adiabatic performance of No.3 coating was best at lower temperature, but No.4 and No.5 coatings had better performance at high temperature. No.5 coating has no crack phenomenon after high temperature experiment, so No.5 coating got best adiabatic performance in all coatings.





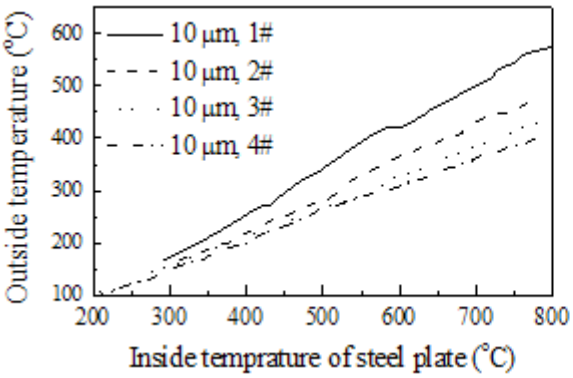


Fig.7 Inside And Outside Temperature On No.3-No.5 Coatings

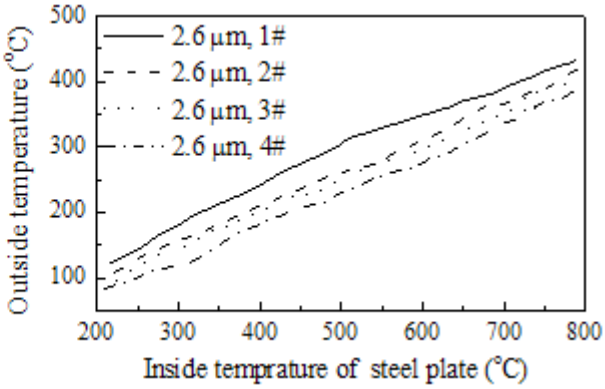
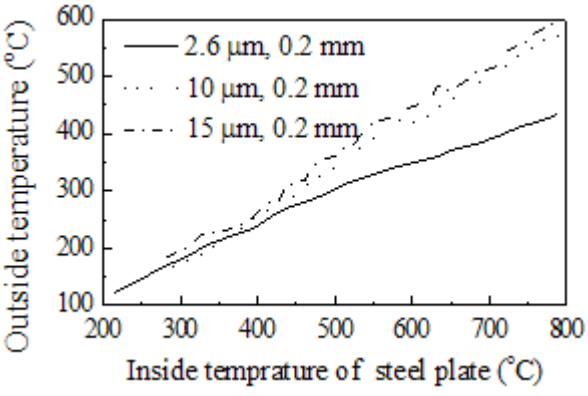
To study effect of the thickness on adiabatic performance, No.5 coating was classified as 3 sizes, 15 μm, 10 μm, 2.6 μm, No.1-No.4 steel plates (0.2-0.8 mm coating) were respectively tested, see Fig.8. Fig.8 illustrated that outside temperature of steel plate decreased with the increase of thickness

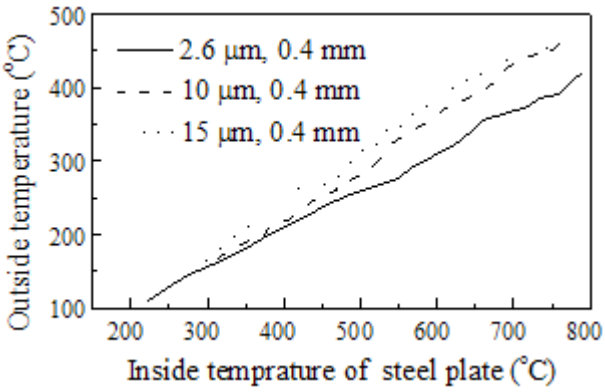


at same inside temperature of steel plate, and the temperature difference of inside and outside was proportional to inside temperature. Generally, the thicker coating may get better adiabatic performance[4].

(a)

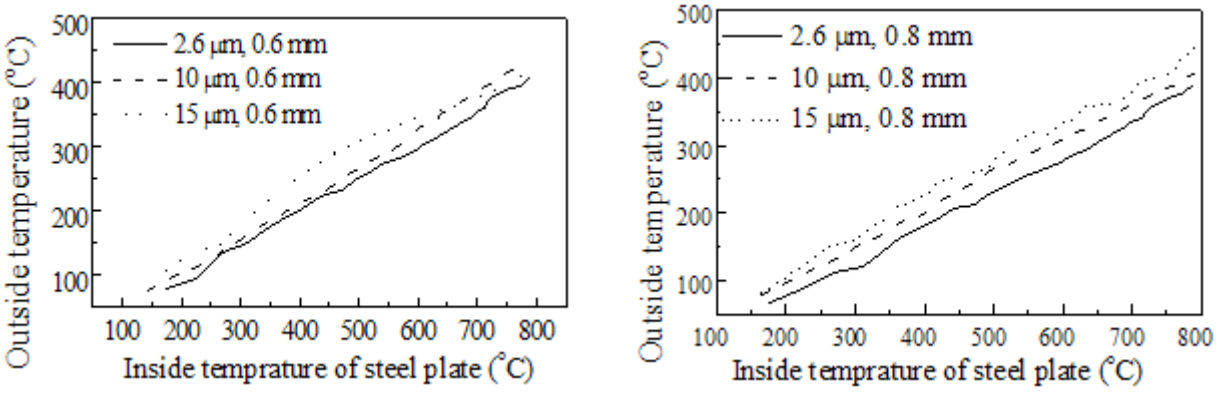


(b)



(c)

Fig.8 Inside And Outside Temperature Of Steel Plate With Different Size Of Hollow Tiny Bead



To research effect of hollow tiny bead size on adiabatic performance, No.5 coating was classified as 3 types with different hollow tiny bead size, 15 μm, 10 μm and 2.6 μm. Fig.9 showed that 2.6 μm tiny bead received best adiabatic performance. Experimental temperature had more obvious effect on adiabatic performance of thinner coating. 3 types of coatings had no obvious difference at lower temperature, but remarkable difference appeared at higher temperature (inside temperature of steel plate was more than 500°C). Smallest bead size can get optimal adiabatic performance, see Fig.9. 0.8 mm coating and 2.6 μm tiny bead may reach best adiabatic performance[5].

(a)

(b)

(c) (d)

Fig.9 Inside And Outside Temperature Of Steel Plate With 0.2-0.8mm Coating

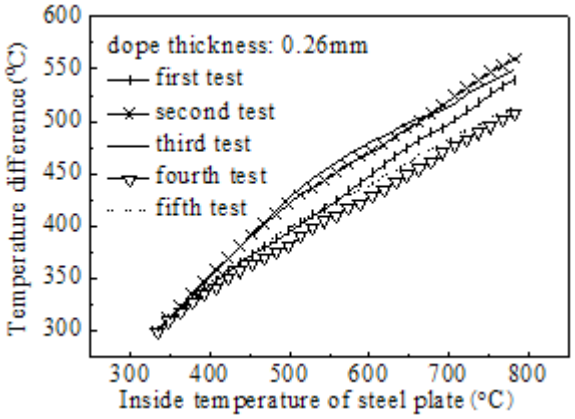


Fig.10 Antifatigue Experiment With 0.26mm Coating

After carboxymethyl cellulose was introduced as thickener, base experiments illustrated that coating didn't crack at 800 °C, so carboxymethyl cellulose, Na_2SiO_3 solution and 2.6 μm tiny bead were applied to produce the coatings for antifatigue experiment. Steel plate that had 0.26 mm coating experienced temperature rise experiments for 5 times, the results that inside-outside temperature difference changed with inside temperature were illustrated in Fig.10. After experiments for 5 times, coating still kept in good condition, this result was imperative to next industry application.

One-Dimensional Unstable State Heat Transfer Model

No.5 coating had best adiabatic performance by experiments, heat transfer model is made to analyze by applying Fourier law and energy conservation law. 1.5x100x200 mm A3 steel plate, 15 μm hollow tiny bead, different coating thickness, No.5 coating is introduced to build mathematic model. There is no inner heat source in heating period, convection occurs on outer boundary of steel plate, outside temperature changes with inside temperature. Following hypothesis is made to build one-dimensional unstable-state heat transfer model: uniform internal components of coating, isotropic nature, heat transfer that occurs in one section doesn't be influenced by other adjacent sections.

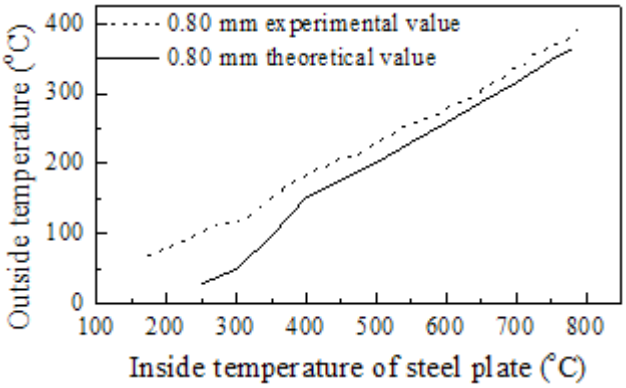
Based on above-mentioned hypothesis and theory, math model is given in Eq.1.

$$\frac{\partial}{\partial x}\left(\lambda\frac{\partial \mathrm{T}}{\partial x}\right)+q_v=\rho c_p\frac{\partial T}{\partial \tau} \tag{1}$$

$q_v = 0$ (no inside heat source)， Eq.1 is in unstable state.

λ: the conductivity (W/(m·°C)); c_p: mass heat capacities at constant pressure (J/(kg·°C)); ρ: the density (kg/m^3); T: the temperature (°C); τ: heating time; x: coordinate in thickness direction. Test result is: ρ: 1200 (kg/m^3); c_p: 1000 (J/(kg·°C)); λ (known boundary condition): 0.03-0.12

(W/(m·°C)), at the beginning of test, inside temperature of coating is 25°C, inside-outside temperature difference of steel plate increases gradually, heat transfer proceeds on outside of steel plate, heat transfer coefficient (α) is 20 W/(m^2·°C).



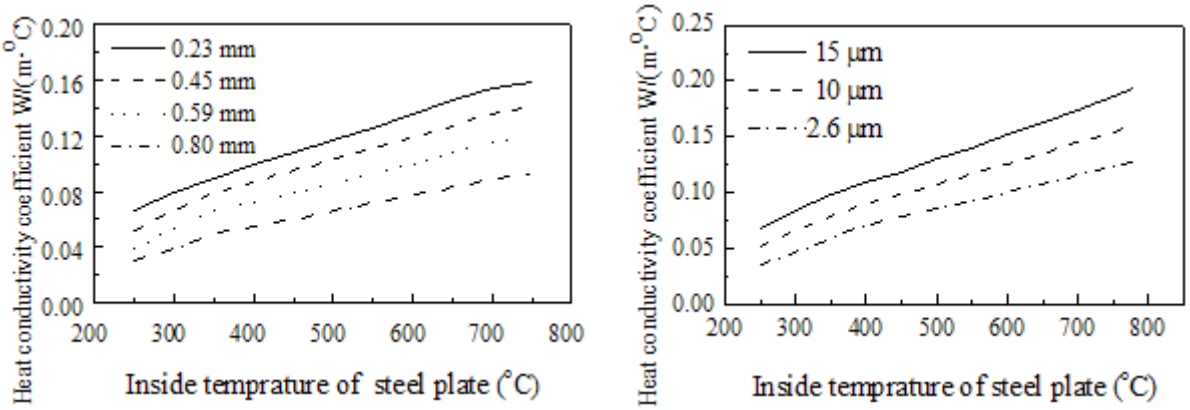


Fig.11 The comparison of outside temperature with 0.8mm coating

Fig.11 was the comparison of theory and experiment. Experiment value was close to theory value at thicker coating. At low temperature (<400°C), the higher temperature and thinner coating reduce the difference between theory and experiment. Generally, the results between theory and experiment were most similar at 0.8 mm coating.

(a) (b)

Fig.12 Inside temperature and heat conductivity coefficient at different status

When hollow tiny bead size was 2.6 μm, heat conductivity of coatings with different thickness was shown in Fig.12. Heat conductivity was inversely proportional to coating thickness at same inside temperature of steel plate. Heat conductivity increased with inside temperature, hollow tiny bead size had more obvious influence on heat conductivity at higher temperature. Bigger hollow tiny bead size was corresponding to lower heat conductivity and better adiabatic performance[6].

Industry Test On Ladle

Based on lab experiments, adiabatic coating was used in 30 t ladles of a steel plant. In terms of proportion of mixture in lab experiments, mixture contained 2.6 μm hollow tiny bead, sodium silicate, pure water, carboxymethyl cellulose. After weighed respectively, these substances were mixed evenly, then the coating was painted on internal surface of ladle. During the test period, operators recorded detailed datum. Statistics illustrated that average temperature drop on testing ladle was 2.3 °C/min, but that on normal ladle was 2.71 °C/min, so adiabatic coating had significant effect on molten steel.

Conclusion

Influencing factors of adiabatic performance were studied by experiments, antifatigue ability was tested, one-dimensional heat transfer model was made to testify experimental value. The conclusions are as follows:

(1) Na_2SiO_3 improves adiabatic performance at lower temperature, but it's not suitable for high temperature. Performance of hydrophilic inorganic heat-resistant resin is better than that of silicone resin at higher temperature[7].

(2) Experimental results expressed that thicker coating can get better adiabatic performance, but rational and affordable thickness should be determined.

(3) Smaller size of hollow tiny bead may realize better effect. The size of hollow tiny bead, coating thickness and experimental temperature affect adiabatic performance commonly. Generally, smaller size of hollow tiny bead and thicker coating are better choice.

(4) Antifatigue experiment showed that adiabatic performance has no direct relation with experiment time, so adiabatic coating can be applied in industrial production.

(5) After lab experiments, adiabatic coating was used in ladles of a steel plant. Test result expressed that temperature drop of molten steel can be decreased, it may reduce energy consumption for steelmaking, bring economic benefit for steel plants.

Acknowledgement

First and foremost, I would like to show my deepest gratitude to my teacher, Dr. GUO Hanjie, a respectable, responsible doctor, who has provided me with valuable guidance in every stage of the writing of this thesis. His keen and vigorous academic observation enlightens me in this thesis and my future work. Last but not least, I' d like to thank Dr. LI Lin and Dr. LI Yongqi, especially for their encouragement and support, they are my sincere friends.

Keywords: Superhydrophobicity, Transparency, Silica aerogel.

Abstract. A simple, versatile method has been developed to fabricate the transparent superhydrophobic surface via granuliform silica aerogels. The effect of ageing on the wettability, microstructure morphology and chemical structure of the dried gels has been investigated. Silica aerogel (dried alcogel with ageing) has a 3D porous network exhibiting the high surface area and pore volume. In comparison, large aggregates of silica nanoparticles exist within the backbone of the silica xerogel (dried alcogel without ageing). Both the aerogel and xerogel exhibit analogous chemical composition with abundant of methyl groups on the surface. The rough surface due to the high porosity and low surface energy provided by the methyl groups of aerogel contribute to the superhydrophobicity. Meanwhile, glass slides coated with aerogel film is highly transparent because the roughness created by the aerogel film is limited.

Introduction

A superhydrophobic surface with a water contact angle (WCA) greater than 150° and low contact angle hysteresis (CAH) has been extensively investigated due to its importance in both fundamental research and practical applications[1,2]. Since the wettability of a solid surface is mainly dependent on its chemical composition and the geometrical structure[3,4], a variety of techniques[5-7] have been developed to fabricate superhydrophobic surface. However, tedious procedures and unique equipment are always essential for most of these techniques.

SiO2 aerogel is such a kind of solid material which consists of SiO2 nanoparticles and has a continuous random structure filling with gaseous dispersive medium[8]. SiO2 aerogel shows an instinct rough surface due to its extremely high porosity. Meanwhile, selecting proper precursors can introduce the chemical groups with low surface energy into the structure of the prepared aerogel [9]. Therefore, rough surface and hydrophobization can be realized via one-step processing, which is beneficial for the highly efficient fabrication of superhydrophobic surface[10].

In our previous work, methyltrimethoxysilane (MTMS) was chosen as the precursor and monolithic aerogels with low bulk densities were produced at ambient pressure without the need for any solvent exchange and surface modification[11,12]. It is observed the high concentration of methyl groups attached to network skeleton and the extremely porous structure of the areogel render the superhydrophobic property of the MTMS derived aerogel. In this study, we develop a simple method to fabricate highly transparent superhydrophobic solid surface via granuliform silica aerogels. The effect of aging on the chemical composition, the geometrical structure and the wettability of the prepared aerogel is systematically investigated.

Experiment

Materials

All chemicals used including methanol (MeOH, 99.8% purity), MTMS (95% purity), oxalic acid, ammonium hydroxide were purchased from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China) and used as received.

The Preparation of Silica Alcogel

The silica alcogel was prepared via a two-step, acid-base catalysis sol-gel process[11]. In the first step, MTMS was mixed with MeOH while fixing the MeOH/MTMS molar ratio of 21. The aqueous solution of oxalic acid (0.01M), as an acidic catalyst, was then added to the reaction media. The mixture was stirred at room temperature for 24 hours to complete the hydrolysis process. In the second step, the aqueous solution of ammonium hydroxide (10M), acting as a basic catalyst, was added dropwise to the as-prepared silica sol while stirring. Molar ratio of MTMS/the oxalic acid solution/the ammonium hydroxide solution was kept constant at 1:4:4. The prepared silica alcosol was transferred into a glass test tube which was then made air-tight and placed at 30 °C for the gelation. After gelation, some amounts of fresh MeOH were added into the test tube and the alcogel was aged in MeOH for 48 hours at 60 °C. At last, the MeOH solvent was removed from the test tube and the aged alcogel were obatined. Meanwhile, the alcogel without ageing was also prepared.

The Fabrication of Superhydrophobic Glass Surface

The silica dispersion was prepared by homogenizing the above alcogel with MeOH using an ultrasonic cell disruptor for 3 minutes. The as-obtained homogenized alcoholic dispersion was spin-coated on glass slides which were pretreated in an ultrasonic cleaner by soap-suds, deionized water and MeOH respectively. At last, the coated glass slides were dried in an oven at 40 °C.

Characterisation

The adsorption–desorption isotherms of the aerogels for nitrogen at 77 K were obtained using a Micromeritics TriStar II 3020 analyzer. The microstructure of the aerogels were examined by transmission electron microscopy (TEM, JEM 2100F), scanning electron microscopy (SEM, Hitachi S4800) and a scanning probe microscope (SPM, NanoScope IV). The chemical structure of the aerogels was characterized by an infrared spectrometer (ATR-IR, Nicolet Avatar380). The hydrophobicity of the glass slides was evaluated using a contact angle system (Kruss DSA 30) . The optical transparency of the glass slides were measured by a UV-vis spectrophotometer (Hitachi U-3310).

Results and Discussion

Contact Angel

In this study, the wettability of various glass slides was investigated (Fig. 1). The pristine glass shows a hydrophilic surface with a static contact angle of 22.1° (Fig. 1a). When the alcogel was directly homogenized after gelling without ageing and subsequently spin-coated onto a glass slide, the contact angle of the coated glass slide increased to 144.0° (Fig. 1b). Once the alcogel was aged in MeOH at 60 °C for 48 hours before homogenization and coating, the wettability of the coated glass slide shows superhydrophobicity and the contact angle reaches to 175.5° (Fig. 1c). Meanwhile, it is widely recognized that lower CAH plays a more significant role in determining hydrophobicity than the static WCA. The glass slide coated with aerogel exhibits very low CAH and the water droplets can easily roll away on these surfaces by a gentle vibration, while the glass slide coated with xerogel shows much higher CAH.

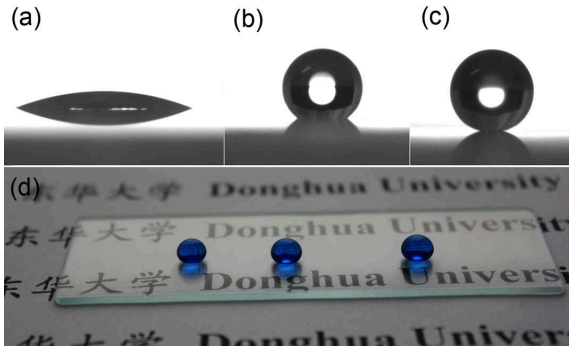

Fig. 1. Optical Images of Water Droplets on a Pristine Glass (a), Glass Coated with the Xerogel (b), Glass Coated with the Aerogel with Ageing (c) and a Photograph of Water Droplets (Colored with DyStar Procion blue H-ERD) on the Glass Coated with the Aerogel

SEM and TEM

SEM and TEM were used to investigate the effect of ageing on the geometrical structure. Fig. 2(a, b, c) shows the FESEM images of the xerogel with different magnifications. It is obvious that large voids and aggregates can be confirmed within the gel backbone network. Fig. 2(d, e, f) exhibit the FESEM images of the aerogel, in which small clusters and highly homogeneous pore structure can be confirmed. Both samples exhibit rough surface while larger fraction of air can be trapped within the network of aerogel in comparison with the xerogel. During ageing, the conversion of unreacted Si-OH to Si-O-Si continued and the alcogel network is further strengthened. Therefore, the skeleton of the aged gel can withstand high interfacial forces (capillary force) during the ensuing ambient pressure drying, resulting in low volume shrinkage and high porosity. Meanwhile, the pore structure collapses and small particles firmly connect with each other within the xerogel.

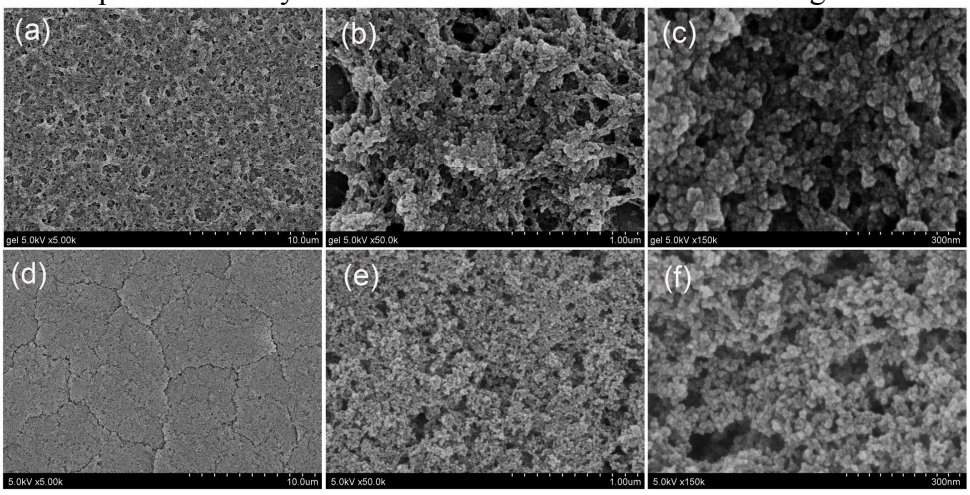

Fig. 2. FESEM Images of the Xerogel and the Aerogel with Different Magnifications (a,d) Scale Bar 10um , (b,e) Scale Bar 1um ,(c,f) Scale Bar 300nm

Fig. 3 demonstrates the HRTEM images of the xerogel (Fig. 3a, 3b) and aerogel (Fig. 3c, 3d). Both samples are composed of interconnected approximately 15 nm sized particles. However, larger aggregates can be obviously observed in the xerogel comparing with the aerogel. This is consistent with the FESEM results. According to the Cassie-Baxter model, increasing the fraction of air between water and the solid surface is advantageous to obtain superhydrophobic surface with a high WCA and low CAH.

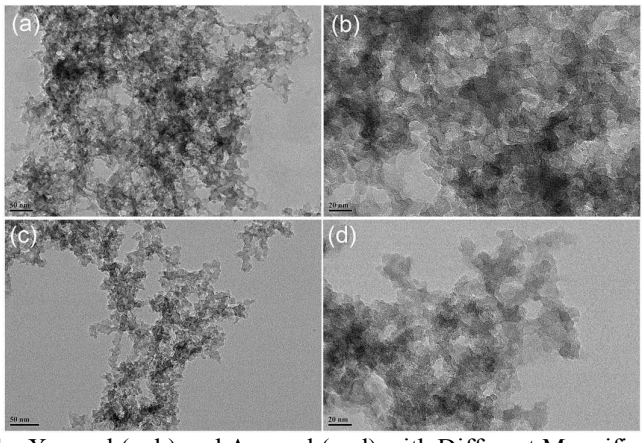

Fig. 3. HRTEM Images of the Xerogel (a, b) and Aerogel (c, d) with Different Magnifications (a, c) Scale Bar 50nm, (b, d) Scale Bar 20nm

BET Surface Area And Pore Size Distribution

Fig. 4 shows the nitrogen adsorption-desorption isotherms and pore size distributions of xerogel and aerogel. Both samples show a type Ⅳ isotherm, while the aerogel exhibits a much higher specific surface area and total pore volume than the xerogel. Meanwhile, the pore size of the aerogel shifts to larger range than the xerogel. For the xerogel, numerous smaller particles aggregate together to form large clusters after ambient pressure drying. That's the reason why the xerogel displays small pore sizes. Ageing leads the aclogel to a stiffer gel network, resulting in more resistance to gel shrinkage

during drying. Therefore, the strengthened gel network and relatively large pores ensure that the porous structure can be maintained in the prepared aerogel. This is in agreement with the previous FESEM and HRTEM results.

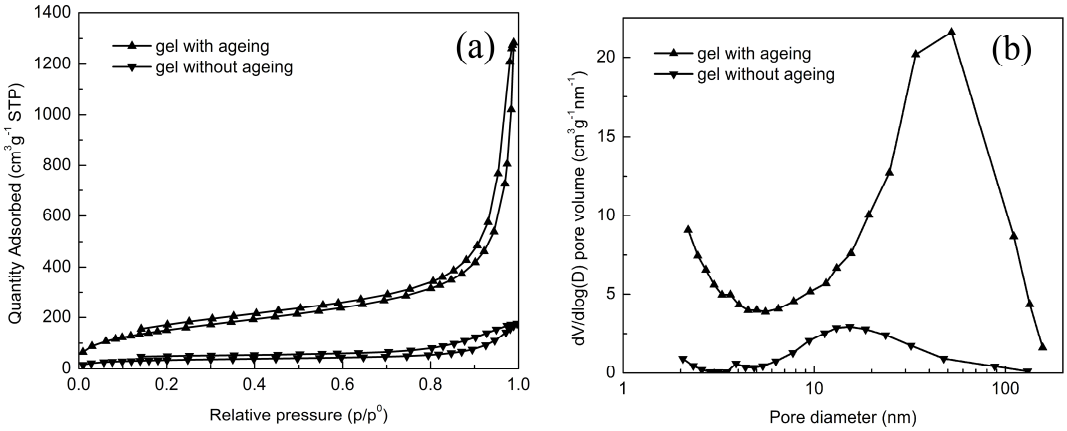

Fig. 4. Nitrogen Adsorption-desorption Isotherm (a) and Pore Size Distribution (b) of Xerogel and Aerogel

FTIR

The chemical composition and functional group were identified by ATR-IR (Fig. 5). Fig. 5a shows ATR-IR spectrum of MTMS. The peaks at 1193 and 1087 cm-1 are assigned to C-O stretching vibration mode of Si-O-CH3 while the peaks at 2841 and 1460 cm-1 are assigned to C-H stretching vibration and bending vibration mode of Si-O-CH3. All these peaks disappear in the MTMS based xerogel and aerogel, demonstrating that MTMS has been fully hydrolyzed. ATR-IR spectra of MTMS based xerogel and aerogel in Fig. 5b and 5c show the peaks around 1030 and 1110 cm-1 which are assigned to stretching mode of Si-O-Si. Meanwhile, the peaks around 2971, 1409 and 1272 cm-1 which are attributed to C-H stretching and bending vibration modes of Si-CH3 are sustained in the MTMS based xerogel and aerogel, indicating the condensation of hydrolyzed MTMS and the presence of methyl group. Fig. 5b and 5c have a high similarity except that the MTMS based xerogel shows a higher intensity of the band of Si-OH stretching vibration (~919 cm-1) than the areogel, implying more residual silanol group and incomplete condensation between hydrolyzed MTMS in the xerogel.

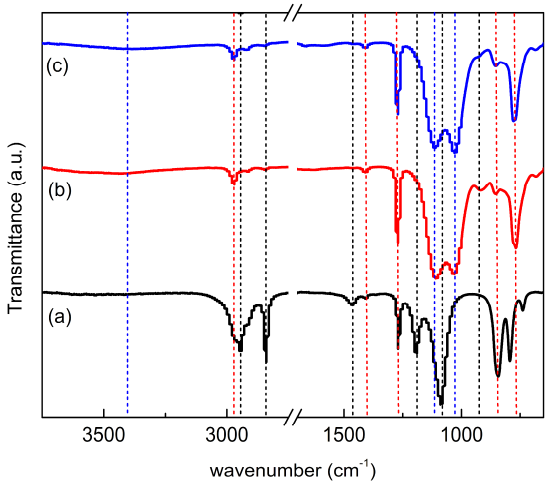

Fig. 5. ATR-IR Spectra of MTMS (a), MTMS Based Xerogel (b) and MTMS Based Aerogel (c)

Light Transmission

Since transparency is a very important property during the application of superhydrophobic surface (e.g. solar cell, glass) [13], Transmittance of the aerogel coated glass was investigated (Fig. 6). The underlying text can be clearly seen, indicating that the coated glass is highly transparent. The transmittance of the glass coated with the silica aerogel is further investigated by the UV-vis spectra. The coated glass exhibits the similar transmittance in the range of 600-800 nm and a slightly lower transmittance in the range of 400-600 nm.

Rough surface fabrication, which is important in preparing superhydrophobic surface, may lead to the decrease of the transparency because of the Mie scattering from the rough surface. The roughness

dimension of the surface must be controlled less than 100 nm to achieve high transparency. AFM was used to investigate the surface topography of the glasses. The surface roughness, rms, increases from 0.248 nm for the pristine glass to 77.288 nm for the spin coated glass. The relatively low surface roughness (<100 nm) renders the coated glass transparency.

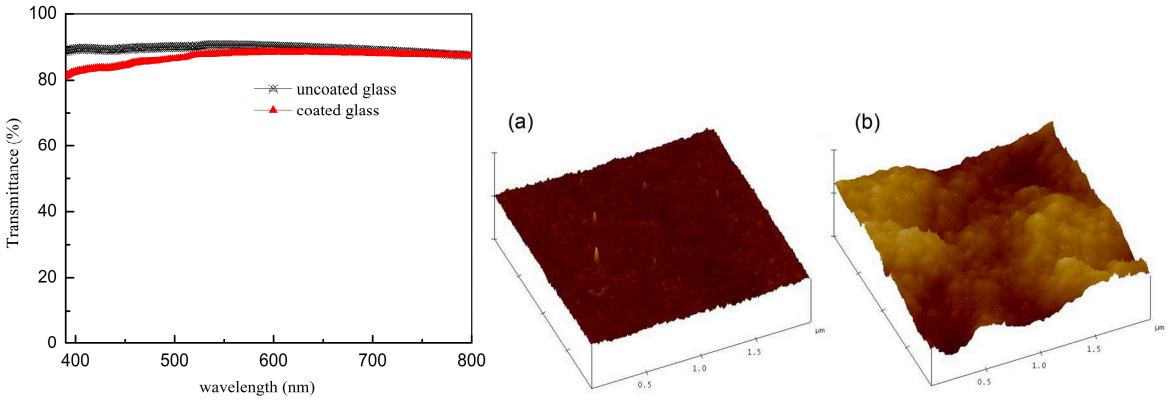

Fig. 6. Transmittance and AFM Images of the Pristine Glass (a), the Glass Coated with the Aergel (b)

Summary

In conclusion, a simple method to create the highly transparent superhydrophobic surface (static WCA larger than 175°) has been developed by spin-coating granuliform silica aerogel particles on the solid substrate. SEM and TEM images indicate that the ageing of the alcogel would provide the aerogel with a very porous 3D network structure while the xerogel without ageing shows large clusters and voids within its structure. IR spectrum demonstrates that complete hydrolysis and condensation take place for the areogel and abundant of methyl groups with low surface energy exist on its structure. Furthermore, the film shows a high transparency because the roughness dimension of the aerogel film is within 100 nm. This method can be extended to a wide range of substrates to prepare surperhydrophobic surface.

Keywords: Cryogenic treatment, coating, chromium nitrite, CrN, PVD, aluminum, ULTP, micro-scale abrasion.

Abstract: The endurance of components made of aluminum and aluminum alloys is often limited by their low yield strength and by their low wear resistance. The aim of this paper is to investigate the effect of different methods that can improve wear resistance of aluminum alloys. As a first approach, a highly wear resistant chromium nitrite layer was deposited by plasma vapor deposition on the surface of the aluminum alloy AA 6101-T4. In the second method, an ultra-deep cryogenic treatment was selected. Both methods have been previously used to improve the wear resistance of other harder substrate materials, like tool steel. To investigate the impact of the two methods on the wear resistance of such alloy, micro abrasive wear tests were carried out and an analysis based on the Archard's law was considered. The results showed a decrease of the wear rate by 29% and 26% for the coated and for the cryogenically treated specimens, respectively, when compared to the as received material. The work also investigated the performance of three different methods (Allsopp, Double Intercept and Polynomial AT) usually considered to calculate the wear rate of coated samples. The three methods presented similar measures of wear rate for the substrate and for the coating.

Introduction

Aluminum and aluminum alloys are rarely used for mechanical applications subjected to highly abrasive environment, since their wear resistance are known to be low [1,2]. For this reason, there is a limited amount of published material on the wear of aluminum and its alloys. The advantages of aluminum are the low costs of production and manufacturing, its good resistance against corrosion [3], its low density among others [4]. However, in some applications aluminum components are exposed to damage mechanisms such as fretting fatigue or fretting wear. These mechanisms either damage the component due to an irrecoverable material loss or lead to premature crack initiation, which can drastically reduce the strength of the component [5].

One example where aluminum components are exposed to an abrasive environment, is the overhead conductor used to transmit electrical energy. The conductors are usually made of aluminum or of aluminum alloys wires wrapped together. The damage normally occurs in points where the displacement of the cable due to Aeolian vibration is restricted, as in the assemblies between cable and suspension clamps, which are fixed to the towers [6]. Due to this oscillatory movement of the conductor a minute relative displacement will occur in the interface between cable and clamp, generating fretting wear and fretting fatigue [6].

The damage of overhead conductors leads to high maintenance costs and sometimes even to extensive black outs if a conductor experiences complete failure. The increase of the wear resistance of aluminum alloys can provide longer operational lives for these lines and reduce the costs of repairing. In this setting, this paper investigates the application of two different treatments in order to improve the wear resistance of aluminum. The deposition of wear resistant coatings is a technique that works well for hard materials like tool steels. However, more recently the deposition of wear resistant coatings for soft materials like aluminum and polymers [1,2,7] have been successful. Here, the effect of a chromium nitrite (CrN) layer deposited on an AA 6101-T4 alloy was examined.

Deep cryogenic treatments (Ultra Low Temperature Process, ULTP) have also been used as an alternative to improve the wear resistance (not only on the surface but also in the core) of tool steels [8]. The effects of cryogenic treatment on steels is somehow well understood [8,9,10]. For these materials the cryogenic treatment leads to the precipitation of hard carbides in the microstructure [11,12,13], which are believed to be the main factors in the improvement of their wear resistance. There are evidences that a ULTP can improve the mechanical properties of other metallic alloys [12,18,19]. In this setting, the effect of a ULTP on the wear resistance of the AA 6101-T4 alloy was also investigated in this work.

Materials and Methods

To carry out the micro abrasive tests extruded bars of AA 6101-T4 aluminum alloy were provided by an electrical fittings producer. The extruded bar was cut in small block specimens with dimensions 25×20×13 mm. All specimens were extracted from the same bar. The chemical composition of the alloy was determined in laboratory to confirm its specification and is reported in Table 1.

Table 1: Elements contained in the aluminum alloy in %.

Cu	Si	Mn	Cr	Fe	Zn	Mg	Ti	Al
< 0.01	0.50	< 0.01	< 0.01	0.18	< 0.01	0.49	0.01	> 98.78

To generate similar surface conditions among the specimens their surfaces were grinded with sandpaper P 600 (particle size 25 μm). The surface preparation occurred before the studied processes were applied. To investigate the effect of the different treatments, a series of three specimens was considered.

The first treatment, a chromium nitride (CrN) coating was executed by a company (Platit) in Brazil. According to the manufacturer, the temperature occurring on the surface of the specimens during the PVD process was 100 °C. The deep cryogenic treatment was also performed by contract work from an external company (Kryos Cryogenic Engineering, Brazil). The deep cryogenic process starts at room temperature and goes down to the target level (190 ºC) within a period of 12 h. This target temperature is then maintained for further 12 h. After this dwell time, the temperature is increased to room temperature within the same 12 h ramp. Before the liquid nitrogen was induced in the chamber, it is evaporated to enable a controlled cooling and to prevent a severe gradient of temperature between the surface and the core of the specimens [11].

In order to examine the wear resistance of the different specimens, micro abrasive wear tests were performed. The micro-scale abrasion device uses a free-ball system (Calowear, CSM instruments). Due to the fact that the tested aluminum alloy can be classified as a soft material, the test conditions needed to be properly adjusted [1,2,15]. In order to generate craters with the negative shape of the rotating balls, the following test parameters were set:

(i) the contact force, (ii) the abrasive and (iii) the velocity.

The load applied during the tests was 50 mN (0.05N). This load proved enough to generate the crater shape sought and also to generate a three body wear regime in the crater [15]. The force reduction was reached by positioning the ball close to the center of the drive shaft, as shown in Fig. 2 (a). This position reduces the contact force, which is only generated by the weight of the ball. All tests were carried out using alumina (Al_2O_3) with a mean particle size of 1μm as abrasive slurry. A concentration of Vol. 10 % Al_2O_3 was dispersed in deionized water [16]. The abrasive slurry was dripped at a rate of at least ten drops per minute. For the tests, a steel ball with the radius of 10 mm was used. The sliding velocity adjusted at approximately 0.1 m/s. On each specimen a series of six craters were generated with distinct sliding distances. After the predefined sliding distances were reached, the tests were interrupted and the diameter of the crater was measured. The interruptions of the tests occurred at a sliding distance of 21, 32, 48, 64, 80 and 107 m. The diameter of the crater generated by the rotating ball was measured subsequently. The mean external diameter *b*, which is used in the analysis, was determined from two measurements taken in a 90 ° angle to each other, being one parallel and the other perpendicular to the sliding direction (Fig. 1).

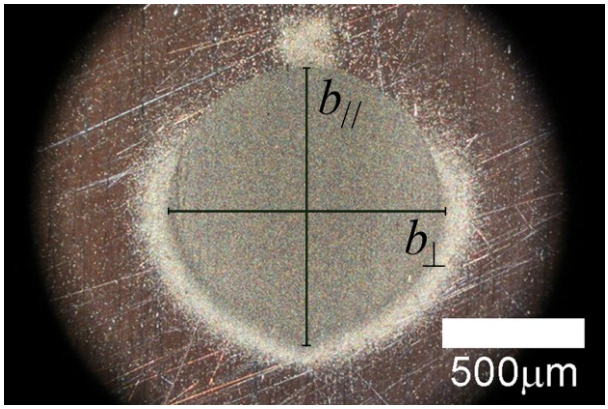

Fig. 1. Exemplary measurement of the crater diameter of an uncoated specimen. Three body wear was found.

All the tests were conducted using the same experimental routine. The applied wear rate calculation is based on the Archard's law (Eq. 1), which implies that the removed volume V depends on the sliding distance S and on the contact force N. The mean wear rate of all specimens was calculated using such law [14]. In Eq. 1 the volume is summarized in the second term, where b is the diameter of the crater and R is the diameter of the ball.

$$\kappa = \frac{1}{SN}\frac{\pi b^4}{64R} \tag{1}$$

In order to enrich the analyses, the coated samples were submitted to a second analysis as proposed by Gee et al [16]. According to Eq. 2 from Rutherford and Hutchings [17], the wear rates of the substrate and of the coating ? o_s and ? o_c respectively, can be calculated separately using the volume of the substrate V_s and the volume of the coating V_c.

$$SN = \frac{V_c}{\kappa_c} + \frac{V_s}{\kappa_s} \tag{2}$$

Three methods were selected to calculate the wear rates ? o_s and ? o_c. These methods (methods that perforate the coating) do not measure the values of κ_c and κ_s directly, but can numerically determine them. To calculate ? o_s and ? o_c directly, non-perforating methods can be used. However, as the thickness of the deposited CrN layer was too low these methods could not be considered in this work.

Allsopp Method: The first method used was the so called Allsopp or Vc-AT method (Eq. 3).

$$\frac{SN}{V_c} = \frac{1}{\kappa_s}\frac{V_s}{V_c} + \frac{1}{\kappa_c} \tag{3}$$

With this method, the wear rates can be calculated with the inclination and with the interception of the linear regression for the data plotted in a graph of SN/V_c against V_s/V_c. The volumes V_s and V_c can be obtained from a pre-determined value of the coating thickness t and the measured outer diameter of the crater b.

$$V_c \approx \frac{\pi t}{4}\left(b^2 - 4Rt\right) \tag{4}$$

$$V_s \approx \frac{\pi b^4}{64R} - \frac{\pi t}{4}\left(b^2 - 4Rt\right) \tag{5}$$

Double Intercept Method: The double intercept method (DI) (Eq. 6) is another rearrangement of Eq. 2 and offers another option to calculate the different wear rates [16].

$$\frac{1}{\kappa_s}\frac{V_s}{SN}+\frac{1}{\kappa_c}\frac{V_c}{SN}=1 \tag{6}$$

The DI method calculates the wear rates by the interceptions of a linear fit of V_c/SN versus V_s/SN with the axes of ordinate and abscissa.

Polynomial AT Method: The third option is the polynomial AT method (Poly-AT) (Eq. 7). In this case, the wear rates can be calculated with the inner crater diameter a and the coating thickness t.

$$SN=\frac{\pi}{64R\kappa_s}a^4+\frac{\pi t}{4\kappa_c}a^2+\frac{\pi R t^2}{\kappa_c} \tag{7}$$

Since the inner crater diameter was not measurable (Fig. 1), a was calculated using the predetermined values of t and the outer crater diameter b.

$$t\approx\frac{1}{8R}(b^2-a^2) \tag{8}$$

The measurement of the coating thickness could be only conducted using a scanning electron microscope (SEM) and a special technique to prepare the specimens, which was developed during this research. The preparation technique is called half corner crater preparation (HCC). Within this technique, a crater analog to the wear tests is generated on the edge of the specimens (Fig. 2b). With the HCC the coating thickness can be measured accurately, since no polishing that normally causes rounded edges is needed. To determine the coating thickness a crater needs to be generated on the edge of the specimen (Fig. 2a). The coated side of the specimen is facing to the down side. Using this specimen position, the crater is generated orthogonal to the coated surface. To reach a reasonable crater depth, the sliding distance should be sufficient to remove the rounding of the edge. The HCC was generated under the same conditions of the micro-scale abrasion tests (abrasive, force, velocity).

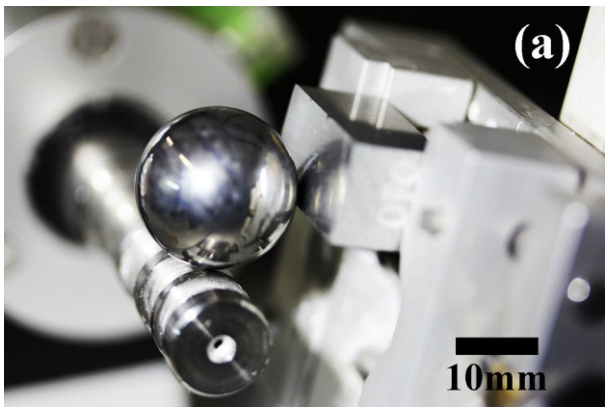

Fig. 2. (a): Illustrative position of the ball to produce a HCC.

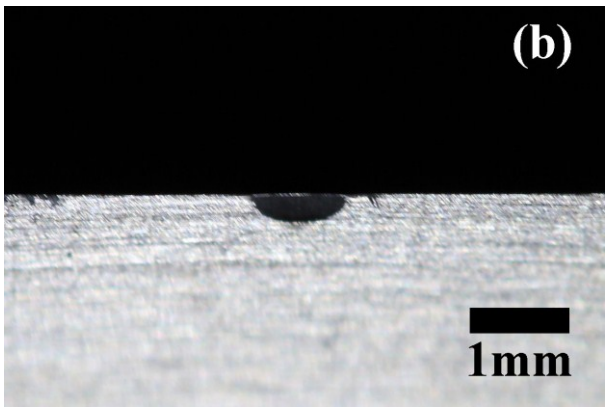

Fig. 2 (b): HCC on the edge of the specimen.

Results

As described already in the introduction, the shape of the crater can influence the measurement significantly. In order to prove if the shape of the crater is comparable to the shape of the ball, profilometric measurements were performed with a Mitutoyo SJ201 contact roughness tester (Fig. 3a). If the shape of the crater differs from the shape of the ball, the calculated removed volumes do not represent the actually removed volume. In Fig. 3a the profile measurement of one crater is plotted. Above the measurement shown as a black line, the theoretical profile of the ball is shown in red with a distance of 1 µm. This gap corresponds to the used mean particle size of the abrasive slurry.

Due to the low thickness of the surface coating, the coating thickness could not be measured using the images of the craters. To determine the coating thickness, SEM investigations were carried out. In Fig. 3 b, one coated specimen is shown.

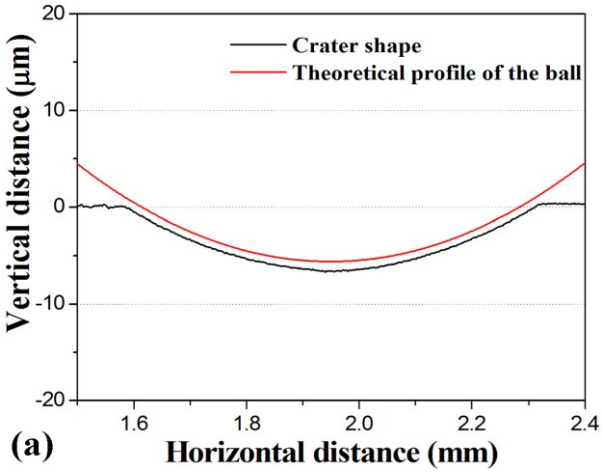

Fig. 3 (a): Geometry of crater depth against the theoretical profile of the ball.

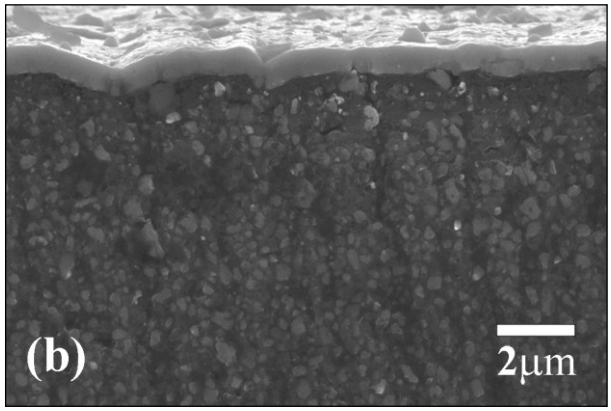

Fig. 3 (b). Determination of the coating thickness using SEM.

Fig. 3 b illustrates the sectional view of a coated specimen. The bright area on top of the picture shows the coated surface of the specimen. The darker area represents the bulk material of the aluminum alloy in a 90 ° angle to the coated surface. In between these areas, a section though the CrN layer is presented (light gray layer). Based on a series of SEM pictures, a mean coating thickness of 660 nm was measured. This value was used for the wear rate calculations of the coated specimens.

The results of the wear tests are shown in fig.4. fig.4a shows the removed volume over the sliding distance multiplied by the contact force of the different test series.fig.4b illustrates the wear rate of the same specimens using the same scale and unity for the x-axis.

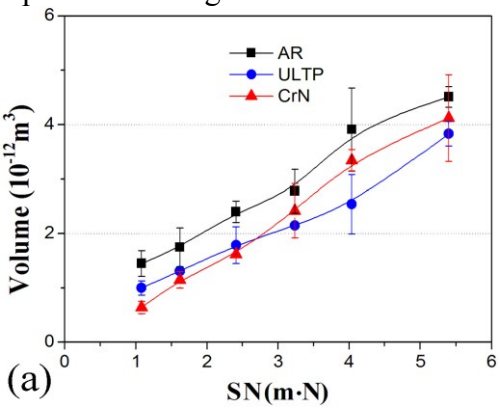

Fig. 4a. Removed volume *versus* the sliding distance multiplied by the contact load.

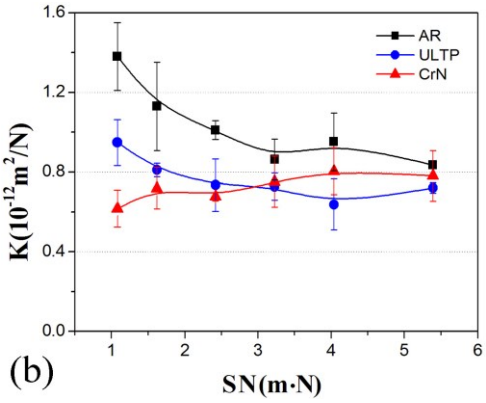

Fig.4b. Wear rate versus sliding distance multiplied by the contact load.

As expected, the amount of removed volume increases with an increasing sliding distance, whereas the AR specimens show the highest volume loss in all measurement points. A reduced removed volume was measured for the coated and the cryogenically treated specimens. Comparing

the results of the coated and cryogenically treated specimens, an intersection of both curves can be recognized. The wear rate of the test series shown in Fig.4b show a comparable behavior. The specimens tested AR have the highest wear rates, which is decreasing with SN. Analog to the analysis of the removed volume, the curves of the treated specimens are crossing each other. This means that the wear rate of the coated specimens is increasing with SN. A contrast behavior was found for the cryogenically treated specimens.

To compare the wear rates at all measurement points with each other, the mean wear rates are shown in Fig. 5a. Each bar represents the mean wear rate of three equally treated specimens. On each of them, six craters were generated. The shown error bars illustrate the standard deviation between the mean wear rates calculated for each specimen. In Fig. 5b, the calculated wear rates of the coated specimens are shown. To compare the calculated values with the reference materials (AR), the wear rate of the untreated specimens is additionally shown in the graph.

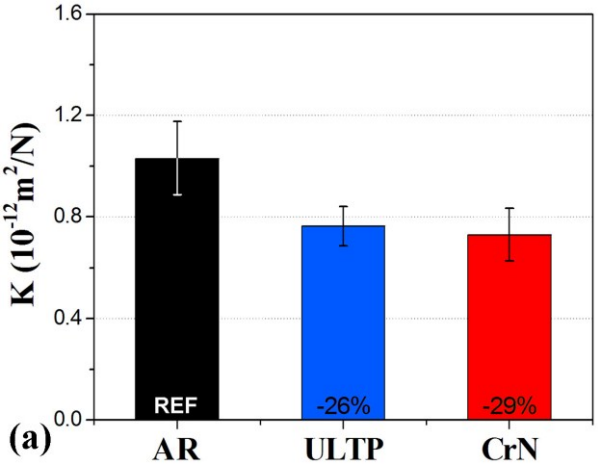

Fig. 5. (a): Mean wear rates of the investigated test series.

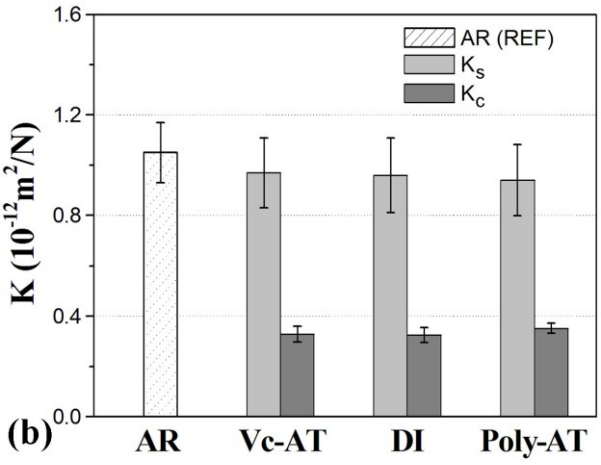

Fig. 5(b): Comparison of the applied analysis methods for the coated specimens.

The applied treatments show a significant effect on the wear behavior of the tested aluminum alloy. A reduction of 26 % was measured for the cryogenically treated specimens. The specimens coated with CrN show a wear rate reduction of 29 %, compared to the AR specimens.

In Fig. 5b the wear rate of the specimens tested AR are compared with the calculated wear rates of the bulk material using the calculation methods Vc-AT, DI and Poly-AT. Furthermore, the calculated wear rate of the CrN coating are shown. The calculated values for ? o_s agree well with the reference material. Furthermore, only very small differences between the single calculation methods were found. The wear rate ? o_c is significant lower than the wear rate of the substrate. Likewise to the ? o_s, only slight differences can be seen between the single calculation methods.

Discussion and Conclusion

As shown in Fig 4a, all tested specimens showed higher volume loss with an increasing SN. For this graph, the removed volume is plotted versus the contact force multiplied by the sliding distance. Since the contact force was kept constant during the tests, the Archard's theory, which claims that the volume increase with the sliding distance, can be confirmed. As expected, the as received specimens show the highest volume loss at all measured sliding distances. It is worth of notice in this figure that the curves of the coated and of the cryogenically treated specimens cross each other after the third measurement point. This effect can be explained by the effective range of the applied wear improving treatments. As the surface coating only increases the wear resistance on the surface, the effect of it to reduce the volume of material removed mainly occurs at low sliding distances. After the coating is perforated, the contact area between the rotating ball and the specimen involves a zone of CrN coating and another zone of the aluminum alloy. With an increased wear volume, the coating/aluminum ratio in the contact area decreases significantly. For this reason, the wear rate of the coated and of the as received specimens converges with an increase in the sliding distance. On the

other hand, the curve progression of the cryogenically treated specimens shows a reverse effect. At low sliding distances, the volume loss of the cryogenically treated specimens is lower than the untreated specimens, but higher than the coated ones. Since the effect of the cryogenic treatment is not limited to the surface area [13], the improved wear resistance can also be felt (and then measured) at higher sliding distances.

The same tendency can be seen for the results of the wear rate (Fig. 4b). In theory, the wear rate of the uncoated and the cryogenically treated specimens should be constant over the whole sliding distance [14]. Anyhow, several effects can influence the wear rate in dependency of the sliding distance. The most probable effect for the difference observed in the wear rate is an overestimation of the removed volume at low wear rates due to the difficulty to measure the diameter of the crater [16]. As shown in Fig. 1, the uncoated specimens show a large scuffed area around the crater. This turns the measurement of its diameter and consequently of the volume loss a less precise task. Other authors found similar behavior for uncoated soft materials [15]. Besides this, further measurement difficulties in this test can be caused by craters that do not mirror exactly the shape of the ball. Other scientists report about two possible effects [17]: first, a ridge can be formed around the crater. This mainly happens if soft materials are used, which was the case here. To avoid or at least minimize this effect the contact force was reduced to 50mN (0.05N). Second, the crater can show an elliptical shape (sectional view) with softened edges. In both cases, the calculated volume does not represent the actual removed Volume. In order to verify if such phenomena occurred, contact profilometry was used to determine the shape of the craters. As shown in Fig. 3a, none of such effects could be found in the tested specimens.

The results also showed (Fig. 5a) that the cryogenic treatment reduces the wear rate in 26% (over the whole sliding distance) compared to the as received specimens. This represents a clear improvement in the wear properties of this aluminum alloy associated to such treatment. Less clear at this stage of the work are the material changes that cause such improvement. Other authors raise the possibility of the formation of hard second phases, which could be formed during the cryogenic treatment [12,18,19]. Some possible second phases found by other researchers that also researched about the effect of cryogenic treatments on comparable aluminum alloys are $Mg_{17}Al_{12}$, $AlCu_3$, Al_7Cu_2Fe, $MgZn_2$ or Al_2Cu [12,18,20,21]. As shown in Table 1, the elements Mg, Cu and Fe are present in the tested aluminum alloy. In order to investigate the formation of the mentioned phases, XRD measurements will be carried out in the near future. Furthermore, a microstructure analysis and a micro hardness measurements will be performed.

A wear rate reduction of 29 % could be reached due to the coating with CrN. CrN is known to be a good wear resistant coating, for which reason a reduction of the wear rate was expected [1,2]. The coating of soft materials is not riskless, since delamination or crack formation can occur easily in the case of high contact loads or deformation of the substrate [7]. Due to the low contact forces used between the rotating ball and the specimens, none of the mentioned failures was found. The wear rate reduction of 29 % is anyhow higher than expected, since the coating is just 660 nm thick.

As already mentioned in Methods section, the coating thickness could not be measured with an optical microscope after the wear tests, what would be the classically used method. The small thickness of the coating avoided a measurement of the inner crater radius. For this reason, the coating thickness was measured inside an independent crater generated from the test series, which was placed on the specimens edges. The already described HCC preparation was the only possibility to measure the coating thickness without an interference of the polishing process which would produce rounding edge effects.

The determined coating thickness was used to calculate the wear rate of the substrate and the wear rate of the coating within the same analysis. Three different analysis methods have been tested. These methods showed similar results, despite their different ranges of emphasis. All the methods are based on the Archard's law and use the volume loss and the diameter of the crater to calculate the wear rates [22]. Each calculation method has some positive and negative aspects. For this reason, the result of each method is slightly different. The double intercept method, for example, puts emphasis to low sliding distances, which are normally the ones with the highest possibility for inaccurate

measurements. On the other hand, both wear rate are divided by SN, which can be measured much more accurately than the diameter of the craters, what decreases the measurement deviations [22]. The Allsopp (Vc-AT) method also puts high emphasis to the smallest craters, since it is using a linear regression to calculate the ? o_s. The problematic involved in the analysis based on linear regression is the big weight of single measurement points. Therefore, the third method works with a fit of a polynomial function to avoid this huge influence. Using this method, the emphasis is on larger craters [22].

Keywords: wear, pvd thin films, TiN, ZrN

Abstract: Production and processing of titanium alloys are expensive and its alloys show low wear resistance. Substrates of Ti-40Zr, used for orthopedic implants, were obtained from the elemental mixture of hydrogenated powders, followed by a sequence of cold uniaxial and isostatic pressing and vacuum sintering. Aiming wear resistance increase, samples were coated by physical vapor deposition using electron beam technique (EB-PVD). Multilayer coatings with three different configurations were undertaken: Ti/TiN, Ti/TiN/ZrN and Ti/TiN/ZrN/TiN. Micro-abrasive wear tests were conducted by ball-cratering, with abrasive slurry of silicon carbide (SiC). The wear craters were measured at intervals corresponding to increments in the sliding distance of approximately 14 m. Range of the normal force were between 0.35 and 0,45 N. Scanning electron microscopy was used to evaluate the wear crater and the wear mode. All experiments showed three-body abrasive wear and a reduction of one order of magnitude in wear coefficient for two coated samples: $2{,}58\cdot10^{-12}$ $m^3(Nm)^{-1}$ to substrate, $5{,}4\cdot10^{-13}$ $m^3(Nm)^{-1}$ to Ti+TiN film and $7{,}22\cdot10^{-13}$ $m^3(Nm)^{-1}$ to Ti+TiN+ZrN film. In the Ti+TiN+ZrN+TiN experiment the wear coefficient of film is nearer to the substrate, $7{,}58\cdot10^{-13}$ $m^3(Nm)^{-1}$. The multi-layers containing ZrN presented wear coefficient higher than Ti/TiN films, possibly due to existing residual stresses.

Introduction

Biomaterials application has expressive market worldwide, and its increase reached over 150 % from 2009 to 2012 [1]. Considering the increase of life expectance and rise of traffic accidents, gross import and export of implants in Brazil had financial transactions reaching nearly 750 million of dollars, only in 2011 [2-4]. Among several materials used as biomaterials, titanium and its alloys prevails considering its appropriate properties such as: good ratio between density and mechanical properties, low thermal expansion coefficient, compatibility with human tissue and high corrosion resistance [5,6]. Despite its good properties as biomaterial, titanium alloys have poor tribological properties such as low wear resistance and high coefficient of friction [7].

Titanium prosthesis fabrication with powder metallurgy can be an economic alternative, taking into account parts with high precision and porosity control. This process must consider contamination with titanium stable oxides considering that they cannot be removed during manufacturing. Aiming to improve tribological performance, surface coating via physical vapor deposition is being used nowadays. Basically consists on substrate coating with more abrasive resistant material, and is mainly applied to orthopedic implants [8-10]. The objective of this work was to evaluate wear behavior of samples of Ti-40Zr alloys coated with multi-layer films of TiN and ZrN.

Wear volume, V, from material without coating, is related to sliding distance, L, and with contact normal force, N, by a wear model equivalent to the following Archard equation:

$$L \cdot N = \frac{V}{k} \quad (1)$$

where *k* is the material wear coefficient.

However, when there is a coating on the material, and each material has it own specific wear coefficient, Rutherford e Hutchings (1996) propose an extension of Eq (1) [11].

$$L \cdot N = \frac{V_c}{k_c} + \frac{V_s}{k_s} \quad (2)$$

where índex c and s are related to coating and substrate, respectively.

From Eq (2) is possible to establish wear coefficient values, both coating and substrate, by linear adjustment of data. Kusano et al. (2004) evaluated several methods aiming wear coefficient determination [12]. The best results were obtained by Eq.(2) rearrangement, dividing its terms on one hand by coating volume, Vc, and on the other hand by substrate volume, Vs, represented respectively by the equations (3) and (4):

$$\frac{S \cdot N}{V_c} = \frac{1}{k_s} \cdot \frac{V_s}{V_c} + \frac{1}{k_c} \quad (3)$$

$$\frac{S \cdot N}{V_s} = \frac{1}{k_c} \cdot \frac{V_c}{V_s} + \frac{1}{k_s} \quad (4)$$

Using this method, both the wear coefficients of coating, k_c, and substrate, k_s, can be determined in just one experiment, from the coefficients of linear adjustment of graphic SN/Vc against Vs/Vc or SN/Vs against Vc/Vs.

According to Trezona et al (1999) the usefulness of wear coefficient as abrasive wear measurement occur by direct proportionality between worn volume and sliding distance times loading[13].

Figure 1 shows schematically the cap geometry at microabrasive wear test with sphere of radius R. Parameters *t* and *h* are film thickness and total height of cap, respectively, and *a* and *b* are internal and external cap diameter.

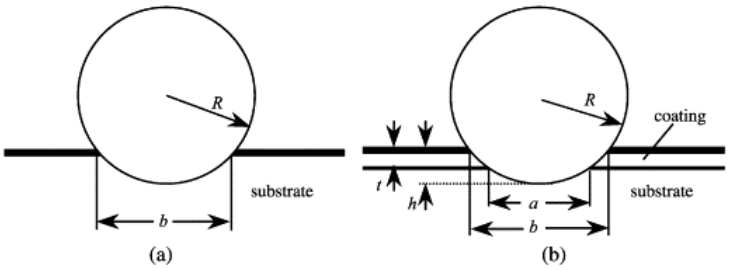

Fig. 1 – Schematic representation of cap geometry at microabrasive wear test with sphere of radius R: (a) uncoated and (b) coated material [12].

Worn volume calculation, either from coating or substrate, can be written either as a function either of external diameter, b, or internal diameter, a, and film thickness, by the following expressions:

$$V_c = \frac{\pi}{64R}(b^4 - a^4) = \frac{\pi t}{4}(a^2 + 4Rt) \quad (5)$$

$$V_s = \frac{\pi a^4}{64R} \quad (6)$$

Materials and Experimental Procedure

PVD coating

The raw materials for samples manufacture was produced by Brazilian Aerospace Institute by hydrogenation process. Titanium and zirconium powders where washed with organic solvent and

dried in air. Hydrogenation process occurred at 500 ^{0}C, in a high vacuum furnace, during approximately 3 hours. After cooling, friable material was blended under 0,23 Pa pressure at titanium grinder, aiming contamination avoidance.

Samples of Ti-40Zr alloys were obtained by blended- elemental technique (BE), from hydrogenated powders, followed by cold uniaxial pressure (with compaction pressure of 60 MPa during 30s), and cold isostatic pressure (pressure of 450 MPa and 30s) and vacuum sintering.

Samples dimensions were 12mm diameter and 3 mm thickness, with and without coating. All samples were grinded and polished before the film deposition process [14.15].

Coatings were carried out via physical vapor deposition by electron beam (EB-PVD), divided in three different experiments, aiming to evaluate the multi-layer films performance. Table 1 shows films coating process and the adopted nomenclature for each sample in this work. The evaporation containing Ti was carried out with current of 0,05 A and those with Zr with current of 0,15 A.

TABLE 1 – NOMENCLATURE ADOPTED FOR EACH COATING PROCESS

Sample	Coating Process
E1	Ti evaporation during 5 minutes + Evaporation of ($Ti+N_2$) during 20 minutes
E2	Ti evaporation during 5 minutes + Evaporation of ($Ti+N_2$) during 20 minutes + Evaporation of ($Zr+N_2$) during 30 minutes
E3	Ti evaporation during 5 minutes + Evaporation of ($Ti+N_2$) during 10 minutes + Evaporation of ($Zr+N_2$) during 30 minutes + Evaporation of ($Ti+N_2$) during 10 minutes

Microbrasive wear tests were carried out with a free sphere equipment CSM, model Calowear.

Normal loads were between 0,37 and 0,45 N (±0,001N) as showed at figure 2. The used sphere was steel 100Cr6, with diameter of 20mm. The abrasive slurry was silicon carbide suspension, with volumetric concentration of approximately 0,20 corresponding to 75g of abrasive in 100 cm^3 of distilled water.

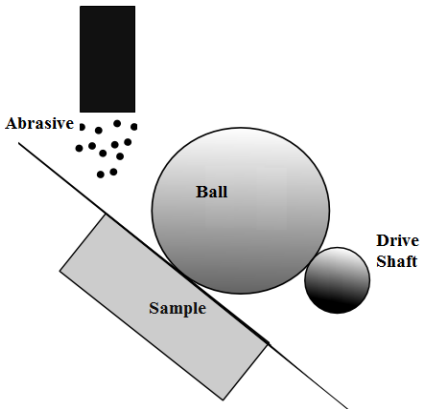

Fig. 2 – Schematic model of microabrasive wear [16]

Scanning Electron Microscopy

Scanning electron microscopy was carried out at samples cross sections aiming coatings thickness measurement. Samples were grinded and polished followed by ultrasonic washing with organic solvent during 30 min. Afterwards the samples were etched at acid solution (10ml of HF, 5 ml of HNO_3 and 85 ml of H_2O) in 30 s [19]. Coating thickness was measured with software installed at SEM

Cap wear was evaluated by scanning electron microscopy, using a FEI Quanta 450. Image of wear crater was collected using backscattered mode aiming to identify differences between atoms from different layer. Vickers microhardness was carried out with a Microhardness Tester FM 700 under 50, 100, 300 e 500 gf (0.49, 0.98, 2.94,4.9 N).

Results and Discussion

Vickers Microhardness

Vickers microhardness was carried out on samples with and without coating aiming to evaluate the performance of coated material. Table 2 shows average microhardness values for each load and its respective standard deviation. Figure 3 show graphically these values.

TABLE 2 – VICKERS MICROHARDNESS VALUES FOR EACH LOAD AND DEVIATIONS

Load (gf)	Substrate		E1		E2		E3	
	Aver.	Dev.	Aver.	Dev.	Aver.	Dev.	Aver.	Dev.
50	401,36	39,04	839,53	81,65	743,59	58,15	922,89	62,07
100	396,24	46,18	710,11	31,53	700,8	39,83	744,37	54,51
300	374,6	29,42	609,03	44,52	597,8	25,61	675,93	72,66
500	393,19	8,85	531,13	46,98	516,71	44,14	576,4	33,14

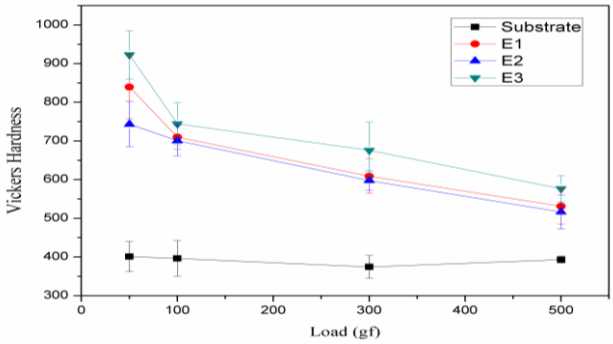

Fig. 3 – Vickers microhardness as function of load

Previous result for microhardness of Ti-40Zr alloy without coating is approximately 350 HV [17,18] and for pure Ti is between 90 and 160 HV. The alloy without coating has hardness values below all coated samples, regardless the used coating.

Comparing the coated samples, one can see that samples where TiN was the last coating (E1 and E3) have better performance at microhardness test. These results can be correlated to surface characteristics of ZrN coating. With load increase hardness values of coated samples has sharp decrease. This result can be correlated to increase of the depth reached by Vickers indenter [9].

Scanning Electron Microscopy

Medium silicon carbide particle size was around 4 μm, as can be seen in Figure 4.

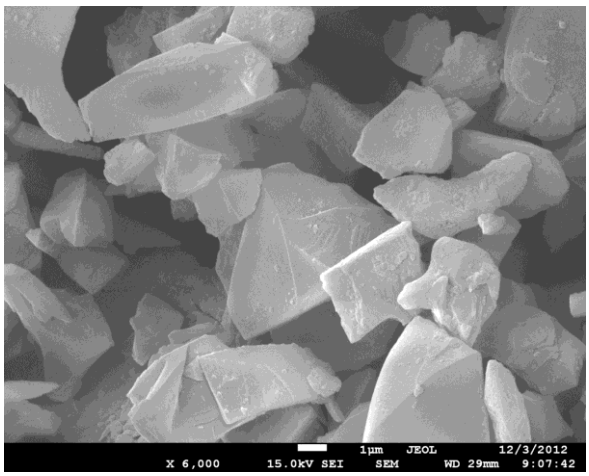

Fig. 4 - SEM image of SiC particles

Table 3 presents the average thickness values. Figures 5,6 and 7 show micrograph of samples cross sections used for films thickness measurements.

TABLE 3 – AVERAGE COATING THICKNESS

Sample	Average (m)	Standard Deviation
E1	2,45E-06	2,40E-07
E2	2,16E-06	9,64E-08
E3	4,91E-06	4,13E-07

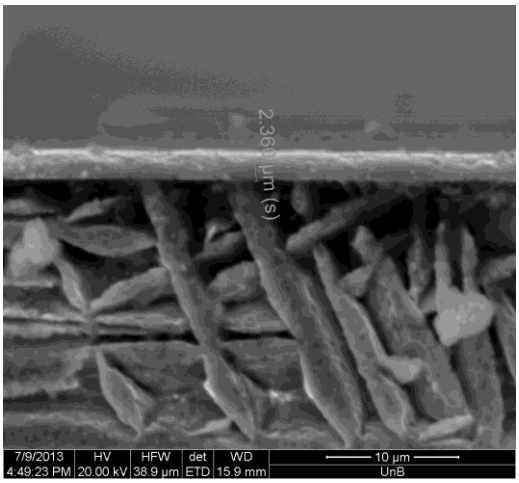

Fig. 5 – SEM of sample cross section of sample E1 with coating thickness measurement.

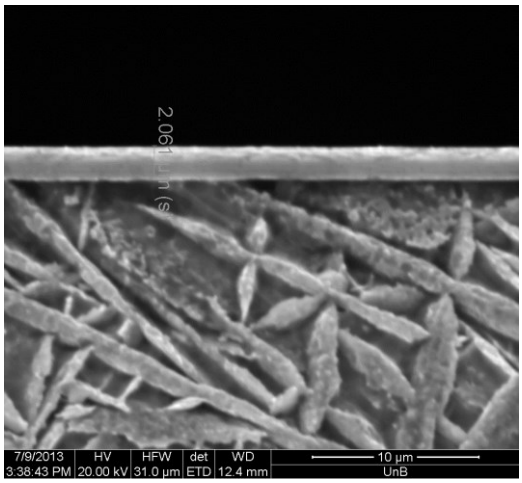

Fig. 6 – SEM of sample cross section of sample E2 with coating thickness measurement

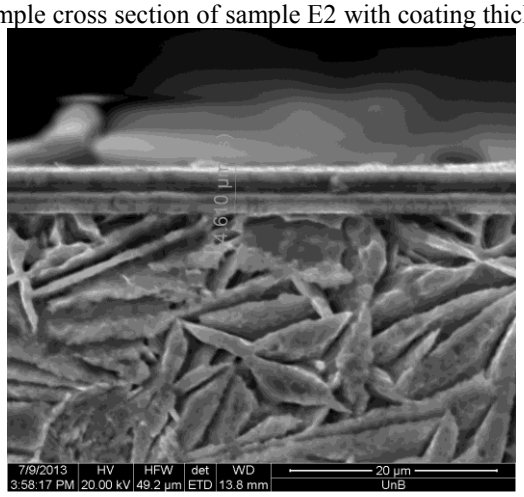

Fig. 7 – SEM of sample cross section of sample E3 image with coating thickness measurement

Figure 8 shows variation of wear crater diameter as a function of time of test, for coated material. It is possible to identify small variations at external and internal diameters. Such variations can be explained by the difficulty of accurate diameter measurements for this sort of experiments. Gee et al. (2003)[16]. Figure 9 shows image of external diameter and the region defined as “scuffing”,

where grooves around the edge of external crater of wear cause difficulties in diameter determination.

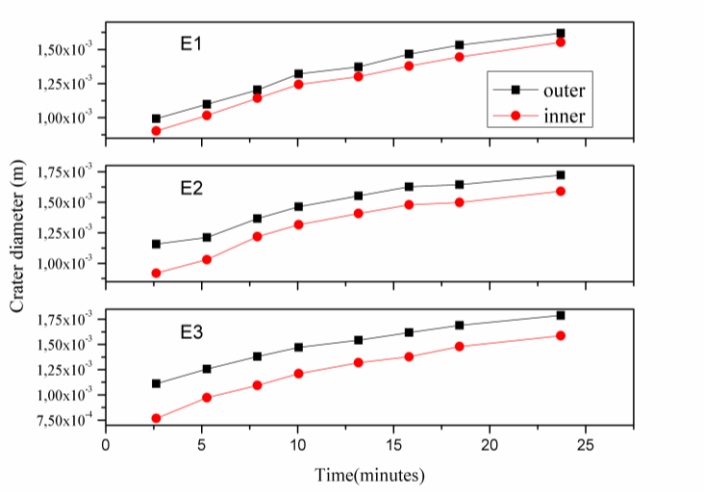

Fig. 8 – Evolution of wear crater diameter with test time.

For wear volume calculation, aiming reduction on edge effect, internal diameter values of wear crater has been used.

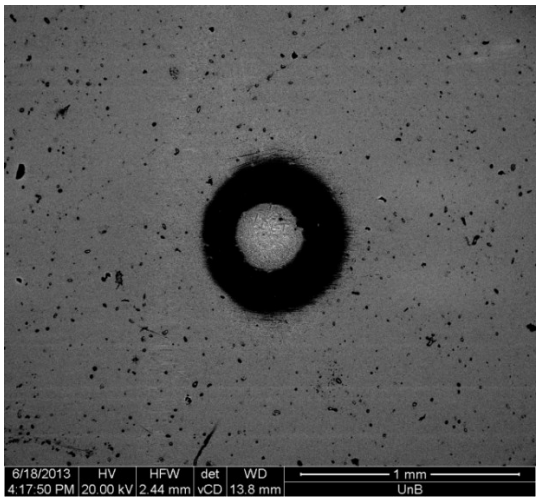

Fig. 9 – Edge effect of wear crater

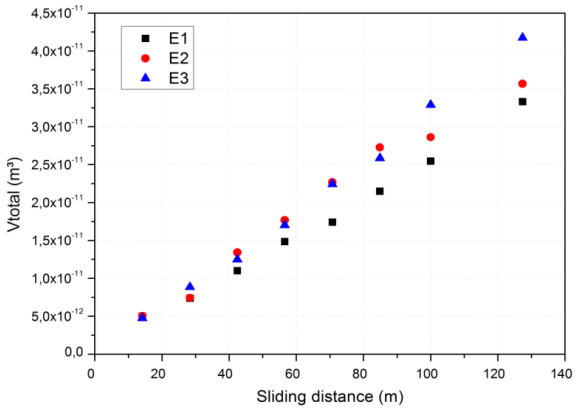
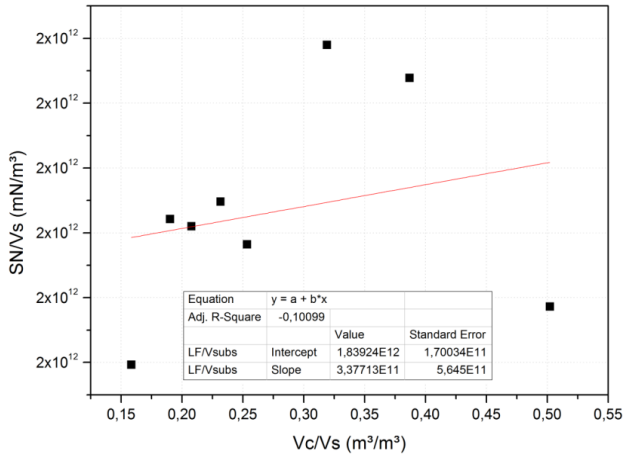
Figure 10 shows total wear volume as function of sliding distance. According Trezona et al. (1999) the linear behavior of this volume is indicative that the permanent wear regime was reached [13].





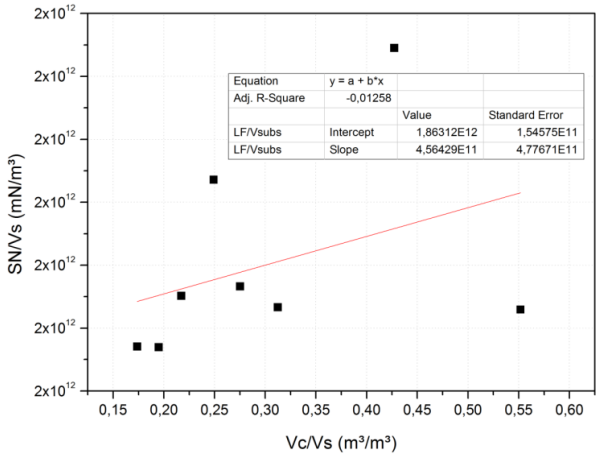


Fig.10 – Worn volume as function of sliding distance.

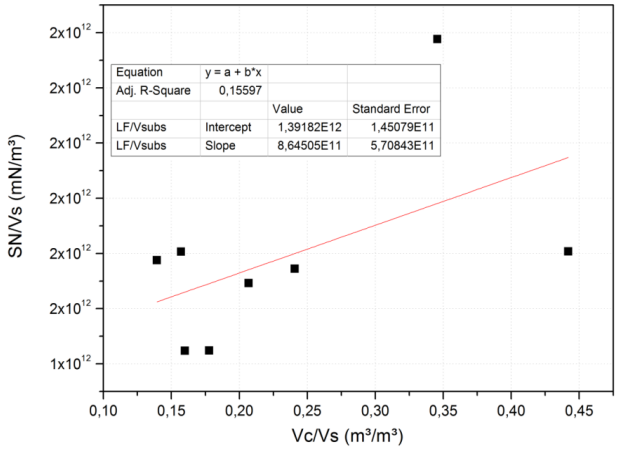
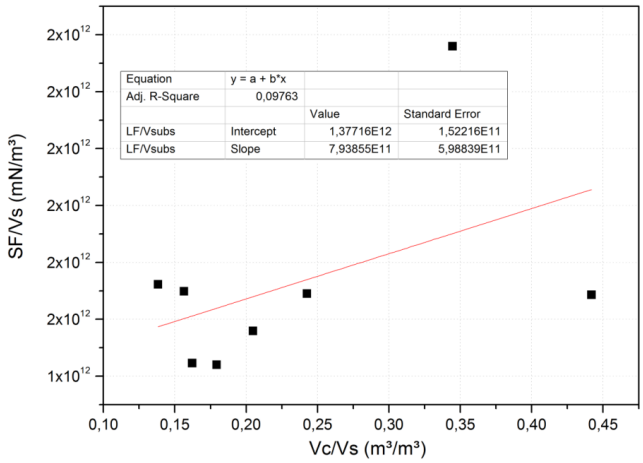
Figures 11 and 13 show the graphic SN/Vs against Vc/Vs, used to calculate wear coefficients k_c and k_s, according to Eq. (4).

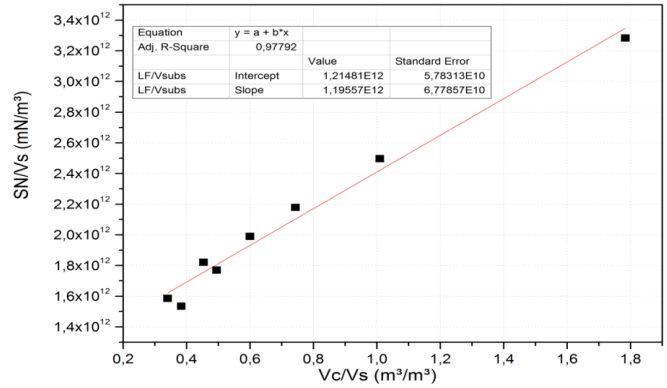


(a)

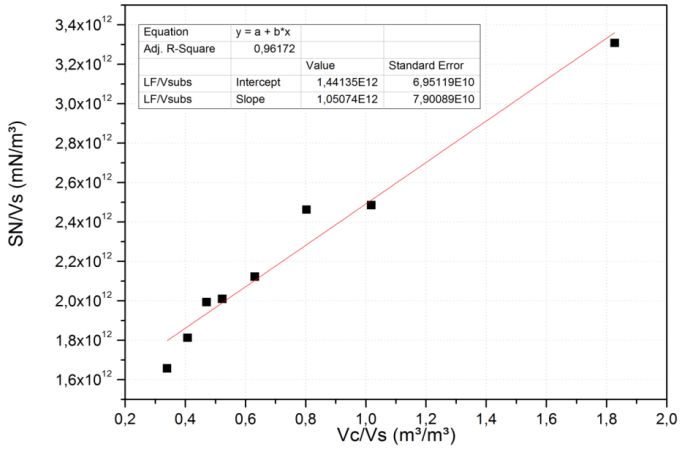


(b)

Fig. 11 – Graphic of SN/Vs against Vc/Vs for coating E1: (a) sample 1 and (b) sample 2



(a)



(b)

Fig. 12 – Graphic of SN/Vs against Vc/Vs for coating E2: (a) sample 1 and (b) sample 2

(a)

(b)

Fig. 13 – Graphic of SN/Vs against Vc/Vs for coating E3: (a) sample 1 and (b) sample 2

With these graphics it was possible the wear coefficient determination for coatings and substrate, according Table 4.

TABLE 4 – WEAR COEFFICIENT VALUES FOR COATINGS AND SUBSTRATE, FOR EACH SAMPLE.

Sample	**E1**		**E2**		**E3**	
	k_c	**k_s**	**k_c**	**k_s**	**k_c**	**k_s**
Sample 1	5,44E-13	2,96E-12	7,18E-13	1,16E-12	8,23E-13	8,36E-13
Sample 2	5,37E-13	2,19E-12	7,26E-13	1,25E-12	6,94E-13	9,51E-13
Average	5,40E-13	2,58E-12	7,22E-13	1,2E-12	7,58E-13	8,94E-13

In accordance with Table 4, all values of k_c were below the k_s values, although at sample E3 these values remained at the same order of magnitude. The biggest difference was at E1, where there is no ZrN coating.

For samples E2 and E3, where the coefficients values are nearer, there is ZrN coatings. Despite being a material with high hardness, the ZrN coating can generate residual stresses and, as a result, low-adhesion and lower wear resistance [8].

Another possibility is higher coating roughness of ZrN coating, lowering its tribological performance [20-22]

Conclusions

The titanium coating applied before deposition of nitride films contributed to coating good adhesion. All coated samples showed higher Vickers microhardness than the substrate without coating. Multilayer coating with high hardness, such those applied to E3 samples had better performance is this test, followed by samples E2 and E3. With the load increase, hardness values present reduction and become similar to substrate hardness, probable because the indenter cracks the coating for higher load.

Samples coating is effective to increase wear resistance of substrate, for silicon carbide abrasive. All coatings from this work showed wear coefficient lower than the measured in the substrate. For the different coated samples, those without ZrN showed lower wear coefficients. A possible explanation for this behavior is the existing residual stress between TiN and ZrN films. Additional evaluation using low angle X-ray diffraction can indicate these stresses.

Keywords: Self-assembly; Deposition; Composite films; Multilayer structure; Tribological property

Abstract: Self-assembled composite films of APTES-GA-APTES were successfully prepared on single-crystal silicon substrates through the cross-linking reaction between glutaraldehyde (GA) and two layers of 3-aminopropyltriethoxysilane (APTES). The optimal time to deposit the GA layer on the APTES monolayer was 3 h, during which most amino groups of APTES reacted with the aldehyde groups of GA to form smooth and uniform APTES-GA composite films. The further deposition of another APTES layer led to the generation of three-layer APTES-GA-APTES composite films. Compared to the APTES self-assembled monolayers, the three-layer films displayed a similar surface morphology but a reduced friction coefficient from 0.23 to 0.15 and an extended wear life from 50 s to 820 s due to the introduction of GA.

Introduction

Self-assembled monlayers (SAMs) have gained growing interest over the past few decades due to their effectiveness in improving the reliability and stability of the microelectromechanical systems (MEMS) by reducing friction and adhesion on the surface of the devices [1,2]. Silicon is the basically used material for most electromechanical components. However, silicon is not a good tribological material because of its high friction, adhesion and wear during sliding. Therefore, various types of SAMs have been constructed on silicon to improve their tribological properties [3-5], among which 3-aminopropyltriethoxysilane (APTES) SAMs have been extensively studied [6,7]. Nevertheless, despite the low friction coefficient, the APTES SAMs exhibit poor antiwear and load-carrying capacities, which will greatly limit their promising applications in the lubrication of MEMS [8].

The durability and load-carrying capability of the organic monolayers can be significantly enhanced by constructing self-assembled multilayer films [9,10]. The high activity of the amino groups (-NH_2) of the APTES molecules makes it possible to prepare APTES-based multilayer films by further chemically adsorbing another molecular layer onto the amino-terminated surface of the APTES SAMs [11-13]. In this study, glutaraldehyde (GA) was chosen for the first time as a cross-linker to prepare the APTES-GA-APTES composite films via the reaction between the amino and aldehyde groups. It is expected that the chemical bonding between GA and two layers of APTES would generate stable multilayer films with improved tribological properties as compared to the APTES SAMs.

Experimental Procedure

The preparation of APTES SAMs was performed according to the method reported in the literature [8]. Briefly, the P-type polished (100) Si wafers were sufficiently cleaned and then hydroxylated in a piranha solution (7:3 volume ratio of concentrated H_2SO_4 and 30% H_2O_2) at 90°C for 30 min. After being rinsed with distilled water and dried, the wafers were immersed in the freshly prepared toluene solution containing 1 mM APTES (99%, Sigma-Aldrich) for 30 min. Then, the wafers were taken out and ultrasonically washed, followed by thermal treatment at 100°C for 1 h to generate stable APTES

SAMs. Subsequently, the Si substrates modified by APTES SAMs were placed in an aqueous solution of 0.5% (w/w) GA for several hours. After being ultrasonically washed with distilled water and dried, the substrates were heat-treated at 100°C for 1 h to allow the formation of the dual-layer APTES-GA films. Finally, the three-layer APTES-GA-APTES films were obtained by immersing the APTES-GA films in 1 mM APTES-toluene solution and following the same procedure for the preparation of the APTES SAMs.

The surface morphology of the films was observed in tapping mode with an atomic force microscope (AFM, Nanoman VS), and their surface roughness was also evaluated. The chemical states of the elements on the film surface were detected by X-ray photoelectron spectroscopy (XPS, Thermo ESCALAB 250Xi). The tribological behaviors of the films were investigated in a ball-on-plate contact configuration using a tribometer (UMT-2MT). The films coated on silicon slid reciprocally against Si_3N_4 balls (φ 4 mm). The sliding speed, normal load and sliding distance were kept constant at 2 mm/s, 0.2 N and 5 mm, respectively. The friction coefficient-versus-time curves were recorded automatically.

Results and Discussion

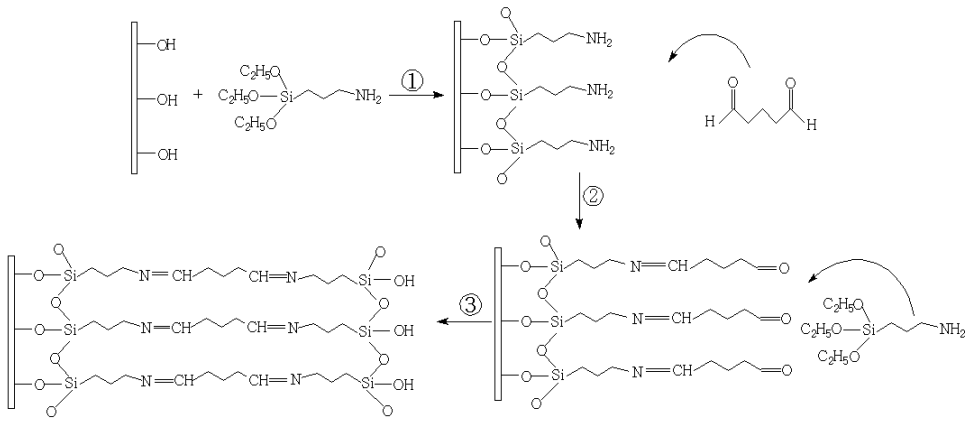

Fig. 1 Schematic diagram of the formation of the APTES-GA-APTES composite films.

Figure 1 schematically shows the formation of the APTES-GA-APTES composite films on Si (110) substrates. Firstly, the APTES SAMs were deposited on the silicon surface through a self-assembly process, as illustrated in step 1. Secondly, the GA layer was chemically grafted to the surface of the APTES SAMs via the reaction between the amino groups of APTES and the aldehyde groups of GA, which led to the formation of the APTES-GA composite films (Step 2). Finally, another APTES monolayer was chemically adsorbed onto the aldehyde-terminated surface and polymerized to attain the APTES-GA-APTES composite films (Step 3). In brief, a novel three-layer film of APTES-GA-APTES was successfully constructed on silicon through a multistep self-assembly process.

Figure 2 shows a series of AFM images taken at various deposition stages of films. It can be observed from Fig. 2(a) that the surface of the APTES SAMs were rough with an average roughness of about 0.951 nm over a scanning area of 10 × 10 μm^2. The film surface seemed still rough after reacting with GA for 1 h (Fig. 2(b)), whereas it became quite smooth and homogeneous after reacting for 3 h (Fig. 2(c)). However, a further prolongation of the reaction time to 5 h led to an increased surface roughness (Fig. 2(d)). The average surface roughness over a 10 × 10 μm^2 area was 0.657, 0.380 and 0.515 nm for the APTES-GA composite films obtained by reacting with GA for 1, 3 and 5 h, respectively. Therefore, it could be suggested that the best time to form the GA layer on the APTES monolayer was 3 h, during which most amino groups of APTES reacted with the aldehyde groups of GA to generate the APTES-GA films with the lowest surface roughness. When the reaction time was

further extended, the remaining GA molecules in the solution might be deposited disorderly onto the smooth GA layer via physical absorption, thereby increasing the surface roughness.

After reacting with GA for 3 h, the substrates were once again immersed in the APTES solution to prepare the APTES-GA-APTES composite films. As shown in Fig. 2(e), the films presented a similar surface morphology to the APTES SAMs (Fig. 2(a)), with the average roughness of 0.786 nm which was slightly lower than that of the APTES SAMs but higher than that of the APTES-GA composite films. These results indicated that a second layer of APTES was successfully formed on the Si substrates by self-assembly.

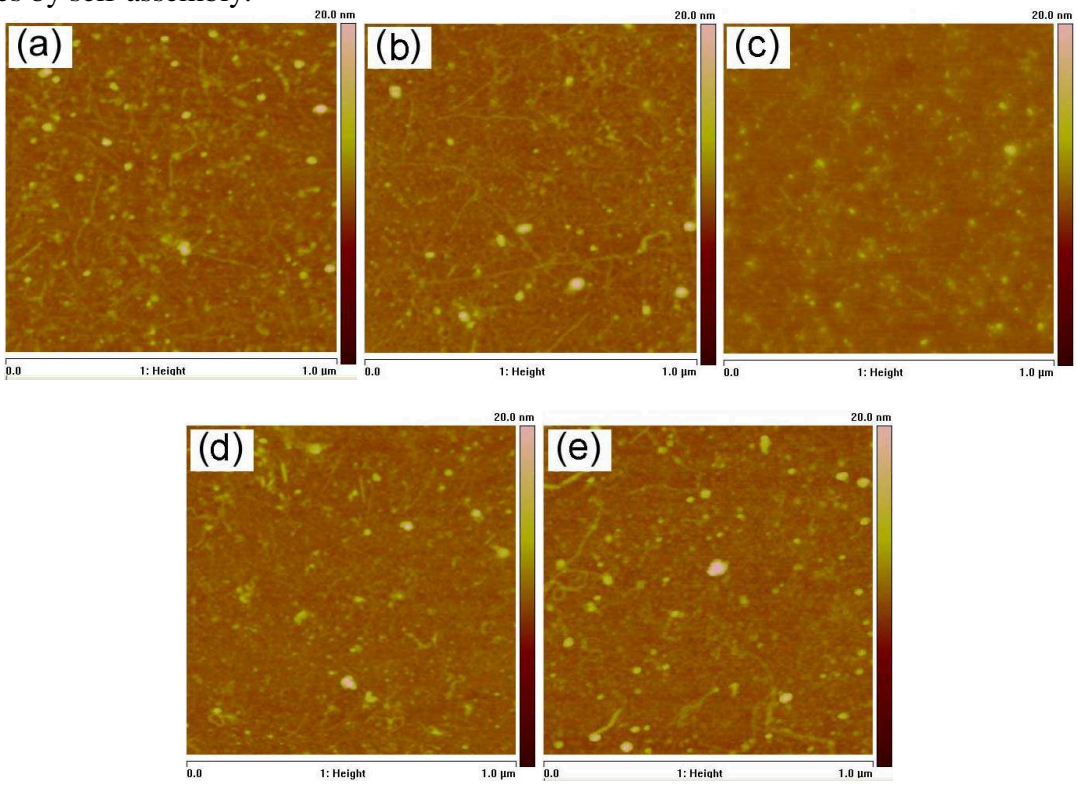

Fig. 2 AFM images of different types of the self-assembled films: (a) APTES SAMs; APTES-GA films obtained by reacting with GA for (b) 1 h, (c) 3 h and (d) 5 h; (e) APTES-GA-APTES films.

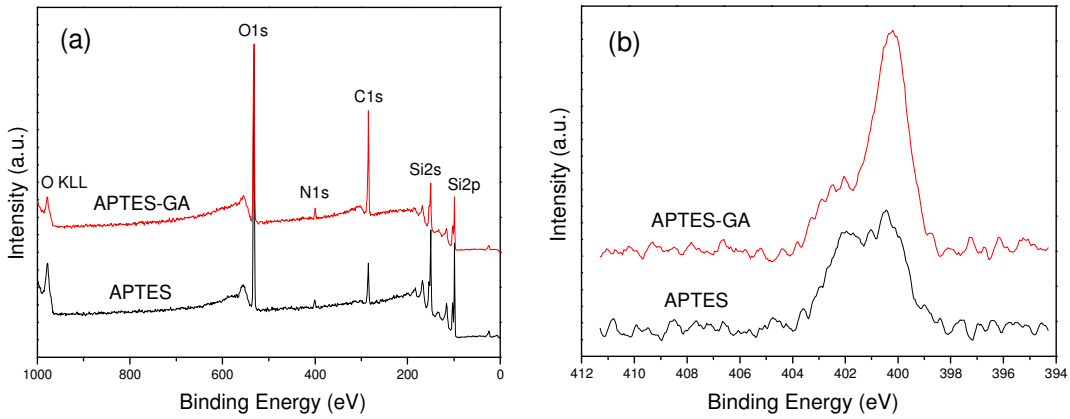

Fig. 3 XPS spectra of APTES SAMs and APTES-GA films: (a) survey scan and (b) N1s regions.

The XPS spectra of the APTES SAMs and APTES-GA composite films were presented in Fig. 3. It could be found in Fig. 3(a) that, except the intensity increase of the C1s and O1s peaks, the APTES-GA composite films displayed almost the same spectrum with the APTEM SAMs. This was because the deposition of the GA layer on the APTES SAMs did not introduce any new elements, but enhance considerably the contents of the C and O elements existing in the films. Furthermore, with the formation of the GA layer on the APTES SAMs, three peaks of N1s positioned at approximately

400.4, 401.0 and 402.0 eV were replaced by a single strong peak at 400.1 eV corresponding to the C=N bonds [14] (Fig. 3(b)). It was inferred that most amino groups remaining on the APTES SAMs had formed a Schiff-base linkage with the aldehyde groups of GA.

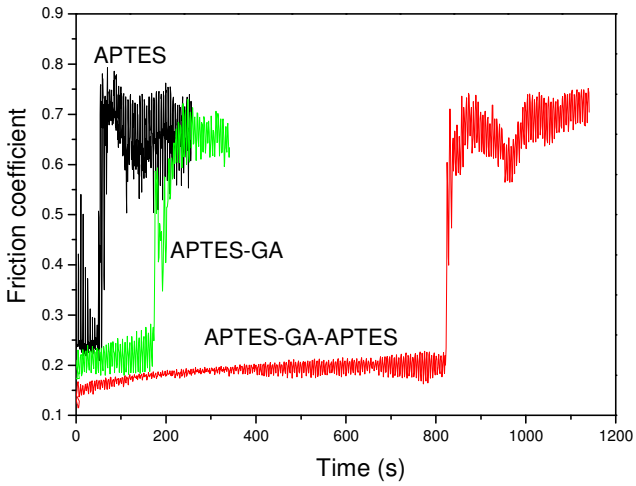

Fig. 4 Curves of friction coefficient vs. time for different types of self-assembled films.

The friction coefficient versus time curves of the self-assembled films were illustrated in Fig. 4.

It was assumed that the lubrication failure of the films occurred when the friction coefficient rose abruptly to a stable value of about 0.7 (a typical value of friction coefficient for the silicon wafer). As shown in Fig. 4, the APTES SAMs revealed a low friction coefficient of ~0.23, but they were easily destroyed in ~50 s under a load of 0.2 N. After being modified with GA, the APTES-GA films exhibited a friction coefficient of about 0.20 and an antiwear life about 170 s, slightly superior to the APTES SAMs. Furthermore, the APTES-GA-APTES composite films displayed a greatly improved tribological properties characterized by a much lower friction coefficient of about 0.15 and a greatly longer antiwear life over 820 s, as compared to both the APTES SAMs and the APTES-GA films.

The remarkable increase in the wear-resistance ability of the APTES-GA-APTES films might be mainly correlated with their stable multilayer structure. As discussed above (Fig. 1), the APTES-GA-APTES films were formed by the cross-linking reaction of GA with the two layers of APTES. Thus, the interlayer combinations of the films as well as the adhesion to the Si substrates were all accomplished by the chemical bonding, which will contribute to the enhancement of the mechanical stability and wear-resistance capacity of the films. In addition, the multilayer structure of the APTES-GA-APTES films permitted the transfer of the films from the Si substrates to the surface of the Si_3N_4 balls after the outer APTES layer was destroyed. It was desirable that the transfer film efficiently improve the tribological properties of the films by reducing the friction and wear.

Conclusions

In this study, a multistep self-assembly strategy was proposed to deposit the APTES-GA-APTES composite films on the single-crystal silicon substrates via the reaction between the amino and aldehyde groups. The composition, morphology and tribological properties at various stages of the film preparation were investigated. The results showed that the APTES-GA dual-layer films with a smooth and uniform surface were obtained after depositing the GA layer for 3 h. The further deposition of another APTES layer led to the generation of the three-layer APTES-GA-APTES composite films which displayed a similar surface morphology to the APTES SAMs. Moreover, as compared to the conventional APTES SAMs, the three-layer films possessed a greatly improved tribological properties characterized by a much lower friction coefficient and a greatly longer antiwear life, thus potentially more suitable for the MEMS applications.

Keywords: 2A12 Aluminum Alloy, Corrosion Protection, Silane Film, Surface Treatment

Abstract: The protective silane film BTSPS was prepared on the surface of 2A12 aluminum alloys by dip-coating method in this paper. The influence factors such as the volume fraction, hydrolysis time, hydrolysis temperature and dip-coating time of BTSPS were studied through orthogonal experiment. The optimum conditions is: the volume fraction is 5%; hydrolysis time is 180min; Hydrolysis temperature is 20℃; Dipping time is 10 min. The silane film performance was investigated by electrochemical test, sodium chloride solution immersion and scanning electron microscope (SEM). The results show that the corrosion resistance of the 2A12 aluminum alloy coated with BTSPS is improved greatly.

Introduction

The 2A12 aluminum alloy is a kind of high-strength aluminum alloy.It is extensively used in making all kinds of parts that can support high load and components (but not including stamping forgings),such as the frame part,skin,frame,ribs,wing beam,rivets and other parts which work under 150℃.However,its corrosion resistance is weak, so its surface must be pretreated before application generally. Traditionally, industrial phosphating and chromate passivation process was applied in large-scale . Although the anticorrosion effect by such a pretreated process is good, but it will cause serious environmental pollution problems .

With the improvement of the public awareness of environmental protection and environmental requirements , the development of environment -friendly metal surface pretreatment and corrosion protection technology instead of the traditional phosphating and chromate passivation process has become more and more urgent. Organosilane treatment is a new type of surface protection technology compared with traditionally Large-Scale application of phosphating and chromium passivation process. It has the advantages of energy-saving, environment friendly, and low cost. However,the silanated effect is not as well as phosphating and chromate passivation currently.

Therefore,how to study the best film-forming process of the silane processing completely instead of toxic and hazardous phosphide chromate passivation process has very important significance.

The studies[1,2,3,4] showed that the dual silane has a greater advantage in the protection of the metal.This paper chose bis-[3-(triethoxysilyl)propyl]tetrasulfide (BTSPS),and the formula is $(H_5C_2O)_3Si(CH_2)_3S_4(CH_2)_3Si(OC_2H_5)_3$, it can inhibit zinc, aluminum and its alloy[5,6], magnesium [7], copper, galvanized steel[8], hot dipping steel[9] and all kinds of metal corrosion. Although some literatures have researched on BTSPS[10~11], but did not introduce the hydrolysis process and the film-forming process.

This article obtained the optimum conditions for BTSPS film preparation on the 2A12 aluminum alloy surface .The results show that it presents good anticorrosion performance throughout the experiments and corrosion test.

Experimental

Materials

Silane coupling agent(BTSPS), used as coupling agent in the research, was purchased from Anhui Xiangfei Lipai Organosilicon New Material Co., Ltd.,China. acetone(analytically pure), supplied by Beijing north Fine Chemicals Co., Ltd.,China,was used as oil cleaning agent.deionized water(homemade),Anhydrous ethanol(analytically pure),supplied by Tianjin Tiantai Fine Chemicals Co., Ltd.,China,was used as the solvent for dissolving silane. Sodium chloride solution and all other chemicals used were of analytical reagent grades.

Instruments

DDS-11 Conductivity Meter,used for measuring the electrical conductivity of silane solution,were obtained from Tianjin second analytical instrument factory, China.DF-101S Collector-type magnetic stirrer was purchased from Jintan Scientific Analytical Instruments Co., Ltd.,China. 501 super thermostat,supplied by Shanghai Experimental Instrument Co., Ltd.,China.KH-700B CNC ultrasonic cleaning instrument was purchased from Kunshan Hechuang Ultrasonic Instrument Co., Ltd.,China.CHI-660D electrochemical workstation was purchased from Shanghai Chen Hua Co., Ltd.,China.DZF-6050 vacuum oven supplied by Shanghai JingHong Experimental Equipment Co., Ltd.,China.And some other commonly used laboratory instruments.

Experimental Procedure

2A12 aluminum alloy surface pretreatment.Concrete steps: polished by fine sandpaper→washed twice with distilled water→ultrasonically cleaned in acetone(65 to 70℃,10min)→ultrasonically cleaned in methanol(60 to 65℃, 15min)→washed twice with deionized water
→drying with vacuum oven→reserve.

Preparation of silane films by the dipping method. Aluminum alloy specimen fully immersed into the hydrolysis of the silane solution,uniform velocity ,removed after a certain time,residual liquid dried by hair dryer,placed it in a vacuum oven, curing and forming.

The hydrolysis solution configurated by BTSPS,ethanol,deionized water with the proportion of 5:5:90, and fully stired 3h in the collector magnetic stirrer, the electrodes of the conductivity meter is inserted into the hydrolysis solution, and detected the conductivity of the solution online. Then the metal substrate is immersed in the hydrolysis solution with 6 min, 8 min, 10 min, 12 min and 14min respectively. The polarization resistance values of each group have been tested by electrochemical workstation.

Results and discussion

The Experimental Results to Discuss.

The Impact of BTSPS Volume Fraction and the Hydrolysis Time

As shown in Fig. 1, when BTSPS volume fraction is 1~5%, hydrolysis time is 2~4h, the conductivity of solution no longer changes, indicating that the solution has stabilized; and when the volume fraction is 7~9%, the conductivity is still changing after it reaches the maximum value, indicating that the solution is unstable. Therefore, in the BTSPS hydrolysis process, the volume fraction should be between 1~5%, and the hydrolysis time should be 2~4h.

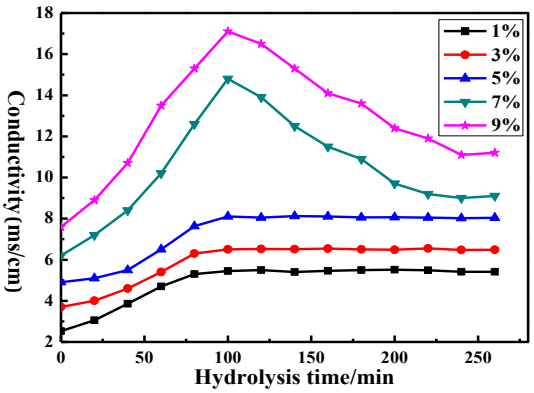

Fig.1 Variation diagram of conductivity with time under different BTSPS volume fraction

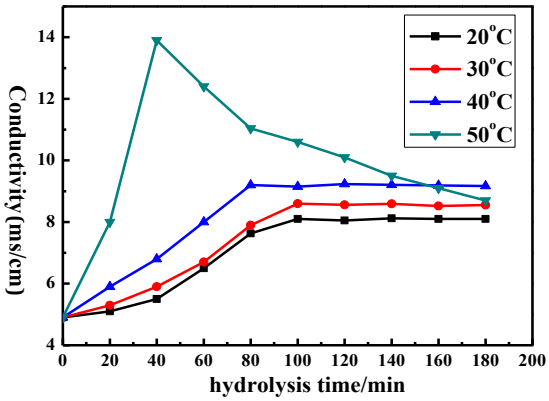

Fig.2 Variation diagram of conductivity with time under different hydrolysis temperature

The Impact of Hydrolysis Temperature

As can be seen from Fig. 2, the higher temperature, the shorter time to achieve the highest conductivity value, but when the temperature was 50℃, the solution is very unstable. And when the temperature is 20~40℃,the solution basically stabilizes after hydrolysis time is more than 2h. Therefore, in the BTSPS hydrolysis process, the optimal hydrolysis temperature should be from 20℃ to 40℃.

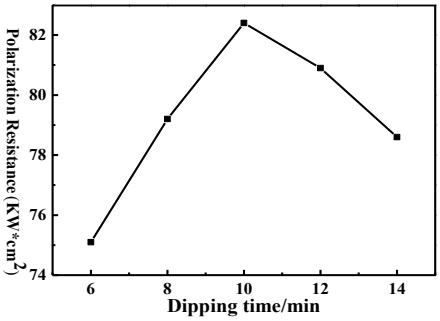

Fig.3 Variation diagram of polarization resistance with dipping time

Dipping Time of the Substrate in BTSPS Solution

As can be seen form Fig. 3, when the dipping time is 8min, 10min and 12min,the anticorrsion effects of the silane films prepared is better than the other two groups. Therefore, in the process of BTSPS film, the optimum dipping time for the metal material in the hydrolysed solution is 8~12min.

Orthogonal Analysis

The analysis results using by the orthogonal experiment software were shown in the following table

TABLE 1 ORTHOGONAL EXPERIMENTAL DESIGN

Factors / E[n]	The silane Volume Fraction[%]	Dipping Time[min]	Hydrolysis Temperature[℃]	Hydrolysis Time[min]	The Experimental Results
E1	1	8	20	60	72.9
E2	1	10	30	120	78.2
E3	1	12	40	180	85.2
E4	3	8	30	180	104.5
E5	3	10	40	120	128.3
E6	3	12	20	60	120.3
E7	5	8	40	120	100.1
E8	5	10	20	180	105.6
E9	5	12	30	60	112.8

MV 1	145.433	159.168	336.933	70.333	
MV 2	217.700	274.700	197.500	99.533	
MV 3	375.833	205.100	104.533	269.300	
ED	258.133	155.533	232.400	170.800	
E:Experiment		MV: Mean Value		ED: Extreme difference	

As can be seen from the table 1, the sequence of influence on the performance of the BTSPS film is: the volume fraction of BTSPS>hydrolysis temperature>hydrolysis time>dipping time.

By the mean size can be seen:

The Best Volume Fraction of BTSPS is 5%

If the volume fraction of BTSPS is too low, the silane molecule adsorbed on the aluminum alloy surface will be few,the film thickness will be thiner, the corrosion resistance of the obtained silane film is poor.

The Best Dipping Time is 10min

The dipping time is shorter, the film formation time is shorter and film corrosion resistance is poorer; The dipping time is longer, it will not increase the corrosion resistance of the film, instead it will deteriorate the performance of the film.

The Best Hydrolysis Temperature is 20℃

The hydrolysis reaction of BTSPS is an exothermic reaction, the condensation is an endothermic reaction, if the temperature is too high, it will inhibit the hydrolysis reaction and promote the condensation reaction. Thereforea lot of silane condense silicone that is not conducive to formate the silane film.

The Best Hydrolysis Time is 180min

If the hydrolysis time is too short, and the number of silanols in the hydrolysis solution will be few, the formed film will be thin, and the corrosion resistance of film is poor.

The Corrosion Resistance of Silane Film on the Substrate Surface

Electrochemical Tests

The substrates were used as working electrode, a saturated calomel electrode(SCE) and a platinum mesh were used as the reference and counter electrodes respectively. and electrochemical tests have been conducted using the integrated test system for electrochemical workstation.The eletrolytic solution is a solution of 3.5% NaCl (mass fraction); the scan rate applied here was 10 mV/s; the sample test area approximately 6 cm^2.

First of all, the resulting polarization curves were used for qualitative analysis using the logarithmic of corrosion current density lg(i_{corr}, A/cm^2) as Ordinate and the corrosion potential (E_{corr}, mv) as abscissa.

As can be seen from Fig.4 that the polarization curves of black experimental group have been moved to the right significantly, and show that the corrosion resistance of the material of the experimental group improved greatly than blank group[12].

Then, the polarization resistance value obtained using an electrochemical test software is used to quantitative analysis the corrosion resistance of material coated with BTSPS film. The polarization resistance value obtained in experimental group is 156.8KΩ·cm^2, and the polarization resistance value of blank group is 1.9KΩ·cm^2, the polarization resistance of experimental group is 82 times of blank group. It's show that the corrosion resistance of material in the experimental group have been improved greatly.

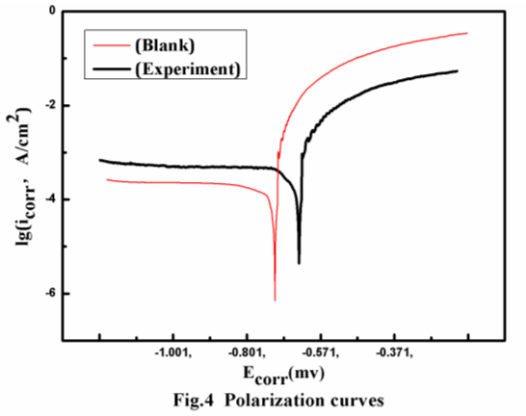

Fig.4 Polarization curves

Fig. 5 Effect diagram of experimental samples were soaked

Immersion Test

Researchers often used seawater or sodium chloride solution immersion test in the study of metal protection intuitive to understanding of the corrosion resistance of the materials[13]. The experimental samples were soaked in 5 mol/L sodium chloride solution for 7 days in this work. As shown in Fig. 5.

In Fig 5, the left part of the aluminum plate was coated with a silane film, while the right part of baseplate was uncoated. It can be seen that the corrosion of the right part of the baseplate was obvious, while that of the left part was slight after soaked in sodium chloride solution, This indicates that the silane film can significantly enhance the corrosion resistance of aluminum alloy.

Detection of SEM

In order to further describe the corrosion resistance of the experimental group of material qualitatively, blank and experimental groups material before and after the immersion test were observed by SEM. As shown in Fig. 6.

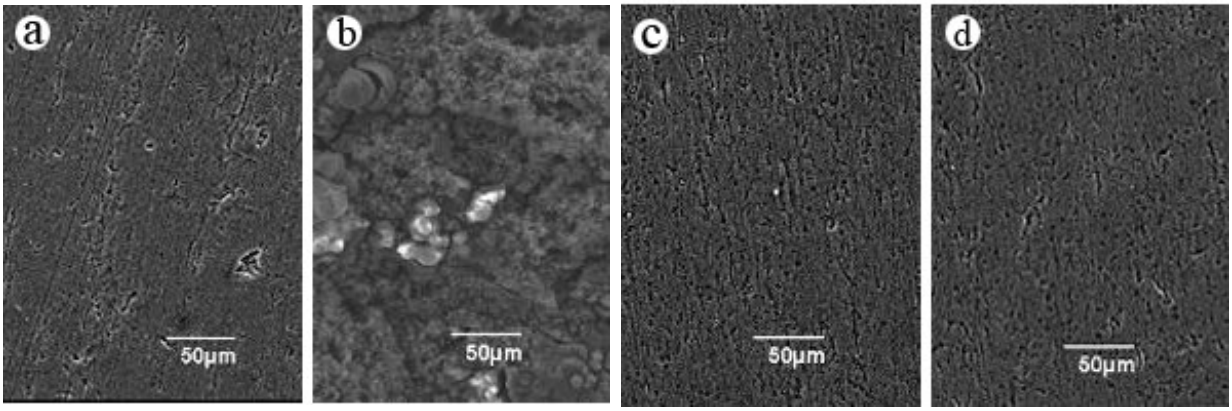

Fig.6 SEM Images

In Fig. 6, Fig. a and Fig. b represent the blank group before and after immersion test respectively, and Fig. c and Fig. d represent the experimental group before and after immersion test respectively. Compared fig. a with fig. c, it can be seen that the surface of material exist scratches and small gaps before treated with the silane; while become smooth and uniform after treated with the silane. In fig. b, the surface of the blank group have been damaged severely after immersion with 7 days; but fig. d shows that no significant changes on the surface of the experimental group before and after the immersion test.

Conclusions

The following conclusions obtained through the above experiment:

Obtained BTSPS hydrolysis conditions after conductivity experiment:the volume fraction is 1%~5%; hydrolysis time is 2~4h; hydrolysis temperature is 20~40℃.

The single-factor tests of BTSPS film dipping time result show that the dipping time is 8~12 min.

The optimum conditions for preparation of BTSPS film obtained through orthogonal experiment: the volume fraction is 5%; dipping time is 10 min; hydrolysis temperature is 20℃; hydrolysis time is 180min.

After electrochemical test,immersion test and SEM experiment,We can see BTSPS film prepared under the optimum conditions rapidly improved the corrosion resistance of the material.

Keywords: beeswax-chitosan latex, water vapour transmission rate, contact angle

Abstract: Both water repellency and water vapour barrier properties were endowed at paper surface by coating with beeswax-chitosan latex. It was found that the water vapour transmission rate of coated paper decreased as the drying temperature increased. However, water contact angle was not affected with it. Although the surface morphology deformed at high drying temperature, the roughness values maintained at micro-scale. Further analysis indicated that the water vapour barrier property of coated paper was influenced by the density of the coating layer.

Introduction

As a natural, biodegradable and renewable polymer, chitosan exhibits excellent film-forming properties. Chitosan possesses good mechanical properties, thus its film is tough, long-lasting, flexible and difficult to tear. More than that, excellent gas-barrier (such as oxygen, nitrogen, carbon dioxide[1]) properties are found in chitosan film due to its high crystallinity and hydrogen bonds between the molecular chains[2, 3]. However, because of the same polar groups, chitosan film easily absorbs water or water vapour and the swelled film leads to a loss of the gas barrier properties. Studies of chitosan coatings on paper and paperboard revealed an improved moisture barrier properties but not sufficient for food application[4]. The hydrophilicity of coating surface was too high that its water sorption was found to be greater than the fibre sorption in the base paper[1].

A feasible approach to improve the water or water vapour barrier properties is to combine hydrophobic lipid materials to form composite films in a form of emulsion coating or bilayer coating. Although the water vapour barrier ability of bilayer coating is superior to that of emulsion coating, the later shows better adhesion onto any substrate due to its hydrophilic and lipophilic nature[5]. The coating process can also be carried out at room temperature, which can be applied on fruits and vegetables to extend shelf lives[6].

The objective of this study is to investigate the abilities of water vapour barrier and water repellency of emulsion coated paper. It is the first time to produce beeswax-chitosan latex with beeswax composition over than 90 wt% in the final solid coating layer, so that both high water repellency and water vapour barrier properties are obtained.

Experimental Details

Preparation of Beeswax-chitosan Latex

Beeswax-chitosan latex was produced by melting beeswax (Aldrich, Canada) in chitosan (Aldrich, Canada) solution (glycerol : chitosan = 1:4 in weight ratio) under acidic conditions at 80 ^{o}C. After stirring with magnetic stirrer for 5 min, each mixture solution was homogenized using a high-shear probe mixer (Power Tool X120, Ingenieurbüro CAT, Germany) for 3 min at 28,000 rpm. Upon completion of homogenization, the hot beeswax-chitosan latex was quickly cooled to room temperature in an ice-bath.

Paper Surface Coating

Copy paper (Xerox Corporation, Canada) was coated with beeswax-chitosan latex using K303 Multilayer (RK Print Coat Instruments Ltd, U.K.) with a bar coating speed of 10 m/min and then dried at different temperatures for 2 h.

Characterization

The particle size of beeswax-latex was tested using Brookhaven ZetaPlus zeta potential analyser. The paper weight and thickness was measured before and after coating, respectively. The water repellency was characterized by water contact angle using Attension Theta Optical tensiometer (Finland) and the water vapour barrier property was measured by water vapour transmission rate (WVTR) on IGA-003 (Hiden-Isochema, Warrington, UK) according to TAPPI standard T464 om-12[7]. The morphology of coated paper was determined using AFM (Nanoscope IIIa from Veeco Instruments Inc., Santa Barbara, CA) with a silicon tapping probe (NP-S20).

Results and Discussion

The Effect of Drying Temperature

Under acidic condition, chitosan was considered to be a good emulsifier to prepare stable lipid latex, because of the interaction between positively-charged chitosan with negatively-charged lipids[8]. The particle size of beeswax-chitosan latex ranged from 150 nm to 650 nm and phase separation occurred after standing for more than ten days. This stability of beeswax-chitosan latex was good enough for paper surface coating. The viscoelastic beeswax was proved previously to be more effectively to reduce water vapour permeation (WVP) than carnauba and candelilla wax in whey protein/lipid emulsion film, and the WVP decreased as the fat concentration increased. Here, beeswax composition of the final coating layer was set as high as 96 wt% to investigate the effect of drying temperature on water contact angle and WVTR of coated paper.

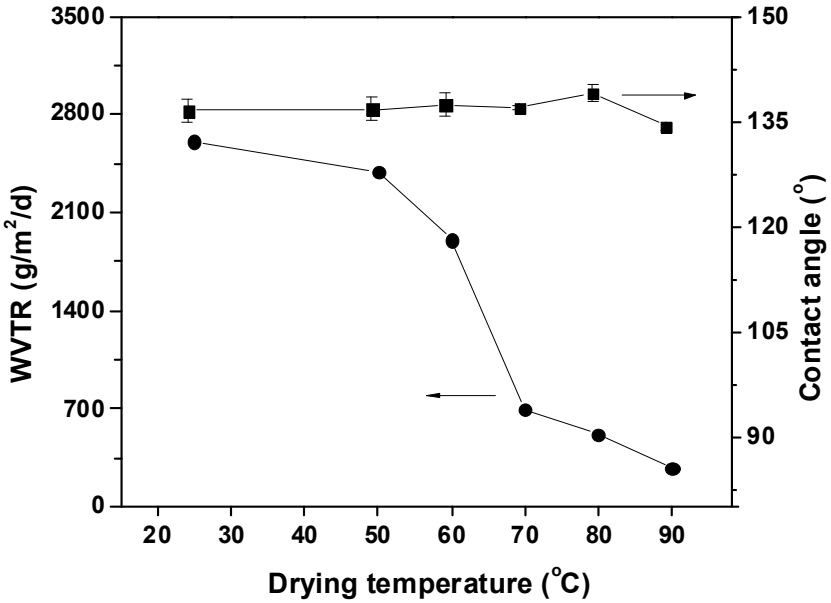

Figure 1. The effect of drying temperature on WVTR and contact angle of chitosan-beeswax coated paper. The beeswax latex was prepared by 1.2 wt% chitosan solution and beeswax composition in the coating layer was 96 wt%.

As seen in Fig. 1, the drying process after coating influenced the water vapour barrier property strongly. The WVTR of latex coated paper reduced from 2610.6 to 273.6 g/m^2/d as the drying temperature increased from 25 to 90 ^{o}C. The degree of viscoelasticity of lipids determined water

vapour resistance property as those viscoelastic lipid droplets might deform, merge and aggregate into network of lipids within the emulsion film[9, 10]. This viewpoint was also certificated by the sharp drop in the WVTR of beeswax-chitosan emulsion coated paper at around 60 °C which was exactly the melting point of beeswax. With drying temperature larger than 60 °C, the enhancement of reduction in WVTR became moderated. An interesting discovering is that the water contact angle of latex coated paper seemed to be almost unaffected by drying temperature, with value of approximate 135°. Since the chemical composition of this surface was same, it could be concluded that surface morphology might be changed slightly during drying process.

Surface Morphology

The AFM height images of different drying temperatures were obtained in an area of 15×15 μm in Fig. 2. Individual beeswax particles distributed over the entire scanning area in the samples dried at room temperature. As the drying temperature increased, beeswax particles began to partially melt to form larger agglomeration. When the drying temperature was higher than its melting point, beeswax particles melted completely to form annular-folds at the surface. The roughness values, Rq, of the beeswax-chitosan coated papers were 614, 876, 969,642, 611, 540 nm, corresponding to drying temperature of 25, 50, 60, 70, 80, 90 °C, respectively. The Rq fluctuated within micro-scale, indicating that the area fraction of the liquid-solid contact was likely unchanged according to Cassie-Baxter model[11] for determining surface wettability.

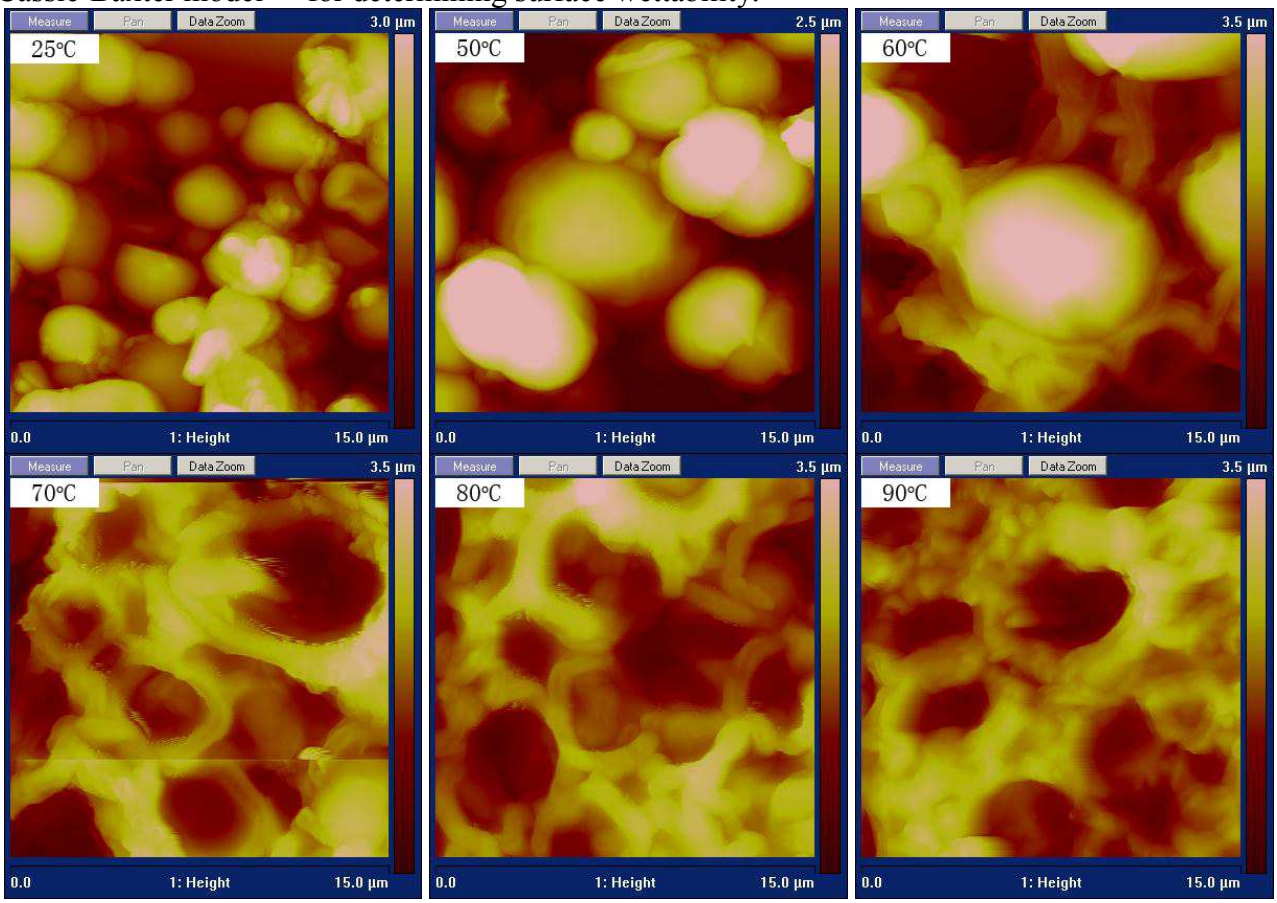

Figure 2. AFM measurements of beeswax-chitosan coated papers at various temperatures.

The Effect of Coating Layer Density

It is a fact that the final barrier properties of coated paper is affected by chitosan concentration, beeswax composition and drying temperature. An indirect factor, coating layer density which was calculated based on the coating weight and thickness, was used to combine these three direct factors together. An interesting relationship between WVTR and density of coating layer was found in Fig. 3. When the density was lower than about 800 kg/m^3, the water vapour resistance property of coated

paper was almost unchanged compared to blank paper. After the turning point, increasing the density of the coating layer correlated with a linear decrease in WVTR of coated paper. The surface and internal structural reconfiguration of beeswax led to the formation of more compact structure which lowered water vapour permeability.

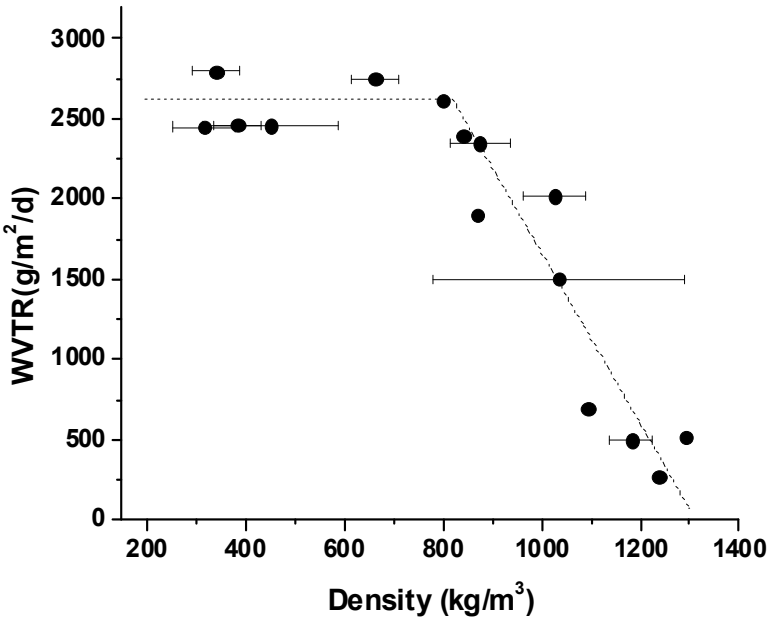

Figure 3. The relationship between WVTR and density of composite coating layer

Conclusion

Hydrophobic paper with low WVTR and high water contact angle was prepared by coating with beeswax-chitosan latex in this study. Water vapour barrier property of emulsion coating was improved through increasing lipid content and drying temperature. It could be explained by deformation and aggregation of lipid within and without of the emulsion coating layer. Although the surface morphology changed, the roughness values fluctuated within micro-scale, which limited the enhancement of water repellence property.

Keywords: magnesium alloy, Corrosion resistance, conversion coatings

Abstract. The conversion coating formed by immersion in a solution containing cerium salt on ZM5 magnesium alloy was studied and the corrosion resistance was evaluated as well. These micrographs of specimen surface were investigated by metallographic microscope. The corrosion behaviors of ZM5 magnesium alloy and conversion coating were assessed by means of potentiodynamic polarization curves and immersion tests. The experimental results indicated that a yellow-brown conversion coating was formed subsequently on the specimen surface. The results of electrochemical measurements and immersion tests revealed that the cerium conversion coating possessed better corrosion resistance than the substrate. In this study, cerium conversion coatings formed on ZM5 magnesium alloy were characterized and the formation mechanism was discussed.

Introduction

Magnesium alloys have quite special properties which lead to specific applications. The high strength-to-weight ratio of magnesium alloys makes the alloys extremely attractive for applications requiring light weight, such as applications in transport and aerospace. However, magnesium alloys are still not as popular as aluminum alloys because of their poor corrosion resistance. So, some sort of surface treatments or coating treatments should be applied to magnesium alloys in order to meet the requirement in practical applications.

Among various surface treatments, chemical conversion treatments for magnesium alloys， for example chromate[1], permanganate-phosphate[2], stannate[3], vanadium[4], organic baths[5], phytic[6] and cerium[7], were extensively investigated. The most successful conversion treatment is based on the use of chromates, in which can give rise to contamination by hexavalent ion of chromium and is strictly controlled due to recent environmental legislation in worldwide application. Therefore, new systems, showing environmental friendliness, must be studied and developed. Among of them, cerium chemical conversion coatings for magnesium alloys are considered to be environmentally acceptable.

Experiment

Cerium Conversion Treatment

The treatments described in this study were performed on 30×20×5 mm die cast plates of ZM5 magnesium alloy, with chemical composition (wt%): Al 8.3%, Zn 0.5%, Mn 0.3%, Si 0.25%, Ni 0.01%, Cu 0.1%, Fe 0.08%. A hole of 2 mm in diameter was drilled in the middle of one edge of each specimen for convenient hanging up in the solution during treatments. The chemical conversion on the magnesium alloy was investigated on the specimens using the following sequence of operations:

(1) Surface polished

The surfaces of the specimens were mechanically polished with abrasive paper (grade 360, 600, 1000 and 2000), ultrasonically cleaned in acetone and rinsed with distilled water, then dried by air.

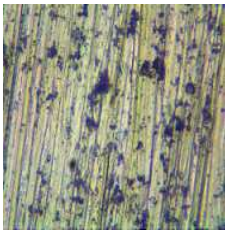
(2) Alkaline cleaning

Sodium hydroxide，25 g/L NaOH，Sodium carbonate，10 g/L Na_2CO_3．Temperature: 343 K，Time: 10 min，Post treatment: Water rinse．

(3) Chemical conversion

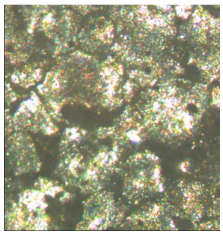
Potassium permanganate, 5g/L $KMnO_4$，Cerium chloride, 3g/L $CeCl_3 \cdot H_2O$. Temperature: at room temperature; Time: 30 min; Post treatment: hot air drying.

Coating Characterization



These micrographs of specimen surface were investigated by XJZ2-1A metallographic microscope. The mass of the specimen was measured with a BS210S electronic scale with an accuracy of 0.1 mg**.** The substrate and the conversion coated specimens were immersed in 3.5 wt. % NaCl solution in 96 hours and degree of corrosion of different specimens was observed.

The anticorrosion performance was evaluated by recording the corrosion potential of the specimens in the corrosive medium upon immersion, which was conducted on a CHI660D electrochemical workstation. A classic three electrode system was used, which contained a working electrode (the epoxy-sealed sample with exposed area 1.0 cm^2), a reference electrode (a saturated calomel electrode), and a counter electrode (a platinum foil). The corrosive medium was 3.5 wt. % NaCl solution at room temperature.



Results and Discussion

Chemical Conversion Coating Morphology

Specimen topography of chemical conversion process is shown in Fig. 1. Fig. 1(a) show that magnesium alloy substrate surface has many tiny holes and processing traces and other defects exist. Fig.1(b) showed that the cerium coating was generated by the cerium conversion treatment and completely covered the surface of the substrate with conversing to 30 minutes.

(a) substrate surface

(b)cerium coating

Fig. 1. Metallographic microscope of specimen

Corrosion Resistance of the Coating

The specimen's macrographs of the substrate and the cerium conversion coating are provided in Fig.2. Compared Fig.2 (a) with Fig.2 (b), it showed that the specimen's surface of the cerium coating has a yellow-brown conversion coating. The specimen's corrosion macrographs of the substrate and the cerium conversion coating are provided in Fig.3. Fig.3 showed the surface of the substrate specimen (only at 6 hours) showed a lot of corrosion pits and the specimen's surface of the cerium coating no corrosion pits, after immersed in 3.5 wt. % NaCl solution. So corrosion resistance of the cerium coating is very good.

The effect of conversion coating on the corrosion resistance of ZM5 alloy was studied by electrochemical tests. Fig. 4 showed the potentiodynamic polarization curves for ZM5 alloy substrate and cerium conversion coating in 3.5 wt.% NaCl solution. The cathode reaction in the polarization curves corresponded to the evolution of the hydrogen, and the anodic polarization curve controlled with active dissolution reaction was the most important features related to the corrosion resistance. The hydrogen evolution rate diminished after ZM5 alloy was covered with conversion coating. The shape of anodic curves was obviously different. The anodic current density increased smoothly with the increasing of anodic potential, indicating that the ZM5 substrate was dissolved gradually. For the cerium conversion coating, the corrosion current density increased slowly when the potential was more positive than −1.2 V_{SCE}. Revealing that no severe dissolution reaction was observed until the potential was more positive than −1.2 V_{SCE}. The corrosion current density *I*corr obtained from polarization curves was summarized in Table 1. As it was scientific to evaluate the corrosion rate by corrosion current density, it can be seen that cerium conversion coating presented a noticeable reduction in *I*corr relative to the substrate alloy. Thus, the cerium conversion coating was the most effective in 3.5 wt.% NaCl solution.

*I*corr (A/cm^2)	1.294×10^{-4}	3.162×10^{-5}

Formation Kinetics and Mechanism

It is well known that Mg^{2+} is the sole stable magnesium species in aqueous solution with pH value less than 8.50. Once the ZM5 magnesium alloy substrate contacts with cerium conversion treating solution, the preformed native (hydr)oxide coating on the substrate surface immediately dissolves. After the dissolution of the (hydr)oxide coating, primary anodic reaction[8] (the dissolution of magnesium) occurs:

$Mg \rightarrow Mg^{2+} + 2e$

Spontaneously, cathodic reaction (the reduction of protons) occurs:

$2H_2O+2e \rightarrow 2OH^- + H_2$

The metallic ions dissolved into the solution and the H_2 escaped from the solution to the ambient atmosphere. The reduction of H^+ resulted in a decrease of the acidic value of the cathodic site, thus the pH value of these local cathodic sites increased. This resulted in the formation of hydroxide. Simultaneously, $KMnO_4$ oxidized the Ce^{3+} to Ce^{4+} and was deoxidized to MnO_2 and MnO, then MnO, MnO_2, $Ce(OH)_4$, and $Mg(OH)_2$ deposited on the surface of the alloy[30], Finally, the hydroxide was dehydrated and conversion coatings were formed on the alloy surface.

$4Ce^{3+} + MnO_4^- + 8H^+ + 2H_2O \rightarrow 4Ce^{4+} + Mn(H_2O)_6^{3+}$

$2\ Mn(H_2O)_6^{3+} \rightarrow MnO_2 + Mn^{2+} + 10H_2O + 4H^+$

$Mg(OH)_2 \rightarrow MgO + H_2O$

$Ce(OH)_4 \rightarrow CeO_2 + 2H_2O$

In addition, the above formation mechanism is used to interpret the coating formation kinetics and anticorrosion performance. Fig.5 illustrates the mass gain curve of the coating upon treating, which describes the coating formation kinetics. At the beginning of treating process, in 0-30 min, mass gain linear increase with time. It showed that the coating formation is rapid at the beginning of cerium conversion treatment. The substrate intimately contacts the conversion solution. and the formation rate is mainly controlled by the producing rate of OH^- or the coupled anodic reaction (the dissolution of magnesium) rate.

As the coating formation proceeds, the substrate surface is gradually covered with cerium or magnesium hydroxides/oxides. The transportation of reacting ions and molecules through the covered layer is necessary for the further formation of the coating, which is limited by the diffusion of various reaction species. The rate of coating formation then gradually slows down. Fig.5 showed that mass gain increase slowly after cerium conversion treatment proceeds is 30min, so the best time of cerium conversion treatment is 30 min.

Summary

(1) After treatment in the bath, a red-brown coating could be formed on the AZ91 magnesium alloy and mainly composed of CeO2, MnO, MnO2, MgO, Mg(OH)2 and Ce(OH)4.

(2) The corrosion resistance of the bare ZM5 alloy in 3.5 wt. % NaCl solution was limited, and the attack morphology was pitting corrosion.

(3) The corrosion resistance of the ZM5 alloy was improved by the cerium conversion treatment.

(4) Before 30 minutes of cerium conversion treating process, mass gain was a linear growth with time. After 30min, mass gain was a slow growth or almost no growth.

Keywords: Laser surface carburizing; Titanium and titanium alloys; Growth morphology; Formation mechanism

Abstract: Titanium and titanium alloys are widely used in many fields due to their some characteristics such as light density, high strength and excellent corrosion resistance. However, their practical applications are limited by their poor surface mechanical properties. Laser surface carburizing can improve the surface properties of titanium and titanium via the formation of titanium carbide and other reinforcing phases. In this paper, the properties of the alloyed coatings, the growth morphologies and the formation mechanism of titanium carbide are discussed.

Introduction

Owing to their excellent properties such as specific strength and corrosion resistance, titanium and its alloys are widely used in many areas such as aerospace, military, sport equipment, chemical engineering, biomedical engineering, etc. However, they are currently restricted to nontribological applications, owing to their poor friction and wear resistance, and high tendency to galling [1-3]. Titanium carbide, TiC, is a refractory material which has a melting temperature about 3170 ℃ and a high hardness ranging between 2500 and 3000 HV. It is widely used as a reinforcing phase to improve the surface properties of titanium and titanium due to its ultra-high hardness. On the other hand, laser surface alloying offers an excellent scope for tailoring the surface microstructure and/or composition of a component and proves superior to conventionally practiced surface engineering. Laser surface alloying involves melting of a pre-deposited coating or concomitantly added alloying elements/compounds with a part of the underlying substrate by the directed energy laser beam to form an alloyed zone confined to a shallow depth within a very short interaction time. In addition, laser surface alloying can overcome some disadvantages of the conventional strengthening methods and has the major advantages of the ability to control the power density precisely, minimum heat affected zone, and processing of inaccessible and localized areas [4]. And it has been actively investigated and applied to improve wear and corrosion properties for various steels, aluminum and titanium alloys.

Laser surface carburizing is a method of laser surface alloying using carbon or graphite as the mainly alloying powder to fabricate the alloyed coating. The surface properties of the metal components are significantly improved due to the formation of hardening titanium carbide. In this paper, recent research progress on laser surface carburizing of titanium and titanium alloys is reviewed.

Laser surface carburizing

Laser surface carburizing uses carbon or graphite as the complete alloying powder and the alloyed coating reinforced by hardening titanium carbide phase is fabricated on the substrate of titanium and titanium alloys. And many researches have been carried out. Laser surface carburizing of pure titanium with graphite powder shows that some above 800 μm thicknesses of the alloyed

coatings, mainly consisting of dendritic TiC, are fabricated on the substrate, which increase the hardness from the substrate about 210 $HV_{0.1}$ to 1200 $HV_{0.1}$ and decrease the wear coefficient from 0.5 to 0.3. The result of dry-sliding friction test of laser carburized pure titanium shows that dry-sliding friction between ceramic and titanium is minimized whereas adhesive wear of the metal is reduced much and its abrasive wear is prevented, which can be attributed to the formation of hardening titanium carbide phase and the self-lubricating action of the rest of graphite powder [5-7]. In addition, Ref. [6] also confirms that titanium carbide phase formed in the alloyed coating is non-stoichiometric carbide phase TiC_{1-x} owing to non-equilibrium solidification. Laser surface carburizing of Ti-46Al-2Cr-1.5Nb-1V with graphite and C + Nb shows that the oxidation and wear resistance of the alloyed coating, consisting of in-situ produced TiC particles, improve obviously, and the sample alloyed with C + Nb exhibits the best oxidation and wear resistance [8-9]. The alloyed coating, with gradient distributed TiC reinforcing phase, is successfully fabricated on γ-TiAl alloy by laser surface carburizing with carbon [10]. The result of high-temperature sliding wear test indicates that the alloyed coating has excellent high-temperature sliding wear resistance. The high hardness and excellent wear resistance of the alloyed coating is the result of the refined rapidly solidified microstructure and the presence of hardening ceramic phase TiC. But it must be noted that although hardening ceramic phase TiC can improve the wear resistance of the samples, excessive volume fraction of TiC in the alloyed layer increases the brittleness and decreases the wear resistance of the alloyed coating.

Laser surface composite carburizing

Laser surface composite carburizing uses mixed powders consisting of C and other powders as the alloying powders to fabricate the alloyed coatings, which consist of TiC and other reinforcing phases. According to the reinforcing phases formed in the alloyed layers, the extra addition powders are divided into the following two kinds: one is the powders formed hard ceramic phases with titanium; the other is the powders formed intermetallic compounds with titanium.

The alloyed layer reinforced by multiple ceramic phases could be achieved better effectiveness than by only one ceramic phase. Laser surface alloying of Ti-6Al-4V with graphite and boron mixed powders shows that the coatings, consisting of TiC, TiB_2 and TiB, have higher hardness (about 1250-1700HV) and are more resistant to wear than the as-received sample [11]. And the composite coating produced by laser alloying with boron and carbon mixed powders has better properties than that alloyed with boron and carbon separately. As is well known, rare earth (RE) oxides are effective in grain refinement of many metallic alloys and thus improve the mechanical properties. Compared with the result of Ref. [11], the microstructures of the coatings are refiner through the addition of rare earth oxides Ce_2O_3 and Y_2O_3 into graphite and boron mixed powders [12]. The mechanism of the microstructural refinement is mainly attributed to the surface activity of the elements Ce and Y, the function of the Ce_2O_3 and Y_2O_3 particles acting as heterogeneous nuclei, and the grain growth resistance of the elements Ce and Y and their oxides. Laser melted BN + C coating on the Ti-6Al-4V titanium alloy has produced the alloyed coating, consisting of hard ceramic TiC, TiN and TiB particles spaced in ductile martensitic matrix, which has a high hardness level of 920 HV [13]. The fracture examination of laser treated zones shows that the heat affected zone displays ductile fracture whereas inside of alloyed zone displays the complex character of fracture. And the propagating crack penetrates the area of martensitic phase and can be stopped on particles of TiC, TiB and TiN phases.

Titanium silicides such as Ti_5Si_3 is confirmed to be good reinforcements for titanium alloys because of its excellent capability including high hardness and wear resistance in many tribological systems, thermal stability at high temperature, high elastic modulus and the similar density to pure titanium. Surface modification of titanium alloys with titanium carbides or silicides is considered to be effective method to improve the wear resistance of titanium alloys Composite coatings consisting of preeutectic TiC and eutectic Ti_5Si_3 + β- (Ti) were fabricated by laser alloying of titanium alloy Ti-6Al-4V with graphite and silicon mixed powders [14]. The test results show that the composite coatings, thickness of about 0.6 mm, surface microhardness of about 1500 $HV_{0.1}$, have a

lower friction coefficient and a much higher wear resistance than the as-received sample. In addition, the analysis also shows the combination of C with Ti at relatively higher temperature results in a shorter diffusion time of the C atoms in the melt pool and thus the titanium carbides formed in the top layer of the coatings. On the other hand, the titanium silicides formed at a relatively lower temperature results in the Si atoms having more time to diffuse deep into the melt pool. So, the compounds in the inner layer of the coatings are mainly titanium silicides.

Growth morphology analysis of titanium carbide

TiC has a NaCl-type crystal structure and is face center cubic crystal. Ti atoms array fcc sub-lattice, while carbon atoms occupy the free place of octahedral configuration forming another fcc sub-lattice [15]. They are completely symmetry with sub-lattice of Ti and carbon. The growth morphology of TiC is a regular octahedron under equilibrium solidification and free growth conditions, and each of the corners is faceted by {111} planes, requiring that growth velocity $V_{\{111\}}$ normal to each {111} planes must be equal. However, the carbide growth morphologies under non-equilibrium solidification conditions often deviate from its equilibrium growth morphology, indicating sufficiently that growth morphology of TiC carbide depends strongly upon solidification conditions. It is well known that the final growth morphology of a crystal is controlled by the following factors: (1) crystal structure; (2) thermodynamic properties such as interfacial energy and phase transformation entropy; (3) growth kinetics and mechanism; and (4) thermal and mass transportation in melt. It is commonly known that a change in solidification conditions must affect the thermal and mass transport in melt. As a result, distribution of thermal field and solute field in the melt would deviate from that under equilibrium solidification conditions, leading to a variety of growth morphologies.

Chen et al. find in their experiment that different morphologies of titanium carbide dendrite are formed in the carburized coating with different laser scanning velocity. Dendritic titanium carbide is the most common morphology in laser carburized coatings. It having a platelet/catenulate growth characteristic on dendrite arms is formed with lower laser scanning velocity, while a well-developed dendrite having a three-dimensional network growth characteristic is formed with higher laser scanning velocity. In addition, different morphologies of titanium carbide are also formed under different cooling rate. With an increase of cooling rate, the growth morphologies of titanium carbide change from well-developed dendrite, cross-petal microstructure to blocky microstructure [16]. Platelet-like microstructure is also observed in laser carburized TiAl coating [17]. Laser carburizing of pure titanium with graphite shows that cellular dendrite and globular microstructure are formed with different laser parameters [7]. In present author's work [18], different morphologies of titanium carbide including globular microstructure, well-developed dendrite, cross-petal microstructure and cellular microstructure are observed orderly from the top surface to the bottom of the carburized coating, as shown in Fig. 1. These differently morphologic titanium carbides correspond to different carbon contents. And there is a strong relationship between the carbon content and the mean microhardness, namely high carbon content corresponds to high hardness. The dense and coarse titanium carbide has higher carbon content, and consequently has higher microhardness. While the finer and shorter titanium carbide has lower carbon content, consequently has lower microhardness. During solidification, the alloying primitive content C_0, the temperature gradient of the liquid phase on solid-liquid interface G and solidification rate R are the chiefly influencing factors on crystal morphology.

Otherwise, laser scanning velocity has an important effect on the microstructures of the alloyed coating. When the scanning velocity is lower, there is a longer laser irradiation time which results in the melt pool absorbing more heat energy. The melt thus takes a longer time for solidification to start and the temperature of the base material becomes higher which results in lower temperature gradient and cooling rate, and prolongs the interaction time between molted Ti and C and the grain growth time. The resulting microstructure exhibits a dense and coarse morphology. With an increasing of the scanning velocity, the laser irradiation time reduces, which induces the decreases of the interaction time and the grain growth time. The microstructure is finer and shorter.

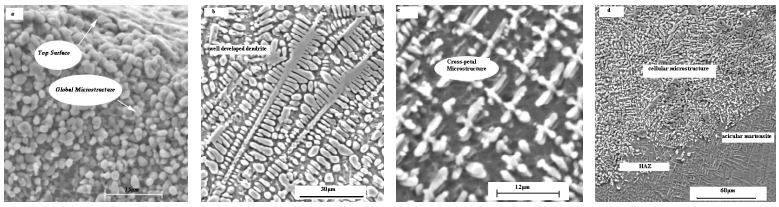

Fig. 1 SEM micrographs of different morphologies of titanium carbide

Formation mechanism of titanium carbide

The formation mechanism of TiC is related to the highest processing temperature. It can be classified into two mechanisms according to the highest temperature: diffusion mechanism and solution-precipitation mechanism [19]. Thermodynamic and kinetic calculations of TiC show that the formation mechanism is diffusion mechanism when processing temperature is lower than 1554K, while the formation mechanism is solution-precipitation mechanism when the processing temperature is above 1554K [20]. Since the processing temperature of laser surface alloying is much higher than 1554K, the formation mechanism of TiC is solution-precipitation mechanism. The formation of TiC particles in liquid titanium can be considered in the following ways:

$$Ti_{(l)} + C_{(s)} \rightarrow TiC_{(l)} + Q_1 \qquad [1]$$

$$TiC_{(l)} \rightarrow TiC_{(s)} + Q_2 \qquad [2]$$

where $C_{(s)}$ is the carbon particle precursor, Q_1 is the heat of reaction, and Q_2 is the heat of solidification. Equation [1] shows a liquid-solid reaction process. The carbon particle diffuses into laser melted pool during laser irradiation. Then, the molten titanium surrounds the carbon particle and reacts at its outer interface. The molten titanium diffuses through TiC layer to react with the unreacted portion of the carbon particle, and TiC dissolves in the liquid phase. As the reaction progresses, the carbon particle and titanium concentrations in melted pool decrease, and the product concentration increases with time. Equation [2] shows a precipitation process. TiC particles precipitate from liquid phase and different morphologies of TiC are formed in this process. The sketch of the formation of TiC is showed in Fig.2 [18].

Fig.2 Sketch of the formation of TiC

a-activated carbon preplaced on the substrate, b-diffusion C into liquid titanium, c-reaction between C and Ti, d-precipitation of TiC

Keywords: corrosion mechanism; corrosion inhibitors

Abstract: In this paper, we state the corrosion mechanism of carbon steel, copper, aluminum and other non-ferrous metal in the seawater; analyze the types and mechanism of corrosion inhibitors. By experiments, we have a good knowledge of the function of corrosion inhibitors to metal in the seawater. We also analyze the application prospects of corrosion inhibitors' application to metallic corrosion inhibition in ocean environment.

Introduction

At present, most ships use metal shells sailing in the ocean, however metal will be influenced by the temperature of seawater, the salinity of seawater, the marine atmosphere temperature and the marine microorganism in ocean environment, so the corrosion degree of metal will be serious. Corrosion not only can reduce the ships' structural strength and service life but also can increase the sailing resistance, reduce the speed of sailing, make the ships' sailing hard and have negative effects on the navigation safety. If the ships have already been corroded under the effects of the external world and there are cracks and perforation, which can lead to the happening of marine casualty and cause heavy losses to people's lives and property. Twenty to thirty bilion yuan will be lost because of metal corrosion every year, of which the corrosion of ship accounts for a very big part.

Since most ships use metal shells, and hull parts touching with the seawater directly are coated with anticorrosive paint, at the same time, protected by the system of the impressed current or sacrificial anode cathodic protection system. When the anticorrosive coatings are washed by seawater off or when the anode is used up, the ships will still be corroded, even the corrosion rate will be faster, shortening the service life of the ships. Therefore, studying how to minimize the corrosion rate when the hull has been corroded is especially important. That is to say, it is important to study the applications and application effect of metal corrosion inhibitor in marine environment.

Mechanism Of Metal Corrosion In The Marine Environment

Corrosion is material's damage or deterioration under the effect of the external environment, including chemical corrosion, electrochemical corrosion and biological corrosion. Materials mentioned here include metal and nonmetal. Metal corrosion is the damage that metal interacts with surrounding medium by chemical or electrochemical reaction, sometimes accompanied by mechanical, physical and biological effects. Non-metallic corrosion is non-metallic materials' damage due to the direct chemical action (such as oxidation, dissolving and swelling, aging, etc). Because most of corrosion in ships occurred in metal, so we will mainly discuss the metal hull corrosion and research the anticorrosive measures of the metal hull.

Chemical composition and environment of seawater are complex, so there are many factors leading to corrosion of metal hull. In addition to the composition of seawater that can cause all sorts of chemical reaction with the metal hull, a lot of factors outside such as temperature, will be the reasons of accelerating hull's metal corrosion.

For hull, corrosion mainly occurs in the underbody and water line. The hull underwater is corroded by electrochemical corrosion and the hull's corrosion at the water line is mainly the chemical corrosion and electrochemical corrosion. The hull underwater is completely immersed in seawater, which is equivalent to immerse in the electrolyte solution.

Carbon Steel Corrosion Mechanism

Carbon steel con tains various components, which mainly are ferrite and cementite (Fe3C). The former is a body centered cubic lattice pure iron, and the latter is a kind of iron-carbon compounds whose electrochemical properties are similar to graphite. When carbon steel is immersed in aqueous solution.

TABLE I. MAIN SALT CONTENT IN THE WATER

composition		NaCl	MgCl2	MgSO4	CaSO4
The percentage of	total salinity/%	77.8	10.9	4.7	3.6
composition		K2SO4	CaCO3	MgBr2	total
The percentage of	total salinity/%	2.5	0.3	0.2	100

Electric potential difference between ferrite and cementite is caused by the electrode potential difference. Ferrite' electrode potential is negative and is the anode, however, cementite' is positive and is the cathode. And the two components are arranged closely cross together, because they are connected by point, free electrons will flow from the ferrite to the cementite. When carbon steel is immersed in aqueous solution, the dissolved oxygen in the aqueous solution will absorb the electron which is released because of iron corrosion in the surface of the cementite to make the corrosion process go on.

And the equation for anodic reaction as in $Fe \rightarrow Fe^{2+} + 2e^{-}$. (1)

The equation for cathodic reaction as in $O_2 + 2H_2O + 4e^{-} \rightarrow 4OH^{-}$. (2)

Solubility of corrosion products Fe(OH)2 is small, depositing and coating on metal surface. And Fe(OH)2 can be further oxidized to Fe(OH)3 which generates rust Fe2O3 dehydrating nH2O. The equation for anodic reaction, as in $4Fe(OH)_2 + 2H_2O + O_2 \rightarrow 4Fe(OH)_3$. (3)

The cathodic reaction equation, as in $2Fe(OH)_3 \rightarrow Fe_2O_3 + 3H_2O$. (4)

Furthermore, Fe2+and Cl- in the sea water will generate FeCl2 dissolving in water, and then spread to the anode zone, generating Fe(OH)2 known as brown rust with OH- of the bulk solution or cathode zone, quickly converting into other forms of rust when encountering the water in the pore liquid and oxygen. FeCl2 generates Fe(OH)2 and it will release a Cl- at the same time, the new Cl- and migrate to the anode area, bring out moreFe2+, accelerating the anodic process. We usually refer to the accelerating anodic process as anodic polarization, Cl-'s t function is anode depolarization.And the anodic reaction equation, as in

$2Cl^{-} + Fe + 6H_2O + 2Fe^{3+} = 3Fe(OH)_2 + 6H^{+} + 2Cl^{-}$. (5)

The cathodic reaction equation, as in

$4Fe(OH)_2 + 2H_2O + O_2 \rightarrow 4Fe(OH)_3$. (6)

Mechanism of Non-Ferrous Metal Corrosion in the Seawater

Copper will be affected by different degree of corrosion in the flowing seawater, the equation that copper is corroded in seawater,equation for anodic reaction, as in $2Cu \rightarrow 2Cu^{2+} + 4e^{-}$. (7)

And the equation of cathodic reaction, as in $O_2 + 2H_2O + 4e^{-} \rightarrow 4OH^{-}$. (8)

Aluminum's corrosion degree is related to its purity in seawater, the purity is smaller, the more serious corrosion. aluminum of not high purity will be a galvanic cell with internal impurities, also electrochemical corrosion in the absence of protection, and the equation of Anodic reaction, as in

$$4Al \rightarrow 4Al^{3+} + 12e^{-} \quad (9)$$

Cathodic reaction equation, as in $3O_2 + 3H_2O + 12e^{-} \rightarrow 12OH^{-}$ (10)

In addition, unprotected aluminum in seawater will appear cavitation erosion intergranular corrosion and stress corrosion cracking.

Corrosion of the Hull Waterline Part

Because the hull waterline part's environment is alternation between sea and air, impacted by sea and air alternately, subjected to chemical and electrochemical corrosion, as a result, its rate is faster; In spite of the waterline coated with anti-corrosion layers, but these layers will fall off under the impact of the water of the sea.

The corrosion reactions above are functioning well when water and the metal are not influenced by the special conditions. In the Marine environment, there are all kinds of variable factors outside, for example change of temperature, the flow rate of seawater and the pressure of seawater. These factors will accelerate the chemical corrosion and electrochemistry corrosion of metal in the seawater, increasing the degree of metal corrosion. So we must take enough consideration to these areas when we research on metal corrosion in seawater factors.

Species And The Corrosion Mechanism Of Metal Corrosion Inhibitors

Corrosion inhibitor is chemical substances or compounds that exists in the appropriate concentration and form in the environment, can prevent or reduce corrosion of material. According to medium, we can make the classification: acid restrainer, alkaline, corrosion inhibitor, neutral corrosion inhibitor, oil soluble corrosion inhibitor and volatile corrosion inhibitor and so on. Now, what corrosion inhibitors people use most are volatile corrosion inhibitor an liquid corrosion inhibitor. So far, main organic corrosion inhibitors people have developed are Low molecular weight amines, dicyclohexyl ammonium nitrite, gasifiable amino acid alkyl ester, heterocyclic compounds, for example: isopropyl amine, β - amino acids, thiazole derivatives were, three nitrogen truxene azole derivatives, morpholine derivative and so on. Liquid phase corrosion inhibitors such as hydrochloric acid pickling corrosion inhibitors are widely used. Moreover, vapor phase corrosion inhibitors are often made into gas liquid corrosion inhibitor with liquid corrosion inhibitor or into composite vapor-phase corrosion inhibitor with several kinds of gas phase corrosion inhibitors .Because metal's environment is not just a simple liquid or gas phase environment, but as a complex multiphase coexistence environment in the real production practice, we should consider materials' erosion of the multiphase flow.

Based on the Influence of the Electrode

For cathode: By changing reaction process of the cathode, to make the corrosion potential negatively shift, reducing the cathodic process, to make metal corrosion potential into passivity potential area, which plays an important role in the corrosion; for anode: the anions of metal corrosion inhibitor of anode type move toward the anode and passivate the metal(oxidization), forming a compact passivation membrane(oxidation membrane),so as to inhibit the corrosion of metals.

Corrosion inhibitors change the process of the electrode reaction, destroy the corrosion of electrochemical corrosion, as a result, the iron, copper and other metal can not react with each other in the way of electrochemical reaction, to have the effect of slowing down the metal corrosion. But if anodic corrosion inhibitor dosage is insufficient, is not fully covering the surface of the anode, as a result, there will be forming small anode and large cathode's batteries of corrosion, which can accelerate the corrosion of metals, it will become a dangerous corrosion inhibitor, instead. On the other hand, the cathode corrosion inhibitors become secure corrosion inhibitor.

Forming a Protective Membrane on the Metal Surface

Some corrosion inhibitors will form dense and adhesional oxide membrane on the metal surface, when the thickness of the oxide membrane reaches a certain level, which will slow down the rate of oxidation reaction, the protective membrane will stop growing; and some corrosion inhibitors and ionic of medium will react with each other generating the undissolved material which directly precipitates on the metal surface to form the precipitation membrane of corrosion resistance, to have played an important role in protecting the metal. This kind of protective membrane attached to the metal surface will separate the metal from the surrounding sea water and air in the seawater, reducing their exposure, which can effectively block the electrochemical corrosion of the underbody and nonferrous metals, also dual corrosion of topsides, to protect the hull.

The Adsorption of Polar Groups and Non-polar Groups

Polar groups make corrosion inhibitor molecules adsorbed on the metal surface, which changes the charged state of the metal surface and interface properties, leads energy state on the surface of the metal to the stabilization, and increases activation energy of the metal reaction, so that the rate of metal corrosion slows down. Non-polar groups can form hydrophobic protective membrane to prevent the corrosive medium or water molecules from spreading to the metal surface diffusion, at the same time, and to prevent the dissolution and diffusion of metalion.

Experiment Analysis

In order to prove that the metal corrosion inhibitor is useful for corrosion and rust of metal in the marine environment, we need to use black and non-ferrous metal to do the experiment.

Nonferrous Metals

1) Experimental material

We chose the fine copper as test object of all the non-Ferrous Metal, and make the sample into $25\text{mm}\times 25mm\times 2mm$.

2) Sample Pretreatment

Samples are copper pieces and should be polished through the 120 mesh and 240 mesh dry abrasive paper step by step, then washed with distilled water.

Divide the preprocessed samples into two groups, the sample surface is coated with metal corrosion inhibitors (group 1), as showing in figure 1, in the first group, when the metal corrosion inhibitor on the surface is dry, put them separately in the seawater prepared ahead of time; While the other group do not do any processing(group 2), as showing in figure 2, and put them separately in the seawater prepared in advance with group 1 at the same time, and immerse respectively for 5 days and 15 days, and analysis their metallographic, compare with the experimental results of two groups which are as follows. And the experimental temperature of immersion is $(25\pm2)^0$C.

Figure 1 Group 1: sample surface is coated with metal corrosion inhibitors

Figure2. Group 2: samples without any processing

3) Comparison of Results (the experimental temperature of seawater immersion is 250C)
4) By comparing the experiment results of two groups, we find that corrosional phenomena of group 2(without any process) is more obvious.

The Ferrous Metals

1) Experimental Material

We chose the industrial steel plate as test object of all the ferrous metals, and make the sample into 25mm×25mm×2mm.

2) Sample Pretreatment

Samples should be polished respectively through the 120 mesh and 240 mesh dry abrasive paper step by step, then washed with distilled water.

Divide the preprocessed samples into three groups, each group into two small groups, the sample surface is coated with metal corrosion inhibitors (group 1) in each group of the first group, as shown in figure 3, when the metal corrosion inhibitor on the surface is dry, we can do the experiment; While the other group do not do any processing(group 2). After tested respectively for 15 days, and analysis their metallographic, finally compare test results of two groups. And the temperature of soak testing is(25±2)0C.In the experiment, the samples of the first group， as showing in figure 3, are all in the water; each of samples in second group is half in seawater, the other in the outside, as showing in figure 4; the samples of group 3 suspended above the seawater, don't immersed in seawater,as showing in figure 5.

3) Comparison of Results

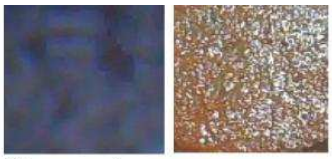

Figure3. Comparison of results for group 1

Figure4. Comparison of results for group 2

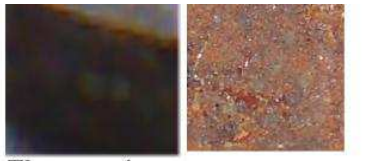

Figure5 . Comparison of results for group 3

Conclusion

By comparing the experiment above and results, we find that the sample whose metal surface is daubed with corrosion inhibitor, is no matter in sea water environment, or atmospheric environment of sea water, its corrosion is lighter or can slow down the corrosion of metal corrosion for a long time, to prove that the metal corrosion inhibitors on the metal surface have antiseptic gentle erosion effect on metal in seawater and marine environment, to prolong the service life of metal material and reduce the costs of maintenance and after-sales service. The application prospect of metal corrosion inhibitor: the metal applied corrosion inhibitor can effectively prevent metal corrosion and slow down the rate of corrosion in the seawater environment, also prolongs service life of metal. Therefore, the metal corrosion inhibitor can be applied to corrosion protection system of the hull part under sea water. Before launching, we can evenly daube it on the hull part of underwater and between wind and water, constituting the anti-corrosion system of ships together with corrosion protection measures such as anti-corrosion coating and cathodic protection technology, as the last line of defense system, which can effectively prolong the service life of ship and greatly reduce the costs of each year for hull anticorrosion and the loss of life and property for this reason. At the same time, on one hand we should use the corrosion inhibitors which are harmless to sea water and marine living beings, on the other hand we should strengthen the research of environmental friendly and anticorrosive effect better corrosion inhibitor.

Keywords: stainless steel, corrosion resistance, EGR

Abstract. 316L stainless steel is a well known advanced material for its good corrosion resistance in many aggressive situations. As the quality of different manufacturer of the stainless steel may vary in some degree, this paper studied the corrosion resistances of three 316L stainless steels which supplied by three manufacturers. The results show that the difference of the corrosion rates of the three 316L stainless steels in 5% H_2SO_4 or 3.5%NaCl solutions is one time in quantity. The reasons for the difference can be explained by compositional and metallographic factors.

Introduction

Exhaust gas recycle (EGR) system can be used in many vehicles (especially for heavy trucks) for more efficient energy usage and less pollutant emission [1-4]. A problem of EGR system is the corrosion of the construction materials which are often stainless steels. Because combustion reactions in engine will more or less produce nitrogen oxide (NOx). Also, most oils contain small amount of sulfur which is the source of sulfur oxides (SO_2, SO_3) in exhaust gas . As water is the inevitably product of hydrocarbon combustion reaction, nitric acid and sulfuric acid may formed in the cold region of EGR system. So, high corrosion resistance of the materials in EGR system is required. 316L stainless steel is widely used in chemical industry and many other demanding applications. It is a good candidate material for EGR system. There are many 316L stainless steel manufacturers in the world. The quality of their products may vary in some degree. In this paper, the corrosion resistances of three 316L stainless steels supplied by three manufacturers were tested by weight loss method and electrochemical method. Optical metallographic and scanning electron microscope examination were used for the material characterization.

Experiment

The Materials

The three 316L stainless steels which were supplied by three manufactures were named as 316L-A, 316L-B and 316L-C in this study. All the material samples were in plate form with thickness vary from 0.27 to 0.48mm. Table 1 shows the compositions of the three 316L stainless steels.

Table 1 The compositions of the three stainless steels (% in weight)

Element	C	Cr	Ni	Mo	Mn	Si	S	P	Cu	N
316L-A	0.027	16.80	10.20	2.00	1.07	0.47	0.001	0.036	0.17	/
316L-B	0.022	16.00	10.17	2.03	1.45	0.57	0.001	0.031	0.13	0.025
316L-C	0.026	17.10	12.14	2.08	0.97	0.62	0.004	0.031	/	/

Dip tests and electrochemical tests

Stainless steel rectangular samples with dimension of 40×30mm were used for dip test. The sample surfaces were first sanded with 1500# SiC paper and then washed in flowing water and cleaned ultrasonically in ethanol for 15min. The samples were weighted by electronic microbalance and were dipped in 5%H_2SO_4 at the boiling temperature for 6hours. After that the samples were taken out and washed with water. The corrosion products on the sample surfaces were removed by dipping in 30% HNO_3 with ultrasonic resonance. The samples were weighted again and kept in dryer for examination.

Two electrochemical test techniques were used. One is corrosion potential measurement. Another is Tafel test. The instrument for the electrochemical test is P4000 of Princeton Applied Research Company.

Metallographic Examinations

The microstructures of the stainless steels were examined both by optical microscope and scanning electron microscope (SEM). A MR5000 microscope was used for optical metallographic examination and a Inspect S50 scanning electron microscope was used for finer examination. For optical metallographic examination the stainless steel samples were first embedded in epoxy resin and then polished with fine alumina and last etched in acid $FeCl_3$ solution. For SEM observation, stainless steel plate specimens were fractured by a tensile tester. The fractured surfaces were observed for microstructure characterization of the materials.

Results and Discussion

Dip Test

Three parallel samples for each kind of 316L stainless steel were used in the dip test. Each sample has 16cm^2 surface area. Table 2 shows the result of the test. The average corrosion rates of the three stainless steels in boiling 5% sulfuric acid are 10.0 g/m^2h or 12.0 mm/a for 316L-A, 18.0 g/m^2h or 20.2 mm/a for 316L-B and 7.2g/m^2h or 8.1mm/a for 316L-C. 316L-C shows the best corrosion resistance in the solution. The corrosion rate of 316L-B is more than one time higher than that of 316L-C. From Table 1 we know that 316L-C has higher Cr and Ni content than 316L-A and 316L-B. So, higher Cr and Ni content are beneficial for corrosion resistance of this type of stainless steel.

Table 2 Test result of three stainless steels dipped in boiling 5% sulfuric acid for 6h

Sample	thickness [mm]	weight1# [g]	weight2* [g]	weight loss [g]	corrosion rate [g/m^2.h]	average [g/m^2.h]

#:weight1=weight before dip, * weight2=weight after dip, $: test failure due to instrument problem

Electrochemical Test

Fig. 1 shows the open circuit potential measurements of the stainless steels in 3.5%NaCl solution. The measurement duration was 2 hours. The potential of 316L-A is relatively stable over the time and it was -0.174V(SCE) at the end of the measurement. The potentials of 316L-B and

316L-C varied a lot over the time and they were -0.234V(SCE) and -0.101V(SCE) respectively at the end of the measurement. There were many abrupt changes of the potential of 316L-B. As 316L-B is the worst of the corrosion resistance among the three stainless steels, the abrupt changes of potential may be the show of less protective property of the passive film of the stainless steel. 316L-C has the highest open circuit potential. It also has the highest corrosion resistance. So, open circuit potential is an important parameter for corrosion resistance measurement of stainless steels.

Fig.2 shows the Tafel plot of the polarization curves of the three stainless steels in 3.5%NaCl solution. From Fig.2, both corrosion potential and corrosion rate can be obtained. For 316L-A, they are -0.257V(SCE) and 6.3×10^{-6}A/cm^2. For 316L-B, they are -0.252V(SCE) and 7.9×10^{-6}A/cm^2. For 316L-C, they are -0.241V(SCE) and 4.0×10^{-6}A/cm^2. Again, 316L-C shows the best corrosion resistance of the three stainless steels. And the corrosion rate of 316L-B is approximately one time higher than that of 316L-C.

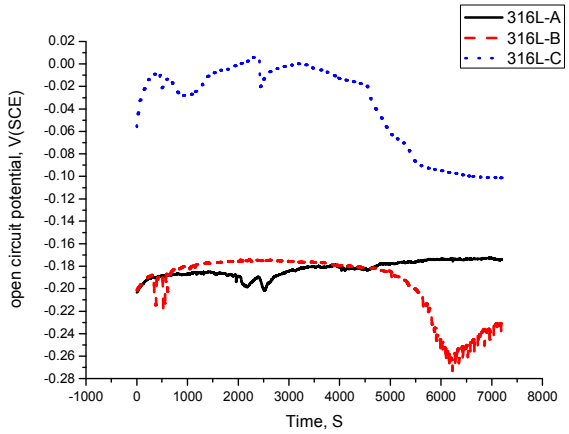

Fig.1 Corrosion potential of the three 316L stainless steel in 3.5%NaCl

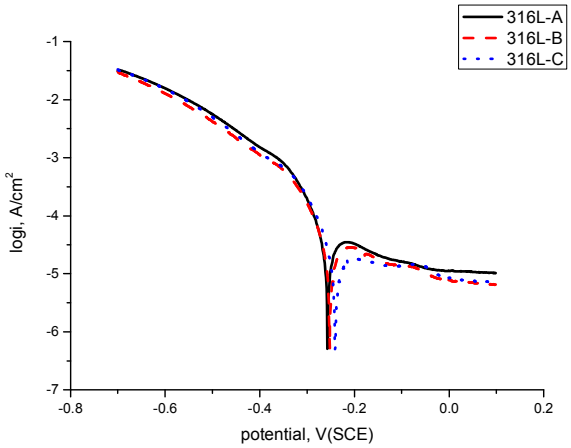

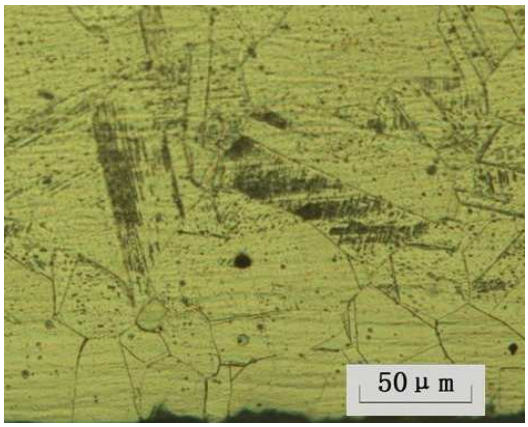

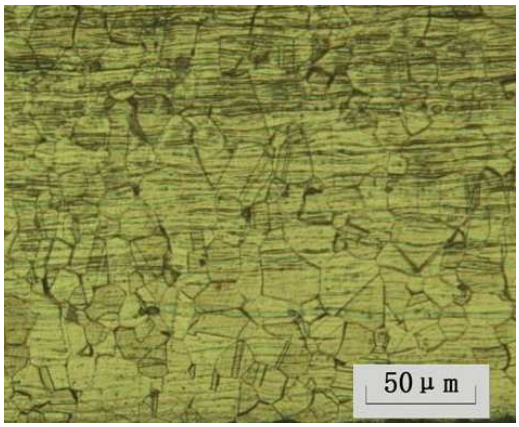

Fig.2 Tafel plot of polarization curves of three stainless steels in 3.5%NaCl

Metallographic Examinations

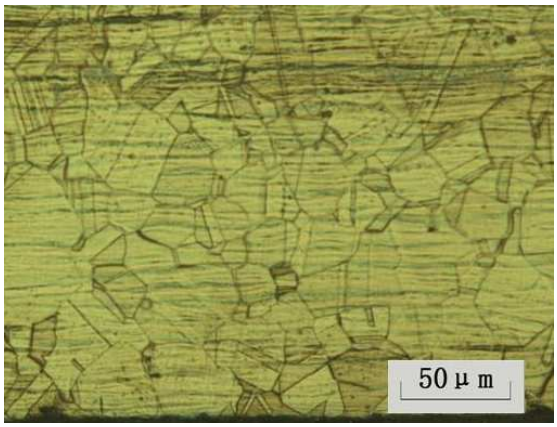

Fig.3 shows the results of optical microscope examination and SEM examination of the three stainless steels. The optical metallographs (Fig.3 a, b, c) show that 316L-A has larger grain size than 316L-B and 316L-C. It also shows that 316L-C has fewer inclusions than 316L-A and 316L-B. The SEM photos (Fig.3 d,e,f) also show the existence of more inclusions in 316L-A and 316L-B.

Fig.3 Results of metallographic examination of the three 316L stainless steels

Discussions

The above results show that the corrosion resistances of the three 316L stainless steels are different. Corrosion rate of 316L-B in 5%H_2SO_4 or 3.5%NaCl was approximately one time higher than 316L-C. The result of the dip test was in consistent with the electrochemical test. To explain the result, both chemical compositional factor and metallographic factor of the materials are needed to consider. To examine Table 1, we find that 316L-C has higher Cr and Ni contents than 316L-A and 316L-B. This is in consistent with the well known rule that higher Cr and Ni content in stainless steel are beneficial for its corrosion resistance. Many present stainless steel standards (such as AISI

in US and GB in China) specify chemical compositions of stainless steel in a range. For example, the Cr and Ni content of 316L stainless steel can be 16-18% and 10-14% respectively [5]. For economic consideration, some manufactures control the Cr and Ni content in stainless steel in the low limit. This study has showed that the corrosion resistance (and the quality) of their products are actually related closely to the Cr and Ni content in the materials.

The SEM micrographs in Fig.3 show the existence of inclusions in all the stainless steels Inclusion composition and morphology is an important factor affecting corrosion resistance of stainless steels [6-8]. It can be seen that 316L-C has fewer inclusions in comparison with 316L-A and 316L-B. This may be one of the reasons why 316L-C has superior corrosion resistance.

Conclusions

From the above results, following conclusions can be obtained: even slight compositional (especially chromium and nickel content) variance and metallographic difference in 316L stainless steel will cause the change of its corrosion resistance.

Keywords: Cu-Ni-Si alloy, corrosion behavior; EIS; seawater

Abstract: The corrosion behavior of Cu-Ni-Si alloy exposed to a nutrient-rich simulated seawater-based nutrient-rich medium in the presence of a deep-sea bacterial (*Erythrobacter pelagi sp.nov*) was investigated by metallographic microstructure observation, electrochemical impedance spectroscopy (EIS) measurement. It was demonstrated that the charge transfer resistance (Rct) and the resistance of oxide film(R_f) dramatically increased within 2 days then gradually decrease and becoming stable because of an patchy or blotchy biofilm formed on the surface of the alloy.

Introduction

Copper-nickel alloys are now being used extensively in electric power, electronics and instrumentation applications due to their electrical and thermal conductivity , excellent mechinability and corrosion resistance [1-3,7-8] .Cu-Ni-Si alloy is one of the most outstanding one due to its combination of high electrical conductivity and high strength, which has been considered as one of ideal materials used for electrical devices, such as semiconductor lead-frames, connectors, high-speed train contact wire clamps, and wear-resistant parts [4]. As a typical age-hardening alloy, this alloy is usually used in an over-aging condition [5-6]. The precipitates responsible for the strengthening effect have been identified as δ-Ni_2Si. So Cu-Ni-Si alloy have a good prospect used in deep-sea environment. It is obvious that previous investigations focused mainly on the properties of Cu-Ni-Si alloy used on land, while few published studies have documented the corrosion behavior of Cu-Ni-Si alloys in seawater environment. It is therefore significant to determine the corrosion behavior of Cu-Ni-Si alloy in the medium with deep-sea bacterial. The present study seeks to gain a better understanding on the influence of deep-sea bacterial on the corrosion behavior of the Cu-Ni-Si alloy as a function of time using electrochemical method.

Experimental Details

Test Specimen

The chemical composition (wt. %) of Cu-Ni-Si alloy in this work is: 90.83Cu, 7.54Ni and 1.63Si. The alloy was supplied as plate with planar dimensions of 100×500mm and a thickness of 1mm.

Metallographic Examination

Specimens were cut from the original plate samples with sizes of 10×10×1mm. Prior to the experiments, the specimens were sequentially ground using a series of grit (400, 800, 1000, 1500, and 2000) silicon carbide emery paper to a smooth surface, rubbed against smooth cloth using diamond (2.5μm) polishing liquid till reaching a mirror bright surface, rinsed with distilled water, and then immersed in solution (2g $K_2Cr_2O_7$，8mL H_2SO_4，4mL saturated sodium chloride solution，100mLH_2O) for etching.

Electrochemical Measurements

Specimens were welded with copper wire, and then encapsulated bare copper wire and weld surface with ethoxyline resin. Exposure area was 1 cm^2. After solidification, the exposure face was sequentially ground using a series of grit (400 and 800) silicon carbide emery paper to a smooth surface, and degreased with acetone and ethanol, then rinsed with distilled water, and finally dried in drying vessel. The electrochemical impedance investigations and polarization measurements were performed using Autolab electrochemical workstation. A conventional three-electrode glass corrosion cell was used. A saturated calomel electrode (SCE) was used as the reference electrode， a platinum slice which area was 4 cm^2 was used as the counter electrode and the Cu-Ni-Si alloy was used as working electrode. Text medium is a 3.5% sodium chloride solution to make sure the corrosion medium is the same. Before EIS measurements, the specimens should be immersed in medium for 30min at room temperature in order to make sure the test process is stable. For all EIS measurements， an excitation amplitude of 10 mV peak-to-peak was used. The frequency range is from 0.01 Hz to 10 kHz.

Results and Discussion

Metallographic Examination

In order to observe the microstructure of Cu-Ni-Si alloy, metallographic examination is carried out on the surface of the alloy. Figs. 1 show the metallographic images of the Cu-Ni-Si alloy. We can clearly observe the rolling direct and some intermetallic compounds. The grain size is about 10~20μm.

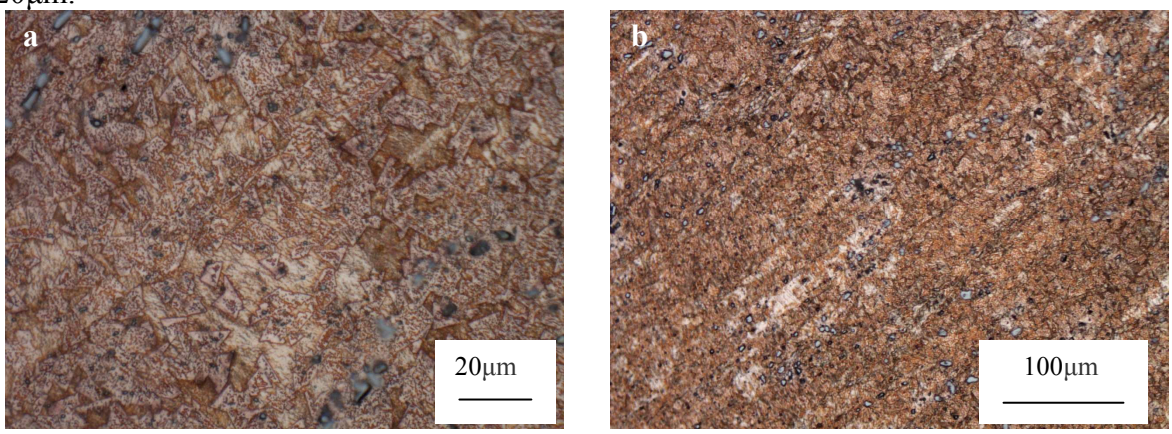

Fig.1. Metallographic structure of the Cu-Ni-Si alloy (a. 200× b. 100×)

Electrochemical Impedance Spectroscopy

Electrochemical impedance spectroscopy (EIS) is a powerful, non-destructive electrochemical technique for characterizing electrochemical reactions at the metal/electrolyte interface and the formation of corrosion products. Impedance spectra are normally displayed either in the form of a Nyquist (i.e., complex plane) plot or a Bode plot [9].Herein, impedance spectra of Cu-Ni-Si alloy immersed in medium with and without bacterial are recorded at the open circuit potential after 1, 2, 3, 4, 5, 6, and 7 days to monitor the corrosion behavior of Cu-Ni-Si alloy. Fig. 2 shows the impedance spectra in medium with deep-sea bacterial as a function of time. As shown in Fig. 2a, it is remarkable that the diameters of impedance loops increased first and then decreased with the immersion time from 0 to 7 days, which suggested first increase and then decrease in the corrosion rates of alloy specimen with time. The variation regulation of impedance loop diameters could be attributed to a corrosion produce film formed on the surface of Cu-Ni-Si alloy. At second day, the number of bacterial was the largest, the metabolic products were the most and the biofilm was thick. This suggested that Cu-Ni-Si alloy could form a biofilm during corrosion and the biofilm could improve the corrosion resistance of Cu-Ni-Si alloy. As shown in the phase angel Bode plots, there are two maxima, one located in higher frequency range and the other in the lower frequency range. Two peak

maxima changed to one from fifth day, this is because the number of bacterial decreased slightly and the biofilm became thinner with time.

The impedance spectra in medium without deep-sea bacterial after different immersion time were illustrated as Fig.3. The diameters of impedance loops fluctuated and the number of maxima varied between one and two. This demonstrated that the Cu-Ni-Si alloy immersed in the abiotic medium did not form biofilm on the surface. So the corrosion rate of alloy did not decreased with immersion time.

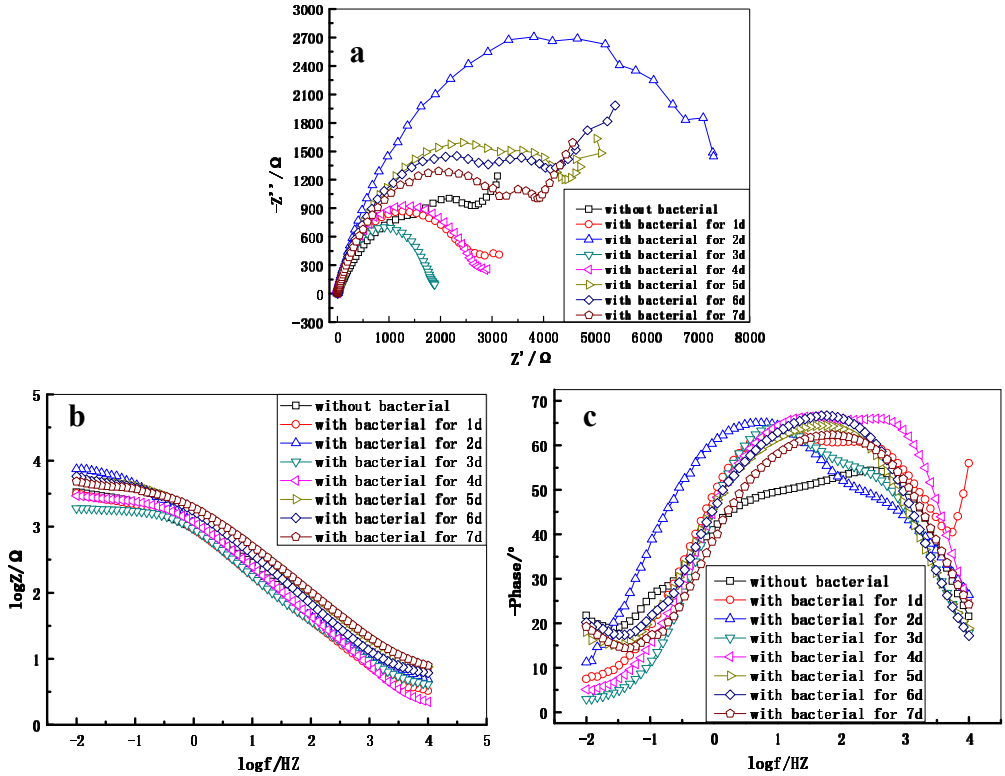

Fig.2. Impedance spectra of the Cu-Ni-Si alloy recorded at the open circuit potential immersed in medium with deep-sea bacterial for 7days (metabolic cycle of deep-sea bacterial)

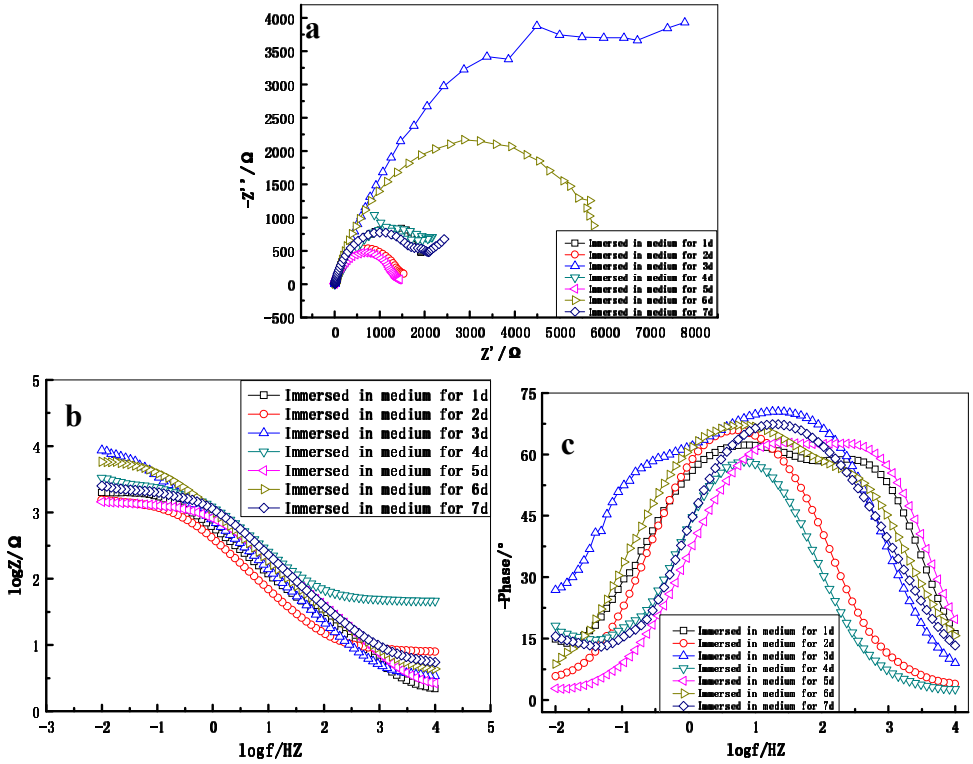

Fig.3. Impedance spectra of the Cu-Ni-Si alloy recorded at the open circuit potential immersed in medium without deep-sea bacterial for 7days

Summary

The corrosion behavior of the Cu-Ni-Si alloy in the absence and presence of a deep-sea bacterial (*Erythrobacter pelagi sp. nov*)in a nutrient-rich simulated seawater based medium as a function of immersion time were investigated using electrochemical methods. The EIS data showed that the corrosion rates of the alloy specimens gradually decreased under the attack of the bacterial cells and its EPS. A patchy or blotchy biofilm was formed on the surface of the alloy and protect inhibit the corrosion of the alloy. While in the abiltic medium, the EIS results showed that the Cu_2O thin oxide film of the alloy was destroyed by chloride ions then the immerged fresh surface was oxidized quickly by oxygen in seawater. The processes of destroy and rebuilt of oxide film occurred continuously, which caused the corrosion resistance of Cu-Ni-Si alloy decreased.

Keywords: titanium alloy, sand blasting and acid etching , corrosion resistance

Abstract. [Objective] The purpose of this study was to evaluate the variation of surface morphology of titanium alloy after sand blasting with different particle sizes of Al_2O_3 sand and acid etching, and its corrosion resistance property. **[Methods]** The surfaces of titanium alloy were first treated with the different sands and then acid etched with mixture of 18% HCl and 48% H_2SO_4. The morphology of samples was investigated by scanning electron microscopy (SEM). The potentiodynamic polarization curves of the various surfaces were obtained by electrochemical workstation (CHI 660E) in simulated body fluid (SBF). **[Results and conclusions]** It is observed that pore sizes on surface increases with the increase of sand grain diameter while there is no obvious change after acid etching. After sand blasting and acid etching, the corrosion resistance of titanium alloy was improved. However, as the pore size of the surface increases, the corrosion resistance gradually degrades and this becomes even more obvious after acid etching. The investigation of the corrosion rate indicates there is an increasing trend with the emergence of small pores.

Introduction

Titanium alloy has a well application prospect in oral medicine due to following characteris：low density，high intensity，suitable thermal conductivity,good biocompatibility and corrosion，no-toxicity，and low mass[1] In recent years,there are researches focus to take titanium alloy as dental implant instead of natural root [2-4]. As an implant, the surface of titanium alloy should be modified with the aim of optimizing osseointegration and stability. Previous studies reported that rough surface was better than smooth surface to increase the mechanical stability of the implant, stimulate cell growth and promote early osseointegration [5, 6]. Sand blasting with acid etching is considered one of the common surface treatment techniques, which has shown great superiority in clinical applications because of increasing the surface roughness and the area contacting with bone [7]. The body fluid is a kind of electrolyte solution containing a variety of organic acid, protein and alkali metal ion, which is a dynamic oxidation environment including protein [8]. After being implanted into the bone, titanium alloy will be immersed in the complex environment for a long time. Under the action of proteins, enzymes and cells, there will produce the corrosion substances such as ions, oxide and chloride around the implant, which contact with adjacent tissue, even infiltrate into the normal tissue or the whole biological system. These factors will affect or stimulate the normal tissue impacting on long-term success rate of implant [9].

Recently, the research of titanium alloy with rough surface mainly focused on the positive aspect of improving osseointegration, while paid little attention to negative effects resulting from the roughing treatment. The study found that the change of titanium alloy surface morphology was likely to

associate with its corrosion resistance. For example, Lautenschlager et al. [10] early evaluated the corrosion behavior of porous metal surface by electrochemistry method. They found that the corrosion resistance property of porous metal was the same with the substrate. And by metal ion dissolution experiments, Cao et al. [11] indirectly proved that the rough surface resulting from sand blasting and acid etching reduced the corrosion resistance property of titanium alloy. At the same time, another [12, 13] reported the different surface roughness could be obtained on the smooth surface of titanium alloy by sand blasting and acid etching. With the increase of surface roughness, its corrosion resistance reduced. Micro-rough surface than macro rough surface had better corrosion resistance. But there were also researchers [14] thought the difference between sand particle diameter and corrosion resistance was no statistical significance. Other relevant researches [15, 16] showed the corrosion rate of the porous implant with higher surface area was higher, but the increase of surface area (5 ~ 10 times) was beneficial to the long-term security of the implant. In this paper, first by sand blasting and acid etching using Al_2O_3 with different particle sizes we produced different rough topography on titanium alloy surface. Then its morphology and structure were analyzed and the corrosion resistance of the different surface was measured by electrochemistry method, aiming to investigate the relationship between the morphology and structure and the corrosion resistance of titanium alloy.

Materials and methods

Preparation of titanium samples

The Ti-6Al-4V were suitably cut into small samples of approximately 10mm× 10mm×1mm and polished using silicon carbide (SiC) papers successively from grade 600, 1000 to1500 grit to remove surface oxidation layer. The alumina (Al_2O_3) particles was loaded into the sandblasting equipment and then titanium alloy surfaces were blasted by alumina (Al_2O_3) particles in the condition of 10cm distance, an incidence angle of 90° and 0.6 MPa pressure for 30s through a blasting nozzle. After treatments, all samples were acid etched with an equal volume of mixed acid solution of 18% HCl and 48% H_2SO_4 (v/v) by immersing in ultrasonic bath for 45min (ultrasonic conditions: temperature 36℃, frequency: 70Hz) and afterwards, the samples were ultrasonic cleaned in distilled water for 10min and then dried by N_2 before using.

Group of experiments

The pretreated titanium alloy samples were randomly divided into four groups: Group 1: Control (Ti). Untreated titanium alloy surface. Group 2: Blasted titanium (S). Divided into three groups, titanium alloy surfaces were blasted by alumina (Al_2O_3) particles with three types of 36#(S36), 60#(S60) and 100#(S100). Group 3: Etched titanium (ATi).Pretreated titanium alloy surfaces were etched with mixed acid solution. Group 4: Sand blasted and acid etched titanium (SA). Divided into three groups, titanium alloy surfaces were blasted by alumina (Al_2O_3) particles with three types of 36#(S36), 60#(S60) and 100#(S100). Next, these blasted surfaces were etched as described above.

Characterization of morphology

The surface morphology of the samples was examined by scanning electron microscopy. In order to improve the electrical conductivity of titanium, gold were produced by sputtering on each sample.

Electrochemical test

Containing 10% fetal bovine serum simulated body fluid (SBF) as medium, the potentiodynamic polarization curves of the various surfaces were obtained by electrochemical workstation (CHI 660E) in simulated body fluid (SBF). The experiment was carried out in the condition of platinum sheet as the auxiliary electrode, saturated calomel electrode as the reference electrode, the samples as the working electrode, initial scan voltage of -2.0V, terminate scan voltage of -0.2V, and scan speed of 0.01V/S. The potentiodynamic polarization curves were obtained by electrochemical workstation and measurement software, to obtain the corrosion potential and corrosion current. At last, we calculated corrosion current density of samples through the formula: corrosion current density = corrosion current / corrosion area.

Results and discussion

SEM

Figure 1 shows the surfaces of sand blasting (S) group and sand blasting and acid etching (SA) group are irregular concave or convex structure resembling crater shape, which of the control group (Ti) are uniform scratches (Fig. 1 a). After sand blasting, the surfaces fluctuate largely. The biger concave pits are up to about 50 microns in diameter (Fig. 1 b); c is less than b, less than 30 microns in diameter; d is less than c, less than 10 microns in diameter. After acid etching, three groups are all visible to the big concave pits inlaid with little secondary pits, and the diameter of secondary pits are about 0.1 ~ 1.0 microns. The surfaces of g and h are obtuse and no gap with honeycomb structure. f shows the excessive concave pits, discontinuous edges. SEM reveals surface concave size obtained by 60# is closest to osteoblast diameter (about 10um), which is most suitable for the growth of osteoblast by previous biology experiments. The roughness has no obvious difference before and after the acid etching, which shows acid etching does not change the rough topography obtained by sand blasting. Combined with Fig.1, the acid etching can make the surface obtuse, and form secondary pitting concaves of 1um average diameter within the primary holes. Zeng et al. [17] investigated the morphology changes of titanium plate after sand blasting and acid etching in HCl/H_2SO_4 mixed acid under 75℃ with 10 to 60 min. They found the etching time of 30min could form 1 ~ 5um small pitting concave in the rough surface obtained by sand blasting, and the surface was uniform.

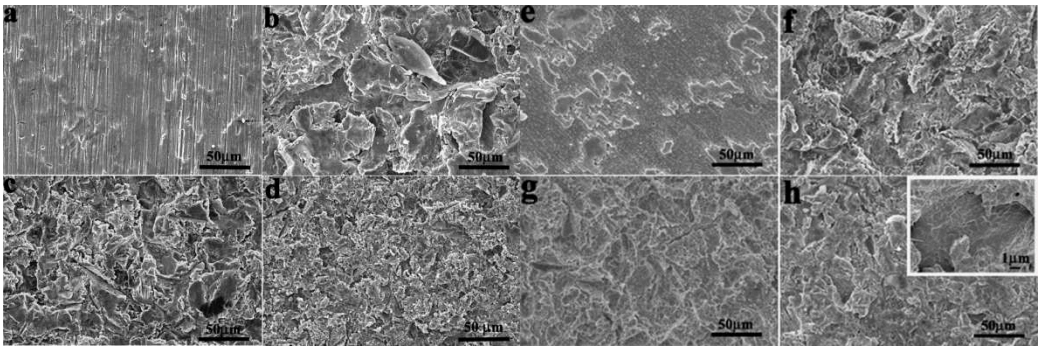

Fig 1 Left: SEM images of Ti alloy after sand blasting with different types of sand. Right: SEM images of Ti alloy after sand blasting and acid etching using 18% HCl and 48% H_2SO_4. ae: control group, bf: 36#, cg: 60#, dh: 100#.

Corrosion Resistance

Fig.2 shows the Tafel curves of titanium alloy in SBF by electrochemical workstation after different treatment. It can be seen that the shape of Tafel curves is basically the same in SBF, which of S60 group is at the right hand side, and ATi group at the left side. The curves of ATi, SA36, SA60 and SA100 are all in the left side of corresponding Ti, S36, S60 and S100. By Tafel curves, the corrosion potential (V) and the corrosion current density (A/cm^2) of different surfaces are figured out, as shown in Tab.1. We find that the negative value of the corrosion potential in S60 group is smallest (-0.9213V). After acid etching the negative values all increase, and ATi group is largest (-1.2893 V). The minimum corrosion current density is 2.874 x 10-6 A/cm^2 in Ti group, which of all groups increase after sand blasting and acid etching and SA36 group is largest (27.425×10^{-6} A/cm^2).

About the phenomenon of metal corrosion, some scholars put forward "model of corroded galvanic cell" [18]. The formation of galvanic cell results in the corrosion of the metal, which weaken the intensity and hardness of implant and also shorten the clinical survivorship. Even the corrosion products make the body produce a variety of adverse reactions, including the local or systemic damage [19]. According to the electrochemical theory，the greater the negative value of corrosion potential, the greater the tendency of metal corrosion, and the greater the positive value of corrosion potential, the smaller the tendency of metal corrosion. Correspondingly, the larger the corrosion current density, the faster the corrosion rate of metal, and the smaller the corrosion current density, the slower the corrosion rate of metal.

The results showed the corrosion resistance of sandblasted samples were better than untreated titanium alloy. In addition, there were no statistical differences between the S60 and S100 group ($P > 0.05$), but both were significantly better than the S36 group. After acid etching, the corrosion resistance of titanium alloy was all significantly weaker, as the ATi group was smallest. When the titanium alloy was acid etched, under the effect of the H^+, there were pitting corrosion reactions, which caused decrease of corrosion resistance and acceleration of corrosion [20]. The corrosion rate of the treated groups was significantly greater than untreated titanium, and with the increase of surface roughness, the speed of corrosion was presented increased trend. Correlation theory [18] has reported most pitting corrosion was occurred on metal materials with passive film or protective film on the surface. When the defective materials were soaked in the electrolyte solution containing the halogen elements such as chlorine, they were more likely to produce pitting corrosion, because the defects of the surface film of the metal were exposed and activated. After acid etching, some small pitting concaves were formed in the passivation film under the effect of acid, thus the corrosion resistance was decreased. Xue et al. [21] investigated the influence of rough surface on metal chemical corrosion, and thought that irregular topography of rough metal surface greatly affected the amount of chemical corrosion reaction thermodynamics, causing or accelerating the chemical corrosion. Li et al. [22] researched the effects of different surface morphologies on metal corrosion and electrochemical behavior and they found that the corrosion rate of the rough surface with small pits is greater, which is consistent with the results obtained in this experiment.

Conclusions

The conclusions of this work are summarized as follows. Different surface roughness can be obtained by using Al_2O_3 with different particle sizes, while there is no obvious change after acid etching. After sand blasting and acid etching, surface morphology and crystal structure are changed, which have an impact on the corrosion resistance of titanium alloy. Corrosion resistance is improved by sand blasting, but with the increase of surface roughness, the corrosion resistance gradually degrades and the decline is even more obvious after acid etching. The investigation of the corrosion rate indicates there is an increasing trend with the increase of surface roughness and emergence of small pores. To conclude, some measures should be taken to avoid corrosion of titanium alloys by simulated body fluid. For this reason， following implantation into oral cavity , implant top should be well protected .

Keywords: Cathodic Protection; anode; jack-up; corrosion

Abstract. Severe corrosion was found on structures and spud leg of "Hai Yang Shi You 931" jack-up drilling unit according to the data of inspection. Some analysis and corrective action was required for Cathodic Protection system. The reason was concluded according to the environmental condition, service life, coating surface area, coating breakdown area, protection surface area and chemical test of anode etc. The electrochemical reaction was rapid suppressed and lost its due utility with the anode was covered by "Sacrifice" product and marine growth. Near the waterline, the oxygen strong bad battery effect was easy to form, and the chance and degree of corrosion occurrence was increased on spud leg.

Introduction

Severe corrosion was found on structures and spud leg of "Hai Yang Shi You 931" jack-up drilling unit according to the data of 2013 inspection. Some analysis and corrective action was required for Cathodic Protection system. But the original calculation sheet and layout plan for Sacrificial Anode system was not found, then the Sacrificial anodes system layout plan that designed by Whale Kapper in 2008 was not approved by CCS and the layout plan for three spud legs was lost. As requirement of client, we carry out inspection, calculation and analysis on anode system of "Hai Yang Shi You 931". According to the environmental condition, service life, coating surface area, coating breakdown area, protection surface area and the type of anode etc., we performed the calculation and assessment for the Sacrificial Anode system of platform and make sure whether the anode is satisfied with the requirement.

Site Survey

Anodes.

There were two types anode on the Spud leg such as shown in fig.1.

Fig. 1 The anode on spud leg and spud can

One was "0"type anode (Size: 55cm×15cm×19cm) which the integrity rate was more than 90%. It was installed on most parts of #1,2,3 spud leg. There were 6 pieces of anode on level poles each layer and installation position was about 50cm from column. Another was "1"type anode (Size: 90cm×12cm×9cm) which the integrity rate was more than 95%. It was only installed on level poles of

6 ~ 12 layer under # 1 spud leg. There were 6 pieces of anode on level poles each layer and installation position was about 65cm from column.

Only one type anodes (size: 150cm×8cm×8cm) were installed on outside surface of three spud can. There some anodes were not found. The corrosion of anodes was more differences in individual.

Fig. 2 Corrosion of jack-up drilling unit

There were two types anode (One: 147cm×5cm×7cm. Another: 20cm ×7cm×15cm) inside spud can. The corrosion of anodes was more differences in individual.

Only one type anodes (size: 150cm×8cm×8cm) were installed on the frame of submersible pump. The corrosion of anodes was more differences in individual.

Site Survey Illustration for Construction Coating

Antiseptic treatment for serious corrosion was performed near the waterline of spud leg. Because the surface of the spud leg was covered by marine growth within approximately 10 meters above spud can, the intuitive judgment should be not taken for the coating condition. The surface coating was in good basic condition on the rest part of the spud leg underwater. The pitting, caviation was found on several coating damage of the pipe. The coating outside spud can was in good basic condition and the obvious corrosion was not found. The mostly surface was covered by rust inside spud can, but the obvious pitting, caviation was not found. The coating of the submersible pump frame was in good basic condition and the obvious corrosion was not found.

The Sampling Introductions.

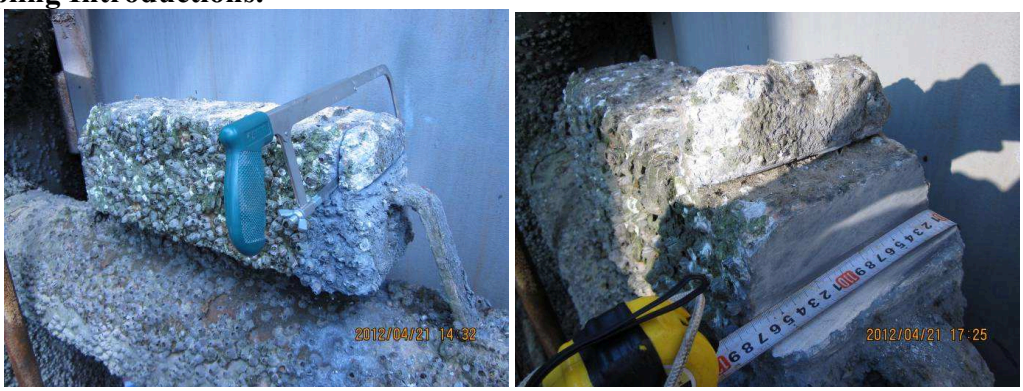

Fig. 3 The sampling of anodes

The "0"type anode on #3 spud leg was random sampled by hand saw. (number:931-0)

The "1"type anode on #1 spud leg was random sampled by hand saw. (number:931-1)

Analysis

Observational Check on Coating

The coating was general in good condition under water, but the obvious corrosion was found on several coating damage.

The main protection was provided by coating for the hull.

The obvious corrosion was found on splash zone.

The coating was damage easily for impacted by wave flow on splash zone.

In the air, sea water near the oxygen strong bad battery effect was formed, and the corrosion was increased on spud leg.

Near the waterline or seafloor, the oxygen strong bad battery effect was also formed due to some places attached marine growth and some places not attached on the spud leg, thus the corrosion was increased.

Check on the Remaining Quantity of Anodes.

A. The anode on spud leg was not obviously consumed and the Integrity rate was more than 90%. According to the calculation, the "0"type anodes lifetime was 15.2 years and the "1"type anodes lifetime was 7.37 years.

The 931 platform has been worked 10 years from 1993, the integrity rate of the mostly anodes should be 0~50% because some anodes was only replaced in 2008 and the others was original.
The actual consumptions of these anodes ("0"type and "1"type") was not satisfied with the design and the rules.

The anodes near the region where the serious corrosion was found after the coating damage on spud leg was not obvious consumed and cathodic protection was not provided.

B. The corrosion situation of anodes outside spud can were more differences in individual and integrity rate was 70~95%.

The anode lifetime was 14.6 years in the position. The integrity rate should be 75% after it served 4 years.

The actual consumption of these anodes was corresponded to the code and did not see the obvious flaws.

C. The corrosion situation of anodes inside spud can were more differences in individual and integrity rate was 0~95%.

The anode lifetime was 4 years in the position. The anodes should be exhausted after it served 4 years.

The actual consumption of these anodes was corresponded to the expectation.

D. The corrosion situation of anodes on the submersible pump frame were more differences in individual and integrity rate was 0~90%.

The situation of these anodes was similiar to that outside spud can. At present the integrity rate should be 75%.

The anodic dissolution was nonuniform for the environmental factor (the position was difference, for example, meet the water, negative side water etc.) was differences.

Electric Potential Inspection Underwater

Anode: -1068~ -1026mv，metal base: -1017~ -970mv.

The electric potential was normal range. In clearing the surface attachments of the anode, potential detection data showed that the anode protection system is in normal operation condition.

Chemical Composition of the Sample

The anode samples was submitted to Guangzhou mechanical and electrical industry physical and chemical measurement center, and material chemical component test was completed, the results such as shown in table 1

TABLE 1 ANODE CHEMICAL COMPOSITION

composition	Zn	In	Cd	Sn	Mg	Ti	Si	Fe	Cu
Inspection Results	4.1~ 4.5	0.008~ 0.0095	<0.01	<0.002	0.003	0.004	0.066	0.063~ 0.079	0.0051
Normal value(scope)	4.0~ 7.0	0.02~ 0.05	-	-	0.5~ 1.5	0.01~ 0.08	<0.1	<0.15	<0.01

The chemical composition of the "0"type anode was closed to the "1"type anode, but it was not c with five types Al-Zn-In sacrificial anode that approved by the national standard

If the anode impurities such as Si, Fe were too much, they could make the anode surface oxidation product not easy to fall off, and then the anodic dissolution was uneven. And indium In was the main elements of aluminium alloy anode, it could partly suppressed the bad influence of the

electrochemical properties caused by Si, Fe of anode impurities. But the sample chemical composition analysis results showed that content of indium In was quite low.

Electrochemical properties test of the sample

TABLE 2 THE RESULTS OF ELECTROCHEMICAL PROPERTIES

	open circuit potential	working potential	actual electric capacity	current efficiency	Consumption rate	Dissolution status
Inspection Results	-1.125 ~ -1.113V	-1.125 ~ -1.055V	2613～ 2631Ah/kg	90.4~ 91.0%	3.35 kg/(A·a)	dissolve uneven
Normal value (scope)	-1.18 ~ -1.10V	-1.12 ~ -1.05V	≥ 2600Ah/kg	≥90%	≤3.37 kg/(A·a)	dissolve even, product easy to fall off

The related performance and parameters of the "0"type and "1"type anode were corresponded to requirements of the rules.

Because the sample anode dissolution was uneven and oxidation product was not easy to fall off, the anode protection ability was rapid decline with the time passing.

Summary

The "0" type and "1" type anodes were not standard type aluminum alloy anode. "Sacrifice" product of the anode was uneven dissolved and not easy to fall off. The electrochemical reaction was rapid suppressed and lost its due utility with the anode was covered by "Sacrifice" product and marine growth. Therefore, normally, the above two kinds of sizes, aluminum alloy anode couldn't meet the practical requirements. In addition, other parts of the anode material were unknown, actual effect had not seen the obvious flaws.

For the splash area was relatively serious corrosion phenomena, we think that we should pay attention to the following factors:

The coating (especially poor quality) was easy to damage when it was impacted by the wave flow.

Near the waterline, the oxygen strong bad battery effect was easy to form, and the chance and degree of corrosion occurrence was increased on spud leg.

Near the waterline or seafloor, the oxygen strong bad battery effect was also formed due to some places attached marine growth and the others not attached on the spud leg , thus the corrosion was increased.

Keywords: pipeline steel; near-neutral pH stress corrosion cracking; electrode potential; soil type; X60

Abstract. The effects of soil type of Shanghai and electrode potential from cathodic protection point on near-neutral pH stress corrosion cracking (SCC) behavior of pipeline steel X60 has been investigated for structural integrity assessment. The SCC behavior was evaluated through slow strain rate tests (SSRT) at various electrode potentials in three solutions containing different typical soils. Results showed that the SCC susceptibility generally increased with decreasing electrode potential in all the three environments, with quick increase happening in the range from -1500 to -700mV(SCE). It is suggested that hydrogen induced cracking should dominate the SCC at low potentials. In cathodic potential range, the rank of the SCC susceptibility for soil type was Near-city soil > Cyan-purple soil > Cyan-yellow soil. In anodic potential range, SCC susceptibility curves mixed each other in the three solutions.

Introduction

SCC from the soil side has become one of the most important issues in the structural integrity of high pressure pipeline, which have resulted in many severe failures of underground pipelines for long distance transmission of gas or oil in the world. The SCC of pipelines is usually divided into two basic forms, that is, high pH SCC occurring in concentrated carbonate-bicarbonate solution and near-neutral pH SCC taking place in dilute carbonate-bicarbonate solutions containing small amount of chloride and sulfate. The latter form was firstly reported in Canada in 1985, with transgranular cracking mode, which has become a common failure mode [1]. Many researches have been attracted to the cracking behavior and prediction methodology. The soil type and electrode potential have been regarded as vital environmental factors in the cracking characterization and prediction, from both academic and engineering points [2-6]) . However, the effects and the mechanism have not been made clear enough. In this work, SCC behavior of X60 used for high pressure gas pipeline network around Shanghai in near-neutral pH soil environments has been studied for structural integrity assessment.

Experimental Procedures

The chemical composition of X60 steel used was (mass %): 0.050C，0.22Si，1.51Mn，0.001S，0.014P，0.044V，<0.02Ti，0.049Nb, 0.042Cr, 0.18Mo and Fe balance. The mechanical properties at room temperature were 650MPa for ultimate tensile strength, 524MPa for yield strength, 18.6% for elongation and 83% for reduction in area (RA). Cylinder specimens with a gauge dimension of Φ4×25 mm were machined from a pipeline in the transverse direction for SSRT

Three soil solutions were prepared for the tests, which were made with deionized water and three types of soils, i.e. Cyan-yellow soil, Cyan-purple soil and Near-city soil, in Shanghai with a ratio of water/soil=1/1 (by weight). All the solutions were kept at 30°C and purged with 5%CO_2 +95%N_2 in tests to simulate near neutral pH environments. Table 1 gives the main chemical characteristics of the soils which were sampled according to soil type distribution and X60 pipeline distribution around Shanghai.

Table 1- Main chemical characteristics of typical soils for X60 around Shanghai

Soil Type	pH[1]	NO_3 [%]	Cl^- [%]	SO_4^{2-} [%]	HCO_3 [%]	CO_3^{2} [%]	Na^+ [%]	All salt [%]	$\Lambda^{2.}$ [MΩ^{1}/cm]	Λ^{3} [MΩ^{1}/cm]
Cyan-yellow soil	8.24	0.000405	0.00345	0.0312	0.0286	Not found	0.00685	0.0823	0.118	0.144
Cyan-purple soil	8.2	0.000368	0.00731	0.0264	0.0274	Not found	0.0112	0.0833	0.142	0.168
Near-city soil	7.76	0.00091	0.00332	0.0912	0.0248	Not found	0.00495	0.154	0.340	0.406

Notes: 1. pH of the solution with a ratio of water/soil: 1/2.5 (by weight);
2. Λ^2, the conductivity of the lixivium with a ratio of water/soil: 1/5 (by weight) ;
3. Λ^3, the conductivity of the mud

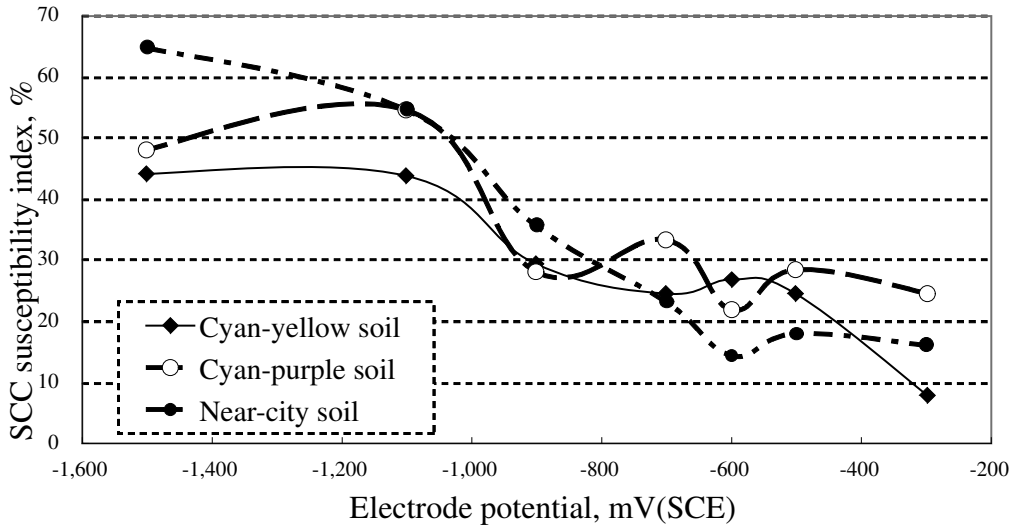
In a test, a saturated calomel electrode (SCE) was used as reference electrode. SSRT was conducted at a strain rate about 1×10^{-6} 1/s. The susceptibility to SCC is expressed by using SCC susceptibility index I_{SCC} ($I_{SCC}=1-RA_S/RA_0$, where RA_S and RA_0 were RA values in solution and in air respectively). The bigger the values of I_{SCC}, the higher the susceptibility to SCC. The fracture surfaces of the tested specimens were examined with optical and scanning electron microscopy. Some specimens were sectioned for further observation of the cracks.

Results and Discussion

Measurements showed that the pH values of the three test soil solutions were reduced into a similar range of 6.1 ~ 6.5. The reduction of pH value as compared with the numbers in Table 1 can be mainly attributed to the continuous purging of 5%CO_2. The corrosion potentials of the steel were in the range of -755~ -720 mV in Cyan-yellow soil solution, in the range of -772~ -723 mV in Cyan-purple soil solution, in the range of -761~ -715mV in Near-city soil solution, respectively.

Effect of electrode potential: The variations of SCC susceptibility index I_{SCC} with electrode potential for the steel in the three soil solutions are shown in Figure 1. In Near-city soil solution and Cyan-yellow soil solution, the susceptibility almost monotonously increased with decreasing electrode potential. Although there were some waves, the susceptibility in Cyan-purple soil solution also basically exhibited similar trend. Fast increase of I_{SCC} happened when potential decreased in the range of -1500 ~ -700mV. The increase tended to be saturated when potentials decreased further.

Examination with scanning electron microscopy showed that the SCC mode was transgranular cracking. Similarly in all the three soil solutions, the SCC cracks produced at potentials typical lower than -700mV were long, deep, in quasi-cleavage type and mainly at 90° to tensile direction, corresponding to high SCC susceptibility. When tested at higher potentials, the cracks were small and mainly at 45° to the tensile direction, corresponding to low SCC susceptibility, as shown in Figure 2.



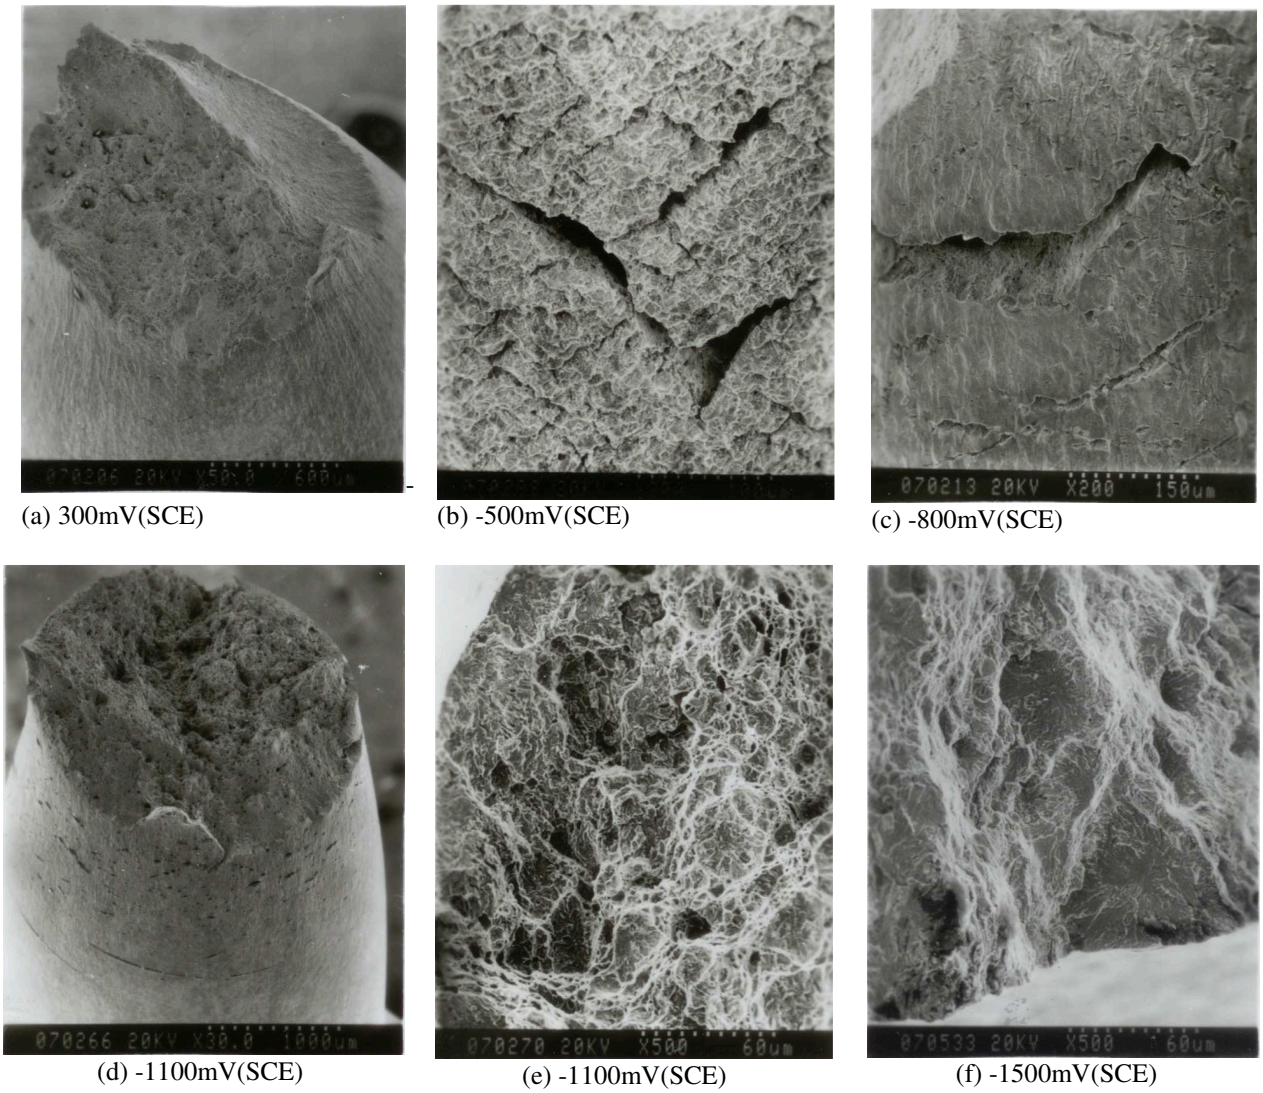


Figure 1. SCC susceptibility index as a function of electrode potential for X60 in three near neutral-pH soil solutions at 30 C

(a) 300mV(SCE) (b) -500mV(SCE) (c) -800mV(SCE)

(d) -1100mV(SCE) (e) -1100mV(SCE) (f) -1500mV(SCE)

Figure 2. Fracture surface morphologies of X60 tested at different potentials in near neutral-pH Cyan-yellow soil solution at 30°C

Above general trend of SCC behavior as a function of electrode potential suggests that hydrogen induced cracking (HIC) should be vital in the cracking mechanism at low potentials. Parkins [7] pointed out that the equilibrium potential for hydrogen discharge ($H_2 = 2H^+ + 2e$), E_{H_2/H^+} or simply

refers to E_H, should be the highest potential for HIC happening system. Based on the pH of the solutions and widely-used Nernst equation, the E_H value was calculated as about -635mV (SCE), as shown in Figure 1, close to the boundary between the low and high SCC susceptibility areas. Based on above results, the cracking mechanism of X60 in the near neutral pH soil solutions is suggested as follows:

When $E \leq EH$ (about -635mV), HIC should be dominant in the SCC, causing the long, deep, 90° cracks and high SCC susceptibility;

When $E > EH$, other mechanism, maybe anodic dissolution, should be important in the SCC, causing the small and 45° cracks and relatively low SCC susceptibility.

From structural integrity point, the parameters of cathodic protection should be carefully optimized in engineering using X60 pipeline steel to avoid possible SCC.

Effect of soil type: It can be seen from Figure 1 that in the cathodic potential range (< -750mV), the I_{SCC} curve for Cyan-yellow soil solution was almost always the lowest, that for Near-city soil solution almost always the highest among the three solutions. In the anodic potential range (> -700mV), three curves for three solutions mixed each other. Presently it is still difficult to explain the complex difference among the SCC behaviors in different soil solutions. However, the results are important for structural integrity assessment of the pipeline buried in the three soils.

Conclusions

1. In three near neutral pH solutions containing typical soils around Shanghai, the SCC susceptibilities of pipeline steel X60 generally increased with decreasing electrode potential. It is suggested that hydrogen induced cracking should dominate the SCC at low potentials.

2. In cathodic potential range, the rank of the SCC susceptibility for soil type was Near-city soil > Cyan-purple soil > Cyan-yellow soil. In anodic potential range, the SCC susceptibility curves mixed each other in the three soil solutions.

Keywords: Iron; Hydrogen; Corrosion; XRD; Raman spectroscopy

Abstract: The effects of charged hydrogen in iron on surface properties of iron in pure water and sodium sulfate solutions of various concentrations were investigsted by open circuit potential monitoring, surface morphology observations, Raman spectroscopy and XRD measurements. Hydrogen in iron shifed the open circuit potential in the negative directions. Hydrogen could change the types of oxide film on iron. Effects of hydrogen on corrosion of iron was More significant in pure water and dilute sodium solutions than those in concentrated solutions.

Introduction

The effects of hydrogen in metal on metallic corrosion and passivation were reported[1-5]. Zeng et al. [2] investigated the effect of charged hydrogen on electronic properties of passive film of iron. Hydrogen decreases the pitting resistance and the stability of passive films [4, 5]. In this work, the effects of hydrogen on corrosion behavior of iron in various concentrations of sodium sulfate solutions were studied by open circuit potential monitoring, surface observation, Raman spectroscopy and XRD measurements, for understanding the combined effects of solution composition and hydrogen in metal on corrosion morphology and corrosion products.

Experimental procedures

Pure iron was used in corrosion tests and electrochemical measurements. Pure iron was annealed at 940℃for 2 h before using. The size of working electrodes was 8×8×2.5 mm. The iron electrode was embedded with epoxy resin with an exposed area of 0.64 cm^2 to test solutions. The surface of the iron electrode was grinded to 1500-grit SiC emery paper and then cleaned in ethanol and in acetone prior to the electrochemical measurements. All tests were carried out in naturally aerated sulfate solutions. Hydrogen charging of iron electrodes was performed by applying a cathodic current density of 0.2 mA/cm^2 in 0.5 mol/L H_2SO_4+1g/L thiourea for 1h at room temperature of around 25℃. The hydrogen-charged iron electrodes were lightly polished by 1500-grit emery paper and cleaned by ethanol and acetone before the corrosion tests. Un-charged and hydrogen-charged iron electrodes were immersed in pure water and in 10^{-4} to 0.5 mol/L Na_2SO_4 solutions for 21 h. Open circuit potentials (OCP) during the immersion tests were monitored by an electrochemical workstation with saturated calomel electrode (SCE) as the reference electrode. The potentials were cited versus SCE. After the immersion tests, the specimens were taken out carefully to keep the corrosion product in the original condition. XRD and Raman spectroscopy measurements were used to characterize the corrosion products formed on iron electrodes after corrosion immersion tests.

Results and discussion

The surface morphologies, open circuit potential versus immersion time, Raman spectra and XRD patterns of uncharged and hydrogen-charged iron electrodes after the immersion tests in pure water, 10^{-4} mol/L Na_2SO_4, 10^{-3} mol/L Na_2SO_4, 10^{-2} mol/L Na_2SO_4 and 0.5 mol/L Na_2SO_4, solutions for 21 h are shown in Figs. 1-20. Results in Figs. 3, 6, 13 and 18 showed that the OCP of un-charged iron moved in the negative direction with increasing immersion time, while the OCP of

hydrogen-charged iron moved in the positive direction with increasing immersion time. The OCP of hydrogen iron was more negative than that of un-charged iron. The difference between OCP (uncharged) and OCP (hydrogen-charged) decreased with time. After 21h immersion test, OCP values of uncharged iron and hydrogen-charged iron in 10^{-4} to 0.5 mol/L Na_2SO_4 solutions, while in pure water the OCP of hydrogen-charged iron were still more negative than that of un-charged iron.

Figures 1,2, 4, 5, 9-12, 16 and 17 showed that charged-hydrogen in iron significantly affected the surface morphologies of iron after immersion tests. After 21h immersion in pure water, un-charged iron only showed several local corroded sites of yellow color while the hydrogen-charged iron was mainly covered by a dark surface layer with local yellow sites of rusts (Fig. 1 and 2). After 21 h immersion in 10^{-4} mol/L Na_2SO_4 solution, the un-charged iron was partly covered with yellow corrosion rusts and partly bright, and the hydrogen-charged iron was mainly covered with a dark layer with several bands of yellow rusts (Figs. 4 and 5). After 21 h immersion in 10^{-3} mol/L Na_2SO_4 solution, the un-charged iron was mainly covered with yellow corrosion rust sites, and the hydrogen-charged iron was partly covered with a dark layer and partly covered with yellow rusts (Figs. 9 and 10). After 21 h immersion in 10^{-2} mol/L Na_2SO_4 solution, the un-charged iron was partly bright and partly covered with a brown rust layer, and the hydrogen-charged iron was mainly covered with a brown layer with several yellow regions (Figs. 11 and 12). After 21 h immersion in 0.5 mol/L Na_2SO_4 solution, the un-charged iron was partly bright and partly covered with a yellow rust layer, and the hydrogen-charged iron was fully covered with a yellow rust layer (Figs. 16 and 17). The effect of hydrogen on the surface morphology of iron after the immersion was more significant in pure water or in dilute Na_2SO_4 solutions.

The results of Raman spectra and XRD patterns for the surface films on iron electrodes after immersion tests are summarized in Table 1. Published XRD and Raman spectroscopy data were referred [6-11]. It should be noted that Raman spectra reflected mainly the near-surface film information, and XRD pattern could reflect the information deeper into the oxide film. Raman spectra data in Fig. 7, 14 and showed that near-surface films formed on un-charged iron in 10^{-4}, 10^{-2} and 0.5 mol/L Na_2SO_4 solutions belonged to the same type, a kind of ferric oxide like γ-FeOOH. In 0.5 mol/L Na_2SO_4 solution, the type of the near-surface film formed on hydrogen-charged iron was similar to that formed on un-charged iron. The type of the near-surface oxide formed on hydrogen-charged iron in 10^{-4} mol/L Na_2SO_4 solution was similar to that in 10^{-2} Na_2SO_4 solution, which was likely magnetite. XRD results showed that the types of oxide films formed on un-charged iron and hydrogen-charged iron in 10^{-4} mol/L Na_2SO_4 solution were different, where a strong peak at for the oxide film on hydrogen-charged iron was observed (Fig. 8). The XRD patterns in Figs. 15 and 20 showed that the oxide films formed on un-charged and hydrogen-charged iron specimens in 0.5 mol/L Na_2SO_4 solution were a similar type that was close to γ-Fe_2O_3.

TABLE 1 RAMAN SPECTRA AND XRD DATA FOR THE SURFACE FILMS ON IRON AFTER IMMERSION TESTS

Immersion solution	Types of measurements	Characteristic peaks for surface films on	
		Un-charged iron	Hydrogen-charged iron
10^{-4} mol/L Na_2SO_4	Raman shit (cm^{-1})	250(I), 374(II), 525(IV), 644(III)	215(III), 282(II), 390(I), 591(IV)
	XRD (degree)	44.6(I*),64.8(III*), 82.4(II*)	35.3(II), 43.0, 44.5(I), 57, 62.5, 64.9(IV*), 82.4(III)
10^{-2} mol/L Na_2SO_4	Raman shift (cm^{-1})	216, 251(I), 378(II), 527(III), 653(IV)	221(II), 250(IV), 290(I), 394(I), 608, 668(III)
	XRD (degree)	35.4(III), 44.6(I),82.4(II)	35.3(III), 36.6, 44.5(I), 65(IV), 82.4(II)
0.5 mol/L Na_2SO_4	Raman shift (cm^{-1})	218, 251(I), 308, 351, 380(II), 528(III), 650	218, 251(I), 308, 351, 380(II), 528(III), 650
	XRD (degree)	44.5(I), 64.8(III), 82.3(II)	36.2(III), 44.6(I), 64.9(IV), 82.4(II)

Peak intensity decreased with increasing number I, II, III and IV. Some peaks with similar intensities are assigned the same number. The XRD peak at 44.5° corresponded to iron.

Conclusions

Hydrogen decreased the open circuit potential of iron in sulfate solutions. Hydrogen accelerated the corrosion of iron in pure water and sulfate solutions at 25 °C. Hydrogen changed the types of near-surface oxide films formed on iron dilute sulfate solutions. In concentrated sulfate solutions, the oxide formed on uncharged and hydrogen-charged iron electrodes were close. The effect of hydrgon on corrosion varied with the solution compositions.

Keywords: Copper; Corrosion; Gemini surfactant; Electrochemical; XPS

Abstract: A new gemini surfactant containing long chain alkyl ammonium headgroups have been used as corrosion inhinbitor for copper in 3.5% NaCl solution. The weight loss and electrochemical methods results showed that presence of inhibitor greatly decrease corrosion rate, gemini surfactant acted as an excellent corrosion inhibitor with inhibition efficiency greater than 96% at an optimum concentration of 30 $mg \cdot L^{-1}$. X-ray photoelectron spectroscopy reveals that the gemini surfactant molecules adsorb onto the copper surface through the two ammonium head groups (N^{+}).

Introduction

Copper has been one of more important materials in industry owing to its plenty of favourable properties, such as high electrical and thermal conductivities, mechanical workability and its relatively noble properties. It is widely used in many applications in electronic industries and communications as a conductor in electrical power lines, pipelines for domestic and industrial water utilities including sea water, heat conductors, heat exchangers, etc. Therefore, corrosion of copper and its inhibition in a wide variety of media, particularly when containing chloride ions, have attracted the attention of many investigators [1–4]. So far, the use of organic inhibitors to protect copper is one of the most important methods. Organic compounds containing polar groups including nitrogen, sulfur, oxygen [5–7] and heterocyclic compounds with polar functional groups and conjugated double bonds [8,9] have been reported to inhibit copper corrosion. The inhibiting action of these organic compounds is usually attributed to their interactions with the copper surface via their adsorption.

Different from conventional inhibitors, gemini surfactant is composed of two hydrophilic head groups and two hydrophobic chains, separated by rigid and flexible aromatic or aliphatic spacers. Due to the special chemical structure of these components, it has been demonstrated that the novel surfactants are more efficient at reducing surface tension and forming micelles than inconventional ways and have lower critical micelle concentration (CMC) [10]. In recent years, gemini surfactants have become the focus of study [11,12]. In most of the available literature, gemini surfactants have been studied as corrosion inhibitors for carbon steel in hydrochloric acid and sulphuric acid solutions [13]. Those works showed that they were excellent corrosion inhibitors.

The purpose of the present research is to prove the hypothesis that cationic gemini surfactant with long chain alkyl ammonium headgroups, which was synthesized by us as shown in Fig. 1, inhibit corrosion of copper when immersing in 3.5% NaCl solutions. The study has been carried out by using potentiodynamic polarization measurement, electrochemical impedance spectroscopy (EIS), weight loss measurements and XPS.

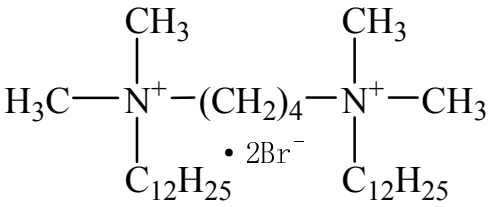

Fig. 1 The structure of gemini surfactant

Experiment

Gemini surfactant was dissolved in 3.5% NaCl solution at various concentrations from 10 mg/L to 100 mg/L, and the solution without gemini surfactant was taken as blank for comparison.

Specimens were mechanically cut into 5.00 cm × 2.50 cm × 0.4 cm (used in the weight loss experiment) and 1.0 cm × 1.0 cm × 1.0 cm (used in the electrochemical experiment) dimensions, abraded with SiC abrasive papers up to 800 grade, washed in distilled water, degreased ultrasonically in acetone, and dried at room temperature.

Electrochemical experiments

Electrochemical experiments were performed in a conventional three electrodes system, copper sealed by epoxy resin with exposure surface of 1 cm^2 as working electrodes, a platinum foil of 1.0 cm×1.0 cm as counter electrode, and a saturated calomel electrode (SCE) provided with a Luggin capillary as reference electrode.

EIS measurement was carried out on steady state open circuit potential (OCP) disturbed with amplitude of 10 mV a.c. sine wave at frequencies from 100 kHz to 10 mHz. The inhibition efficiency (η_R%) obtained from EIS measurement was calculated by

$$\eta_R\% = \frac{R_{ct} - R_{ct}^0}{R_{ct}} \times 100 \quad (1)$$

R_{ct} and R^0_{ct} are polarization resistances in the presence and absence of different gemini surfactant, respectively.

The potentiodynamic polarization curves were obtained from −250 mV (SCE) versus OCP to +250 mV (SCE) versus OCP with a scan rate of 0.5 mV/s. The obtained inhibition efficiency was calculated by

$$\eta_i\% = \frac{i_{corr}^0 - i_{corr}}{i_{corr}^0} \times 100 \quad (2)$$

Where i_{corr} and i^0_{corr} are the corrosion current with and without different gemini surfactant, respectively.

Weight loss experiment

Copper specimens in triplicate for each inhibitor concentration were immersed in the test solutions for 14 d at 298 K. After that, the specimens were scraped, rinsed in water and acetone，and dried in a desiccator. Finally, the loss in weight was determined with analytic balance.

XPS analysis

XPS measurement was carried out on a Thermo ESCALAB 250 photoelectron spectrometer equipped with an Al-anode at a total power dissipation of 150 W (15 kV, 10 mA).

Results and Discussion

Weight loss measurements

Table 1 shows the weight loss values of copper in the test solution in the absence and presence of gemini surfactant.

TABLE 1 THE RESULTS OF WEIGHT LOSS EXPERIMENT

	Concentration [mg L^{-1}]	Corrosion rate [mg cm^{-2} h^{-1}]	η_w%	Θ
Blank	0	1.1071	—	—
Inhibitor	10	0.0713	93.6	0.936
	20	0.0548	95.1	0.951
	30	0.0415	96.3	0.963
	50	0.0443	96.0	0.960
	100	0.0489	95.6	0.956

It can be clearly noticed from Table 1 that gemini surfactant can prevent copper from corrosion efficiently in 3.5% NaCl solution. Their inhibition efficiencies (η_w%) were higher than 96% at the concentration of 30 mg·L^{-1}.

The results in Table 1 also show that inhibition efficiency increases along with the additive concentration of gemini surfactant rising when the gemini surfactant concentration is lower than 30 mg·L^{-1}. However, such increase of concentration does not affect inhibition efficiency significantly, suggesting that a saturated adsorption of surfactant molecules on copper surface is achieved.

Electrochemical impedance spectroscopy (EIS)

The inhibitive performance of gemini surfactant on copper immersed in 3.5% NaCl solution was studied via EIS at 298K. The impedance results were plotted in Fig. 2.

The EIS parameters were calculated by analyzing the impedance plots fitting the equivalent circuit as mentioned in Fig. 3, where R_s is the solution resistance, R_f is the film resistance, R_{ct} presents the charge transfer resistance, CPE_1 and CPE_2 represent the constant phase elementsused to replace the film capacitance (C_f) and double layer capacitance (C_{dl}), respectively, and n shows the phase shift that can be explained as the degree of surface in-homogeneity. The value of the parameters was tabulated in Table 2.

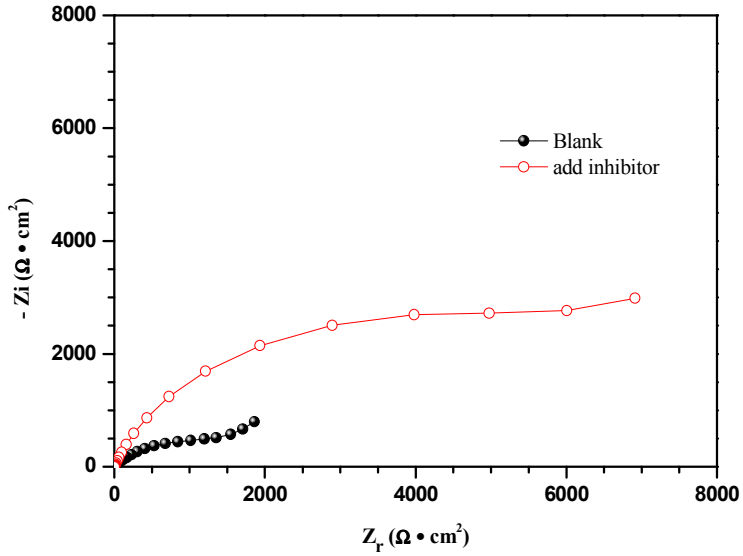

Fig. 2 EIS plots of copper in 3.5% NaCl with gemini surfactant at 30 mg/L

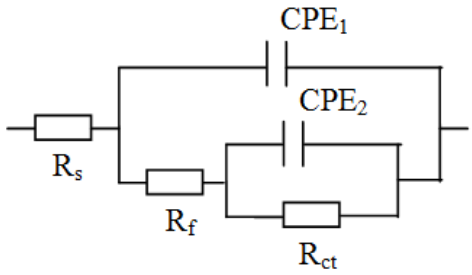

Fig. 3 The equivalent circuit of the Nyquist plot

TABLE 2 IMPEDANCE DATA OF COPPER IN 3.5% NACL WITH GEMINI SURFACTANT AT 30 MG·L-1

Inhibitor	R_s [Ω cm^2]	R_{ct} [Ω cm^2]	C_{dl} [μF·cm^{-2}]	n_1	R_f [Ω cm^2]	C_f [μF·cm^{-2}]	n_2	η_R%
Blank	2.041	1109	475	0.92	87.2	148	0.26	—
Inhibitor	2.256	11840	57.2	0.97	794.3	11.2	0.62	90.6

It can be seen that the values C_f and C_{dl} exhibit a decreasing tendency with adding the inhibitor, which can result from a decrease in local dielectric constant and/or an increase in the thickness of the electrical double layer, suggesting that the surfactant molecules act by adsorption at the metal/solution interface [14]. As a result, the diffusion process of ions from the interface to the solution involved in active corrosion is probably to be retarded.

Polarization curve

Fig. 4 shows the typical polarization curves for the inhibition characteristics of gemini surfactant at the optimum concentration of 30 mg·L^{-1} in 3.5% NaCl solution. The electrochemical parameters E_{corr}, i_{corr}, anodic and cathodic Tafel slopes (β_a, β_c) obtained from polarization measurements are listed in Table 3.

Table 3 and Fig. 4 reveals that: (i) the values of E_{corr} shift toward more negative potential and the values of i_{corr} decreases sharply after adding the gemini surfactant. Such decreas indicates the inhibiting effect of the gemini surfactant, (ii) compared with the blank, the values of Tafel slopes

(β_c and β_a) become larger. This means that the gemini surfactant are mixed type inhibitor which preferentially reretard the anodic process of corrosion.

TABLE 3 POLARIZATION PARAMETERS FOR COPPER IN 3.5% NACL SOLUTION WITH GEMINI SURFACTANT AT THE OPTIMUM CONCENTRATION OF 30 MG·L-1

Inhibitor	E_{corr} [mV/SCE]	i_{corr} [μA·cm^{-2}]	β_c [mV·dec^{-1}]	β_a [mV·dec^{-1}]	η_i%
Blank	-218	4.52	177.2	47.6	—
Inhibitor	-265	0.25	220.1	119.1	94.5

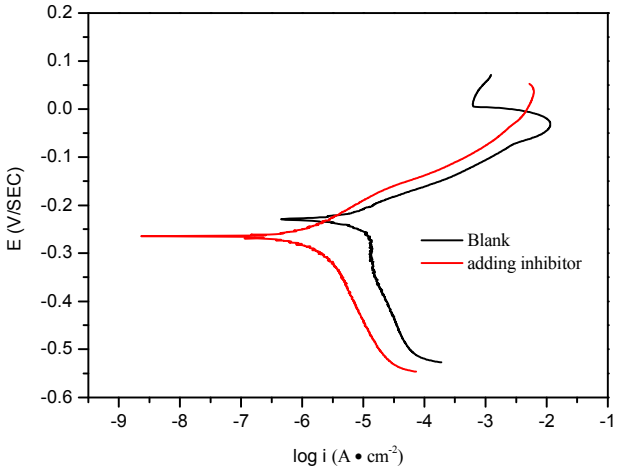

Fig. 4 Polarization curves for copper in 3.5% NaCl with gemini surfactant at 30 mg/L

XPS analysis

In order to find out the adsorption activity area and adsorption mechanism of gemini surfactant, high resolution of XPS spectra of N1s (Fig. 5) regions was recorded to reveal its chemical states. Gemini surfactant located at 399.8, 400.81 eV were used to fit the spectrum. The peaks of the gemini surfactant appeared at higher position than the above values because the coordination bonds between functional group with copper surface brought out the peak shifts to higher binding energy appeared at 399.8 eV [15]. The peak located at binding energy of 400.81 eV has the highest contribution and is mainly attributed to nitrogen in the ammonium group [15].

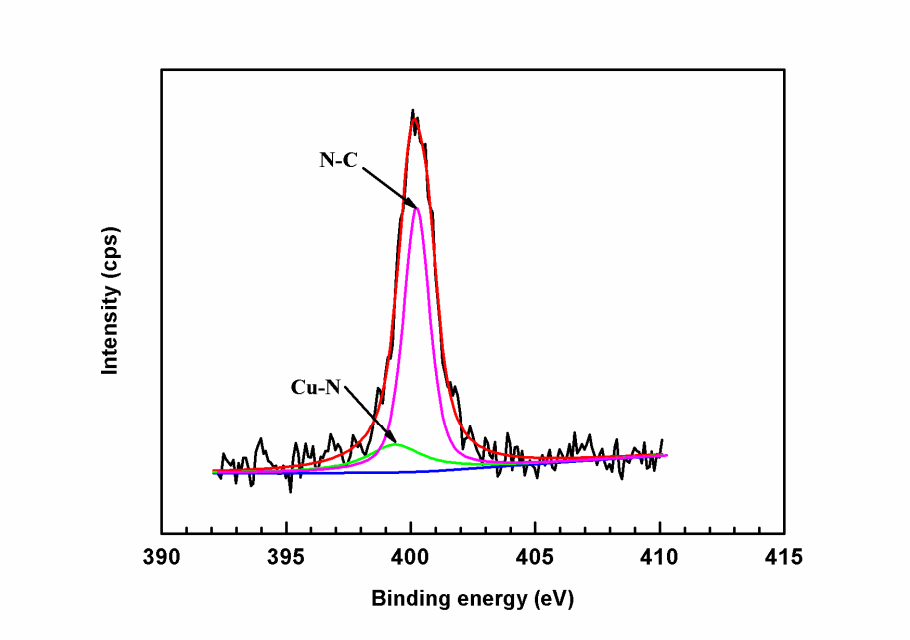

Fig. 5 High-resolution XPS spectra of N1s of copper obtained after 3 h immersion in 3.5% NaCl solution.

Inhibition mechanism

Although the adsorption of gemini surfactant on the copper surface is complicated because the gemini surfactant contain two hydrophilic groups and two hydrophobic groups, the above results enable the authors to propose a relatively simple inhibition mechanism, as Fig. 6 shows.

In 3.5% NaCl solution, Cl^- or $CuCl_2^-$ ions may be preferentially adsorbed on copper surface thereby, making the surface negatively charged. Then, the two quaternary ammonium headgroups (N+) of gemini surfactant molecules could be absorbed on the layer of adsorbed anions by an electrostatic interaction. Subsequently, chemisorption may take place. As a result, the tight adsorbed layer of gemini surfactant on the copper surface can isolate the corrosive media and retard the corrosion reaction.

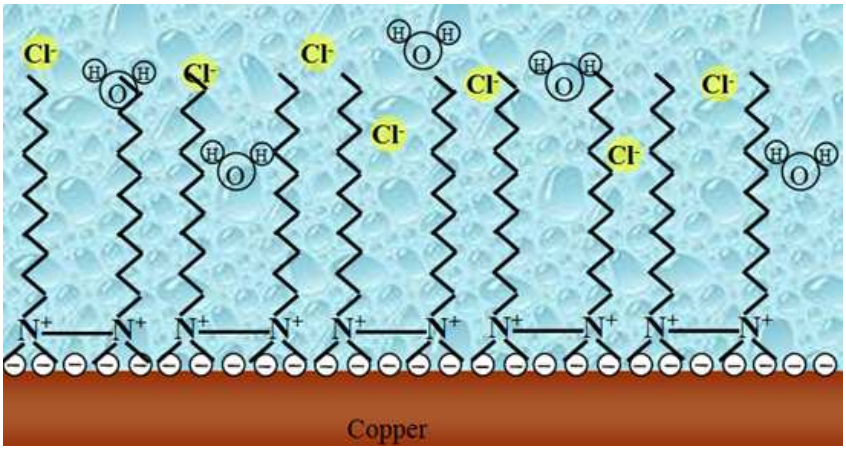

Fig. 6 Proposed adsorption model for the inhibition mechanism of gemini surfactant.

Conclusion

The inhibiting efficiency of the gemini surfactant for copper in 3.5% NaCl solution is higher than 96% at 30 $mg \cdot L^{-1}$ additive concentration. The electrochemical measurements indicate that the gemini surfactant is mixed type inhibitor which preferentially restrain the anodic process of corrosion. XPS analysis revealed that the effect of gemini surfactant is due to adsorption of the two quaternary ammonium headgroups (N+) of gemini surfactant molecules.

Keywords: Ion implantation, M50NiL, Corrosion resistance

Abstract. The corrosion resistance of metal-N double-element alternate implanted M50NiL bearing steel was investigated by potentiodynamic polarization and detection methods of SEM, XPS, AES and TEM. The results showed that ion implanted M50NiL can increase the corrosion potential of substrate, reduce the corrosion active points and inhibit the corrosion reaction induced at the grain boundaries. The formed amorphous layer and strengthening phases take main roles in improving the corrosion resistance of M50NiL bearing steel.

Introduction

As a novel bearing material, M50NiL can exhibit higher structure strength [1]. However, the preservation and operation of aero bearings are often in water, oil and corrosive environment containing S^{2-} and Cl^{-}. Corrosion failure becomes one of the main failure forms of bearings under marine environment.

Ion implantation is an effective technique to improve the surface properties of metal materials. Many elements have been applied as implanted ions in increasing the corrosion resistance [2-5]. Previous studies show that N/Zr and N/Ti ions co-implantations could significantly improve the wear resistance and contact fatigue strength properties of M50NiL materials. However, to our knowledge, the reports of improving the corrosion resistance property by using ion implantation on M50NiL materials are few.

Therefore, in this paper, M50NiL steel was respectively co-implanted with N/Zr and N/Ti ions by using double-element alternate implantation. The potentiodynamic polarization test was performed to investigate the effect of ion implantation on the corrosion resistance. To analyze the corrosion resistance mechanism, SEM, AES, GXRD, XPS and TEM tests were carried out.

Experimental

The chemical composition of M50NiL steel is shown in Table 1. The M50NiL specimens were prepared as cylindrical piece with about 20mm in diameter and 8mm thick. Specimens were polished and ultrasonically cleaned before implantation. The original M50NiL material is composed of fine dispersed granular carbides and super fine martensite phases.

TABLE 1 ELEMENTS COMPOSITIONS OF M50NIL STEEL

Elements	C	Cr	Ni	Mo	V	Mn	Si	P	S
Weight percentage/%	0.12	4.00	3.75	4.25	1.10	0.18	0.12	0.15	0.001

During ion implantations, the base vacuum degree was 3.0×10^{-4} Pa. The educed voltage for metal elements (Zr/Ti) was 45 kV, 40 kV, 30 kV and 20 kV. For Nitrogen implantation, the educed voltage was 80 kV. The detailed implanted process and parameters are as follows: firstly, 80 kV for N ion

implantation, then 45kV for metal ion implantation; secondly, 80 kV for N ion implantation, then 40kV for metal ion implantation; thirdly, 80 kV for N ion implantation, then 30kV for metal ion implantation; finally, 80 kV for N ion implantation, then 20kV for metal ion implantation. The total dose was 4×10^{17} ion/cm^2 and the dose in each step was average.

Electrochemical test was carried out in a equipment using a three-electrode cell system (CHI660D) containing a saturated calomel reference electrode, an assistant Pt electrode (20mm×20mm), and the implanted and non-implanted M50NiL specimens (10mm×10mm) as the working electrode. Specimens were cleaned by anhydrous ethanol and air dried before test. The test solution is adopted as 5wt.% NaCl.

Open-circuit potential (OCP) test was firstly performed and the potentiodynamic polarization was measured when the potential was getting stable (the potential undulation is smaller than 3mV in 120s). Three parallel specimens used for each measurement were polarized at a rate of 20mV/min. The scanning potential range varied from -266mV vs. OCP to 800mV vs. OCP.

Surface morphologies of the test specimens were observed by scanning electron microscopy HITACHI S4800. GXRD was performed by D-MAX-2500 diffraction instrument with the CuKα1 (k =0.154 nm) radiation to analyze phase composition of the specimen. The angle between the sample surface and incident X-ray was set 0.5° and the detector scanned from 10° to 90° at 3°/s. AES was carried out on ULVAC-PHI-700 equipment with the Si sputtering rate of 38nm/min. TEM test was performed using JEOL JEM 2010. Cross section sample was used to observe the structure character at different depths. XPS was conducted using AXIS ULTRADLD instrument with the X-ray source of monochromatic Al target, Al Kα=1486.6eV.

Results and Discussion

Corrosion Results

Fig. 1 and Table 2 show the fitting data of potentiodynamic polarization curves and corrosion parameters for M50NiL substrate and N/Ti, N/Zr double-element implanted specimens (The given value is the mean of three measurements). It is obvious that the corrosion potential of implanted specimen moves toward the anode. It indicates that the thermodynamic trend of corrosion reaction under the system weakens. The average corrosion current density of non-implanted specimen is 5μA/cm^2, while those of implanted specimens are lower, 3~4μA/cm^2. The corrosion resistances of the implanted specimens increase. The polarization current density of implanted specimens with the same anode electrode potential is lower, showing that the implanted specimens exhibit higher anti-solubility in the process of acceleration of anodic dissolution.

TABLE2. FITTING PARAMETERS BASED ON POTENTIODYNAMIC POLARIZATION

Samples	E_{corr}/V	I_{corr}/μAcm^{-2}	Cathodic slope	Anthodic slope
Non-implanted	-0.5220	5.0095	2.8805	12.235
N+Ti implanted	-0.5065	3.4370	2.6385	10.330
N+Zr implanted	-0.4945	3.7938	2.6010	13.289

From the corrosion morphologies (Fig. 2a) of corroded M50NiL samples after electrochemical test, the corrosion of M50NiL substrate occurs mainly in the surrounding of grain boundaries and carbide. The corrosion of implanted samples is mainly pits whose distribution density and size increase with increasing anodic polarization time, as shown in Fig. 2b and 2c. The corrosion products expand and accumulate from the pit inside to outside (Fig. 2d). With the increase of the corrosion products, large cracks occur (Fig. 2e). Similar corrosion process is found in N/Zr co-implanted samples. The implanted elements in the corrosion products are analyzed by XPS. It is found that the implanted elements are mainly in form of TiO_2 and ZrO_2 in the corrosion products Fe_2O_3 or FeOOH, as shown in Fig. 3. Due to the low content of N and organic matter pollution, it is failed to get the information about Ti-N, Fe-N and other substances in the corrosion product. For N/Zr implanted specimen, the Zr element exists in the corrosion product in the form of ZrO_2 from XPS results.

Surface Characterization

Fig. 4 shows the GXRD results for the substrate and implanted samples. Ti_zN compounds are formed on the N/Ti co-implanted specimens. Concerning N/Zr co-implanted samples, Zr-N and Zr-Fe-N form. Fig. 5 shows the concentration-depth distribution of implanted elements in the substrate by using AES technique. The basic elements such as Fe, C, Cr and Mo exhibit similar distribution in the three kinds of M50NiL steels. The concentration peak value of Zr and Ti is consistent, but the Ti concentration peak position for N/Ti implanted sample is obviously deeper than Zr concentration peak position for N/Zr implanted sample. The concentration peak positions of N ions are close to those of metal elements[6]. Under the same N implantation, the concentration exhibits larger difference due to the difference of metal elements, which was consistent with the GXRD peak intensity.

The implantation depth is affected by differences energy and ion radius of ionized state. The concentration-depth profile of N atoms is susceptible to strong nitride forming elements [7-8]. Thus, N atom concentration distribution is mainly affected by the capture of N when forming compounds with Zr/Ti. It further proves that Zr-N and Ti-N compounds form in the concentration distribution region. The same distribution depth of N and Zr is 50nm, while that of N and Ti reaches 250 nm.

In the study of Zr ion implantation into Fe-5%Cr, the zirconium oxide and iron carbide on the implanted substrate are the main factors to improve its corrosion resistance properties [9-10]. In the present study, the corrosion products of implanted metal elements are in form of TiO_2 and ZrO_2. Moreover, after implantation, new corrosion resistant alloy phases, such as various metal nitrides, enrich on the surface structure and can form dense passive film in the corrosive medium to prevent the damage of corrosion medium to the substrate.

and (c) N/Zr Implanted M50NiL Steels

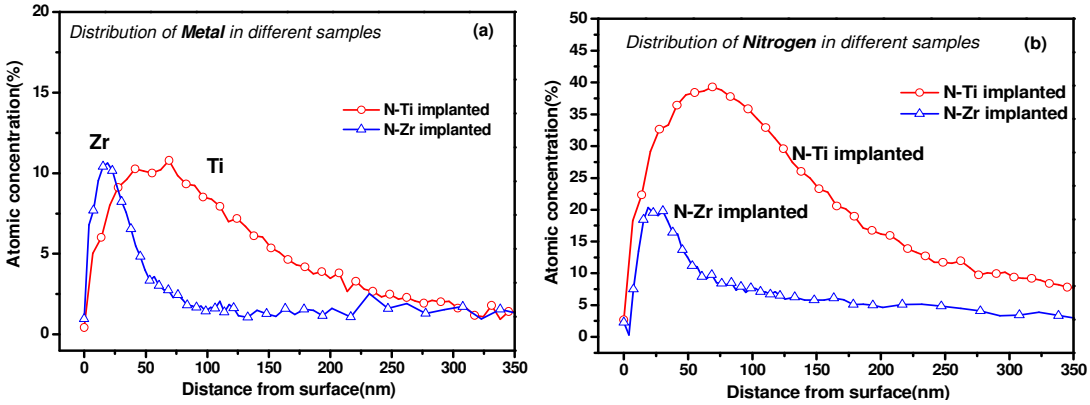

Fig.5 Concentration Profiles of Implanted Elements on M50NiL Specimen by AES

(a) Metal, (b) Nitrogen

Fig. 6 shows high resolution TEM graph of N/Zr implanted sample. An amorphous layer with the thickness of several nanometers appears on the surface. At the same time, certain disturbance of atoms (atom group) with regular arrangement appears in the certain depth, making the arrangement irregular. The implanted particles have the energy of 10~100keV after high speed acceleration. Collision cascades repeatedly occur between the particles with high energy and the substrate surface atoms. Then, energy is transmitted and finally rests in the gap or vacancy of some lattice, even the atoms in the replacement lattice. As the surface is bombarded by large dose or high energy particles, the atoms (atom group) become disordered and ultimately amorphous structure forms.

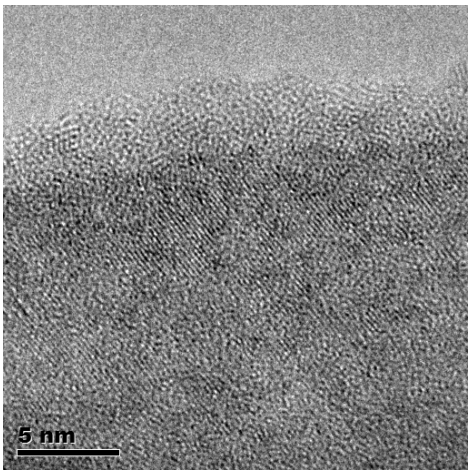

Fig. 6 High Resolution TEM graph of N/Zr Implanted Sample

In terms of surface structure, a layer with amorphous structure[10] is formed in the implanted M50NiL surface. Concerning surface phases, ceramic phases containing nitrogen generate after implantation. In the sense of the rust occurrence time, thermodynamics stability parameters, resistance to anodic corrosion current density and corrosion morphology of grain boundary microstructure, ion implantation improves the overall corrosion resistance of M50NiL substrate by reducing the initiation number of corrosion points, inhibiting grain boundary corrosion and decreasing the corrosion current. It is believed that surface amorphous layer plays the significant role of reducing the number of active sites on the surface and surface energy, while the alloy phases weakening the corrosion strength.

Conclusions

N/Ti and N/Zr ions co-implanted M50NiL can increase the corrosion potential of substrate, reduced the corrosion active points and inhibit the corrosion reaction induced at the grain boundaries to finally enhance the corrosion resistance of substrate.

Amorphous layer and alloy phases are formed on the implantation samples. The surface amorphous layer can reduce the number of active sites on the surface, while the alloy phases can weaken the corrosion strength of substrate.

Abstract: In this study, a improved mathematical model was developed for Nb-Ti microalloyed steel during hot rolling simulation. Using the compression test, the dynamic and static recrystallization characteristics of Nb-Ti microalloyed steel were studied. Though multi-pass hot rolling simulation, it is found that the recrystallization during hot rolling can play an important role, it can make the mean flow stress lower and refine the grains. And respective comparison between calculated and measured data of microstructure showed some of the validation of the built model. Meanwhile, the evolution characteristic of average austenite grain size during hot rolling can be achieved by theoretical model and experiment.

Introduction

Achieving good mechanical properties of the product is important in hot rolling. However, hot rolling is a very complex process, which requires a strict control over a number of different parameters. Meanwhile, there are different complex metallurgical phenomena, such as strain hardening, static and dynamic recovery, static and dynamic recrystallization. Therefore, many workers have studied these complex metallurgical phenomena and have developed equations relating their kinetics to the processing parameters.

Intensive studies recently were carried on simulating multi-pass hot rolling behavior by hot deformation test. Sang Hun Cho[1] established model of flow stress during hot rolling by hot torsion test. M.Umemoto[2] found that the microstructure of austenite just before cooling to room temperature has a major influence on final ferrite microstructure. Therefore, the accurate understand of microstructure evolution in each pass during hot rolling is one of the most important aspects. Manuel Gomez[3] carried out multi-pass continuous cooling hot torsion test observing microstructure evolution during hot rolling. However, the studies did not make us further accurately understand microstructure evolution during hot rolling.

In this work, a improved mathematical model was developed for Nb-Ti microalloyed steel during hot rolling simulation. Multi-pass hot compression tests were used to simulate hot rolling according to the rolling schedule. The flow stress is analyzed and the metallographic each pass is characterized to study microstructure evolution.

Experimental Procedure

Chemical Composition of Experimental Steels

The steel studied was from billet. As Table 1 shows, the steel has 0.06% carbon content and 0.04% niobium and contains 0.013% titanium content. One-pass compression tests were carried out to determine the effects of the deformation variables on dynamic recrystallization. Double-pass compression tests were then conducted over the temperature range 1000-1150℃, inter-pass time range 1-100s, and pass strain range 0.1-0.4. This was done to evaluate the effects of deformation variables on softening.

Table 1 CHEMICAL COMPOSITION OF EXPERIMENTAL STEELS (wt%)

C	Mn	P	S	Si	Al	Nb	Ti
0.06	1.53	0.009	0.002	0.20	0.036	0.04	0.013

Multi-pass hot simulation tests were carried out in a computer-controlled hot compression machine (Gleeble-3500), on specimens with a gauge length of 15mm and a diameter of 10mm. Prior to the compression tests the specimens were austenitized during 5min at 1250℃, a temperature high enough to completely dissolve the Nb precipitates. After reheating, the temperature was lowered to that corresponding to the first deformation pass in each test at cooling rate 5℃/s. Table2 shows resume of the experimental conditions for multi-pass compression testing. After each pass deformation, the sample was immediately quenched to observe the microstructure.

Table2 RESUME OF THE EXPERIMENTAL CONDITIONS FOR MULTI-PASS COMPRESSION TESTING (t inter-pass time)

Pass	1	2	3	4	5	6	7
T(℃)	1130	1125	1119	1108	1101	1092	1083

Results and Discussion

Microstructure Evolution Modeling

For better study of microstructure evolution, the improved mathematical model of microstructure evolution for Nb-Ti microalloyed steel was developed based on Avrami model by one-pass compression test and double-pass compression test.

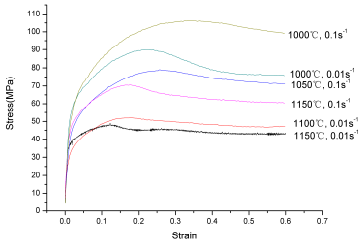

Fig.1.The Typical Stress-Strain Curves for the One-Pass Compression

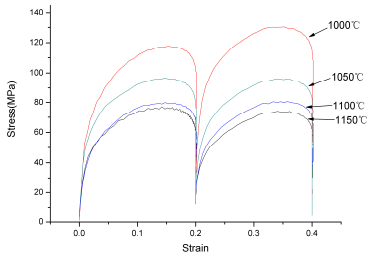

Fig.2 Typical Stress-Strain Curves for the Double-Pass Compression

(t=50s, ε=0.2, $\dot{\varepsilon}$ =1s-1)

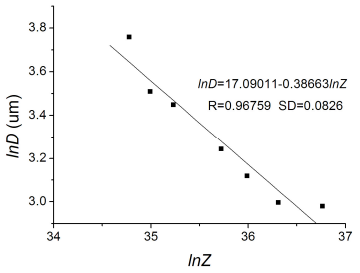

Fig.3 Evolution of Average Austenite Grain Size During Rolling

A)dynamic recrystallization (DRX)

The effect of deformation variables on the flow curves of the one-pass compression test is shown in Fig.1. This was further confirmed by an analysis of the effect of the deformation conditions on peak stress using the hyperbolic sine function and the recrystallization fractional attributable to DRX as follows:

$$Z=\dot{\varepsilon}\exp(\frac{401473}{\mathrm{RT}})=1.94\times10^{14}\left[\sinh(0.012\sigma_p)\right]^{5.4389} \quad (1)$$

$$X_{DRX}=1-\exp\left[-0.5104\left(\frac{\varepsilon-\varepsilon_c}{\varepsilon_p}\right)^n\right] \qquad n=0.01627Z^{0.1489} \quad (2)$$

$$\varepsilon_c = -1.02 + 0.037 \ln Z \qquad \varepsilon_c / \varepsilon_p = 0.717 \tag{3}$$

Here, X_{DRX} is the recrystallization fractional attributable to DRX, ε_c is the critical strain for the initiation of DRX, ε_p is the peak strain, Z is Zener-Holloman parameter, σ_p is peak stress.

n of X_{DRX} is not a constant, but a parameter related with *Z*.

B) Simulation of the double-pass compression test

The effect of deformation variables on the flow curves of the double-pass compression is shown in Fig.2. The model of fractional softening could be obtained by Avrami kinetics, in which the kinetics of recrystallization fractional is given by

$$X_{SRX} = 1 - \exp[-0.694(t / t_{0.5})^{0.2}] \tag{4}$$

$$t_{0.5} = 1.98 \times 10^{-14} \varepsilon^{-1.94203} \dot{\varepsilon}^{-0.4315} \exp\left(\frac{328246}{RT}\right) \tag{5}$$

Here, X_{SRX} is the recrystallization fractional to SRX, $t_{0.5}$ is the time for 50% softening to SRX.

C)Recrystallized grain size.

Fig.3 shows evolution of average austenite grain size during rolling. This does not greatly differ from several equations proposed for austenite recrystallized grain size and inter-pass grain growth C-Mn and microalloyed steels. The evolution of average austenite grain size during rolling could be given by the following expression.

$$D = 26432635.56 Z^{-0.38663} \tag{6}$$

Multi-pass Hot Compression Simulation and Analysis

The flow curves of multi-pass are shown in Fig.4. From the flow curves, it could determine the values of the fractional softening that takes place between passes. The fractional softening was calculated by means of the following expression [3,4].

$$X(\%) = \frac{\sigma_m^i - \sigma_y^{i+1}\left(\sigma_0^i / \sigma_0^{i+1}\right)}{\sigma_m^i - \sigma_0^i} \times 100 \tag{7}$$

$\sigma^i{}_m$ is the maximum stress for the *i*th (at temperature T_i) pass. $\sigma^{i+1}{}_y$ is the yield stress for $(i+1)$th pass. $\sigma^i{}_0$ is the yield stress of a fully restoration material for the *i*th pass. $\sigma^i{}_0$ and $\sigma^{i+1}{}_0$ are determined by the one-pass compression test.

When softening is only partial, some strain is retained into the next pass. Under these conditions the accumulated strain (ε_a) can be calculated from the following relation [5]:

$$\varepsilon_a = \varepsilon_i + (1 - X_{i-1})\varepsilon_{a-1} \tag{8}$$

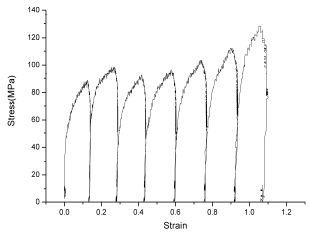

Fig.4 The True Stress-Strain Curves for the Simulation of Multi-Pass Hot Rolling Schedule

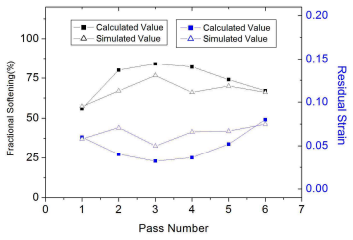

Fig.5 Fractional Softening and Residual Strain for the Simulation of Multi-Pass Hot Rolling Schedule

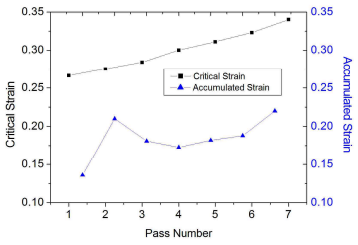

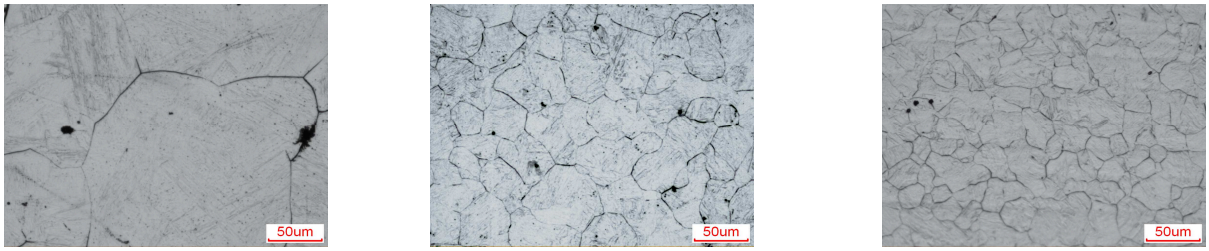

Fig.6 Critical Strain and Accumulated Strain for the Simulation of Multi-Pass Hot Rolling Schedule

It is interesting to note that there is an extreme point in the Fig.5. It accounts for that the fractional softening(X) after the first pass is only 56%, in which the progress of a restoration process happens incompletely, the stress is not fully relaxed, it produces the more accumulated stress. Then, the value of fractional softening(X) reaches about more than 80% after the second, third and fourth pass. With the strain and the time between neighboring pass become more, the stress has been relaxed more, and there is less accumulated stress.

The critical strain for DRX calculated from Eq.3 and the accumulated strain obtained from Eq.6 are compared in Fig.8. As the pass number is increased, the critical strain increases. Accumulated strain of each passes is lower than critical strain. It shows that the passes occurs the static recrystallization.

(a)initial grain size (b) the third pass (d) the seventh pass

Fig.7 Microstructures Obtained at Different Stages of Hot Rolling Simulation

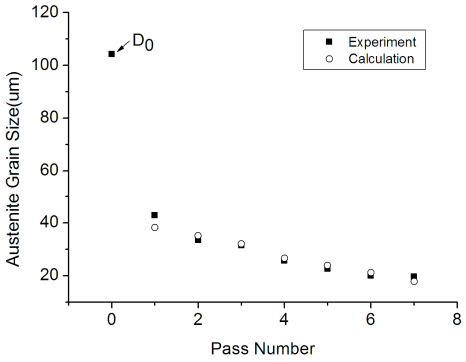

Fig.8 Evolution of Average Austenite Grain Size During Hot Rolling Simulation

Fig.7. shows the microstructure evolution of austenite along the hot rolling schedule. Grain is significantly refined during hot compression deformation. Starting from an initial grain size of 106μm (Fig.7a), grain is significantly refined by successive recrystallization. In Fig.7b, large grains characteristic of the deformed, unrecrystallized austenite are apparent with a few smaller recrystallized grains often located at three grain intersections on prior austenite grain boundaries. The grain size of the last pass (Fig.7c) is almost 20μm.The curve of Fig.8 has been obtained from analysis of Eq.6. In this figure, the evolution of average austenite grain size during rolling is graphically represented against pass number. The results of expression accord with the experimental results. The improved mathematical model could be used for austenite evolution study and it could guide the actual production of the factory.

Conclusion

The improved mathematical model was developed for Nb-Ti microalloyed steel during hot rolling simulation by compression test in this study. It was found that n of X_{DRX} is not a constant, but a parameter related with Z.

According to the simulation results, the predicted microstructure were in good agreement with the measured data. The microstructure evolution model established in this work possessed favorable practicability and accuracy and could be used for austenite evolution study. And it could guide the actual production of the factory.

Keywords: TMCP, tempering, high strength steel, offshore infrastructure, welding, CTOD

Abstract: This paper introduces the study and production on steel plate of Grade E550 in 60mm thick by Thermo-mechanical processing (TMCP) and tempering for offshore infrastructure purpose. The steel plate obtained high strength and good toughness in both the base materials and the weld joints. Microstructure and precipitation characteristics were examined in the plate is comprised of bainite with a small amount of pre-eutectoid ferrite. Parallel arranged lath bainite characterizes the bainitic structure with high density of dislocations and precipitates. Carbides MxCy averaging 200nm in dimension and MC type Carbonitrides in several nano to a dozen nano carbides distribute in the bainite ferrite and the bainte lath interfaces. Compatible mechanical properties were achieved at welded joint. Microstructures were analysed in the welding heat affected zone (HAZ).

Introduction

In recent years, world energy consumption keeps continuously growing. This tendency drives the requirement of steel constructions, especially for offshore oil and gas discovery and drilling. Nowadays, offshore oil and gas drilling is extending to a sea depth up to 3000 meters and extremely low temperature area. In the meantime, offshore windy energy exploration is a blooming form of energy generation which is becoming an important part of the total energy consumption [1-2]. There are two key issues that should concern in offshore steel structure design and fabrication. One is the safety and reliability and the other is the economical efficiency. High strength and low alloy steel plates are most common and steel materials to efficiently manufacture the offshore structures. To meet these requirements, steels for the offshore structure fabrication characterized as higher strength and heavier gauges under strict quality control.

Steel plates for offshore structure fabrication have undergone great progresses in the past three decades. Early oil and gas drilling platforms were fabricated by using the as rolled steel plates up to grade 355MPa yield strength, which the steel plate processing are also named as normal rolling without any further heat treatment. To obtain polygonal ferrite and pearlite microstructures and better Charpy V-notch Impact energy, the as rolled steel plates are processed by normalizing heat treatment where the steel are reheated at the austenitization temperature and then cooling in the air. Steel plates by normalizing rolling which the final deformation temperature is controlled in the normalizing temperature range may achieve an equivalent effect of normalizing. However, with oil and gas drilling performance going deeper into the sea, the above processing technology proved to be many limits to produce higher strength and thicker steel plate. Quenching and tempering process are applied in steel plate production to obtain high strength and toughness. In the 1980's, the critical value of crack tip opening displacement (CTOD) was introduced in evaluating fracture toughness in the welding joint of the steel plate to avoid fabricating risks. The advances in steel industry have made it possible to produce steel plates by thermal mechanical controlled processing (TMCP), which benefit for fine grain structure and favorable mechanical properties. As a result, the first -10^{o}C CTOD proof steel plate at a yielding strength of 355MPa by TMCP was available for offshore oil and gas drilling platform fabrication in the 1980's. Since then, yielding strength from 420MPa up to 550MPa steel plate have been developed for offshore structures.

Thermo-mechanical control process (TMCP) is currently used in producing steel products for a variety of purposes to obtain high strength, excellent toughness and good weldability etc[1, 3-4]. In practice, people sometimes encounter problems such as microstructure control, especially for steel plates with a heavy gauge, 50mm and above for example[5]. In this paper, the authors introduced a

60mm thick steel plate of Grade E550 by TMCP for offshore purpose. In this study, tempering heat treatment was suggested to obtain positive mechanical properties. The performance and characteristics of the steel plate were studied.

Study on the TMCP of E550

The chemical analysis (wt%) of steel in the present study is C 0.07, Si 0.25, Mn 1.65, P 0.008, S 0.003. Nb, V, Ti and Mo are added less than 0.050 (wt%) respectively. Thermo-mechanical simulation and laboratory hot rolling experiments were carried out in the similar steps described in the author's previous works [5-6]. Static and dynamic continuous cooling transformation (CCT) curves are displayed in Fig. 1.

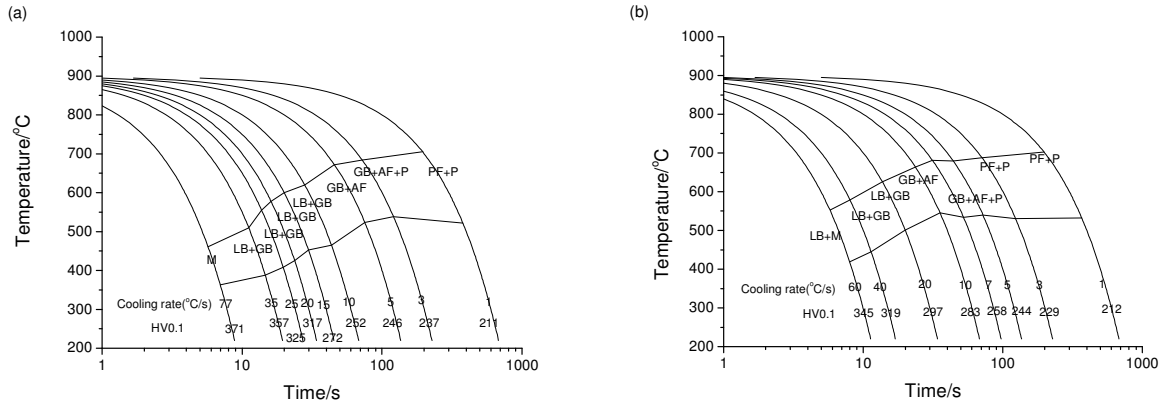

Fig. 1 Schematic of thermal mechanical simulation. (a) Static simulation; (b) Dynamic simulation.

Continuous Cooling Transformation (CCT). The steel is composed of pro-eutectoid ferrite and pearlite when the cooling rate is between 1-3℃/s, as shown in Fig. 1. Lath bainite microstructure may be obtained at cooling rate of 10℃/s when in static CCT curve but at 20℃/s in the dynamic CCT curve. In comparison with the static CCT curve, the dynamic CCT curve shifts to the left, implying an enlargement of the acicular ferrite and granular bainite areas. Lath bainite transformation shifts to the left when in dynamic CCT curve. According to microstructure examination, fine lath bainite is obtained when cooling rate is 40℃/s in the dynamic CCT. Martensite may be obtained when the cooling rate reaches 60℃/s when in dynamic CCT.

Effect of Tempering on Precipitation. Tempering plays a critical role in obtaining propitious mechanical properties and welding performance, as revealed in the author previous study [3, 6-7]. In fact, precipitation behavior in tempering is one of the most important factors in strengthening and/or softening of the steel microstructure.6 The effect of tempering temperature on precipitation was investigated by transmission electron microscope (TEM). Steel plates of 860℃ finish rolling temperature at a 20℃/s cooling rate were tempered respectively from 530 to 650℃ at a holding period of 2min/mm.

Analysis on typical precipitates shows that tempering gives rise to less amounts and small size precipitates in the steel at a lower temperature than at a higher temperature. TEM examinations prove that the precipitates in the steel are comprised of titanium and niobium carbonitrides (MC) in square shape and carbides M_xC_y in irregular shapes that contain iron and manganese. When the steel was tempered at 650℃, large sized M_xC_y about 300nm and MC from 50 to 100nm were found. When temperied at 620℃, the steel was enriched with precipitates, in which the 300nm precipitates were M_xC_y and precipitates from 50 to 100nm were MC. In the meantime, abundant super-fine particles from several to a dozen nano carbides characterized the tempered precipitates at 620℃. The precipitates at 620℃ are studied by selected area diffraction (SAD), as shown in Fig. 2. Analysis on an irregular precipitates confirmed that the precipitate type was $M_{23}C_6$, demonstrating an orientation relationship [011] $M_{23}C_6$ // [721] between the carbides and the base microstructure, as exhibited in

Fig. 2 (a) and Fig. 2 (b). Carbonitrides are characterized in small sizes from 15 to 50nm with a large amount of fine titanium carbinitrides less than 20 nm, in which most of them are titanium nitrides (TiN) in square shape. Diffraction analysis on a typical TiN was carried out along the [001] axis, revealing its Face-centered cubic (FCC) lattice whose constant is approximately 0.43nm, as shown in Fig. 2 (c) and Fig. 2 (d). These small particles play an important role in pinning the dislocations and grain boundaries, which makes the after tempering steel plate characterized with high density of dislocation and fine grains. When tempering at 590 and 530℃, less carbides were found and enriched at grain boundaries. At both 590 and 530℃, the carbides were principally Ti(CN) in square shape with niobium carbonitrides adhesion to the Ti-particles. The tempered precipitates are from 100 to 200nm in size at 590℃. Smaller size particles from 50 to 100nm characterized the carbides at 530℃
.

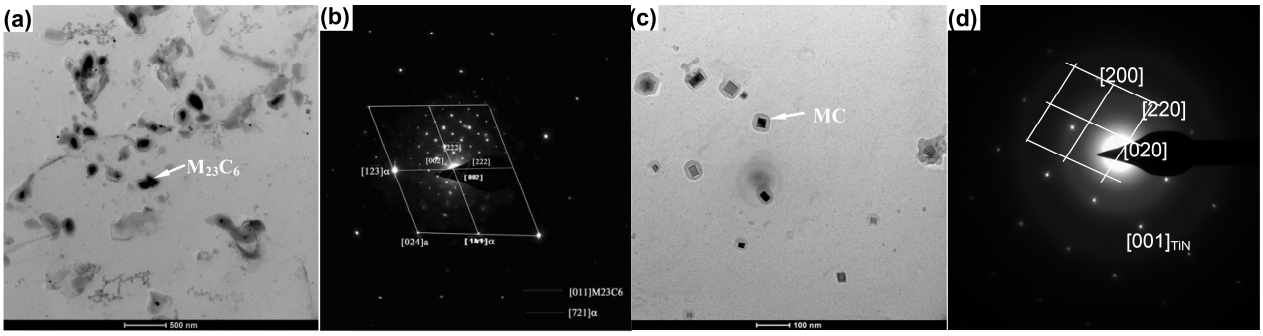

Fig. 2 SAD analysis of typical precipitates. (a) $M_{23}C_6$, (b) SAD pattern of $M_{23}C_6$, (c) TiN, (d) SAD pattern of TiN

Effect of Tempering on Mechanical Properties. The effects of tempering on the steel mechanical properties were also tested, shown in Fig. 3. The tempering experiments were carried out at 630ºC and 650℃ respectively given 1 to 4min/mm holding time on steel plates of 860℃ finish rolling temperature at a 20℃/s cooling rate.

In Fig. 3(a), the tempering temperatures of 630℃ and 650℃ do not obviously affect the steel strength, neither does the Charpy V-notch impact energy. However, as tempering period grows longer, both yield strength and tensile strength decrease while Charpy V-notch impact energy increases. At 2 and 3 min/mm, the steel obtains better toughness. A 2min/mm tempering period at 630ºC is recommended in plate production.

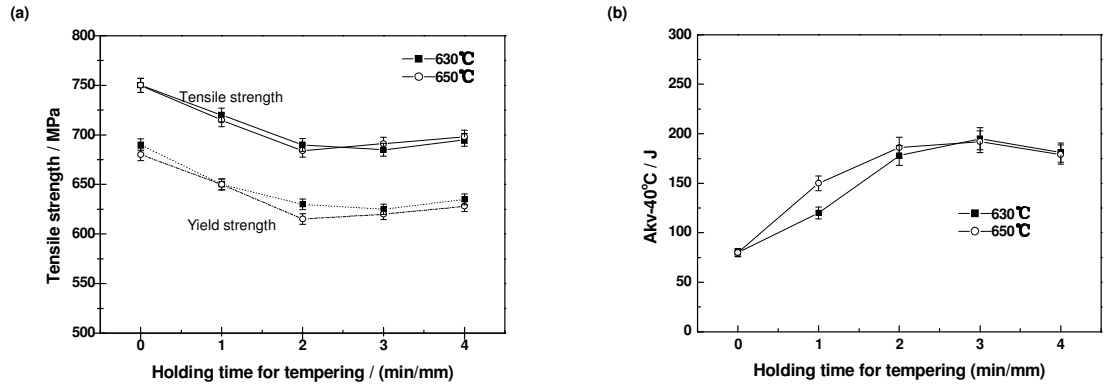

Fig. 3 Effect of tempering on steel strength and toughness.(a) yield and tensile strength; (b) AKv-40℃

Performance of the E550 Steel Plate

Mechanical Properties. A finishing rolling temperature from 850 to 860℃ at a cooling rate of 20 ℃/s was applied in 60mm thick E550 steel plate production. The plates were further processed by tempering heat treatment after the parameters discussed in the previous section. Two pieces of the

plates were examined respectively from both the top end and the bottom end of the top heat from one casting. The examinations included strength and Charpy V-notch impact tests at -40℃ in the top end, the middle and the bottom end respectively at 1/4 and 1/2 thickness of the plate. The above evaluation was also performed at different positions along the plate at 1/4, 1/2, 3/4 of the width from the left and the right edge and both edges. The results of the top end plate are shown in Table 1 and Table 2.

The steel plate demonstrates good Charpy impact energy values. At the 1/4 thickness position, yield strength and tensile strength displays 30MPa and 35MPa difference respectively in the whole plate and, 40MPa and 20 MPa difference at 1/2 thickness position. A maximum difference of 25MPa for both the yield and tensile strength respectively has been found between the 1/4 thickness and the 1/2 thickness in the whole plate. The tensile testing results also indicate larger strength values at the 1/4 thickness position than at the 1/2 and, larger values in the top end than in the middle and the bottom end of the steel plate.

Microstructure. Microstructure of steel plate is comprised of fine grain bainite with a small amount of pre-eutectoid ferrite. Fig. 4 shows the sub-structure whose size is approximately 1 to 2μm. The lath structure in Fig.4 (a) and Fig.4 (b) is bainite, in which high density of dislocation structures were found. Detailed examinations on the high density dislocations and grain boundaries show that many small precipitates in less than 300nm size distribute inside the substructure and at the grain boundary, as shown in Fig.4 (c) and Fig.4 (d).

Welding Performance. Multi-pass submerged arc welding (SAW) tests were conducted under both 7kJ/cm and 50kJ/cm heat input respectively on K-groove and X-groove butt welding according to BS7448. A CHW-SG type welding wire of 4.0mm in diameter was used to accomplish the welding. No pre-heating was implemented and the inter-pass temperatures were controlled under 200 ℃.

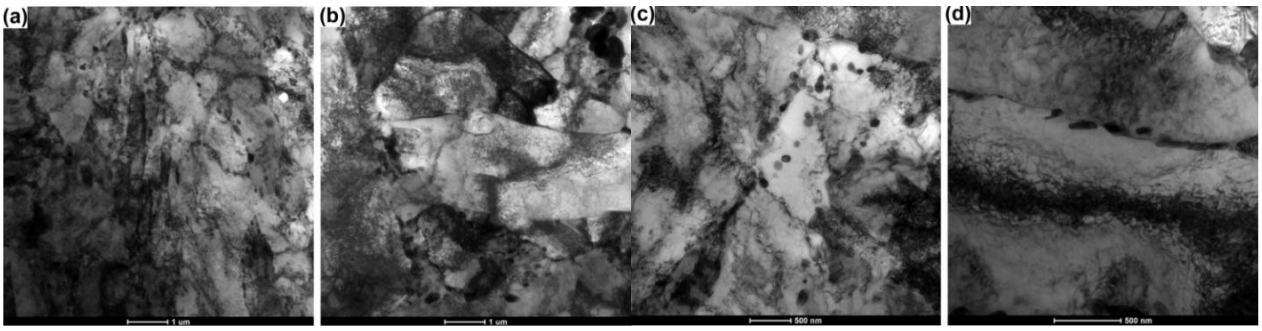

Fig. 4 Microstructure of E550 steel plate. (a) structure, (b) sub-structure, (c) inner-grain precipitates, (d) precipitates at grain boundary

The X-groove welding assemblies were stress released (SR) at 580℃ with 4 hours holding. A Vickers hardness test using a test load of 5kg was performed on both the as weld (AW) and SR specimens taken from the test assembly. The distance between indents is 1.0 mm at 1 to 2mm respectively from both the plate surfaces. Fig.5 shows the hardness distribution across the welding joints, demonstrating small softening in the heat affected zone (HAZ). Charpy V-notch impact at -40℃ tests were also carried out at 2mm from the top surface at both the AS and SR conditions. The absorbed energy after SR heat treatment in the HAZ decreased less than 50J at 7kJ/cm heat input and 100J at 50J/cm heat input. In all tests, the absorbed energy exceeded 100J, as shown in Fig. 5.

In the K-groove welding, Charpy V-notch impact tests at -40℃ were carried out for both the heat input welds in both the square edge and bevel edge side materials with the notch respectively at the fusion line (FL) and at 2mm, 5mm and 20mm from the fusion line (FL+2, FL+5 and FL+20 respectively). The above absorbed energy tests were respectively implemented at 2mm from the top surface, the middle thickness of the plate and 2mm from the bottom surface. The test results are shown in Fig. 6. The average absorbed energy exceeded 110J at each tested position and the minimum value 100J, demonstrating good toughness.

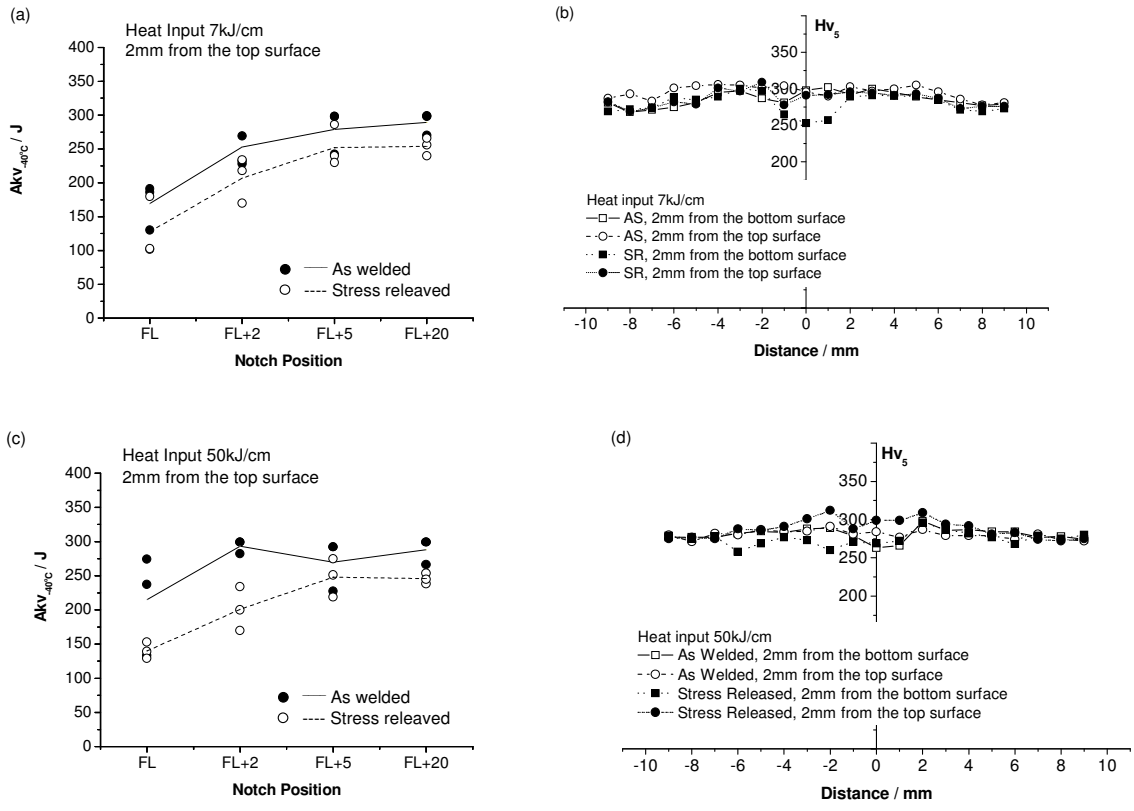

Fig. 5 X-groove SAW testing results

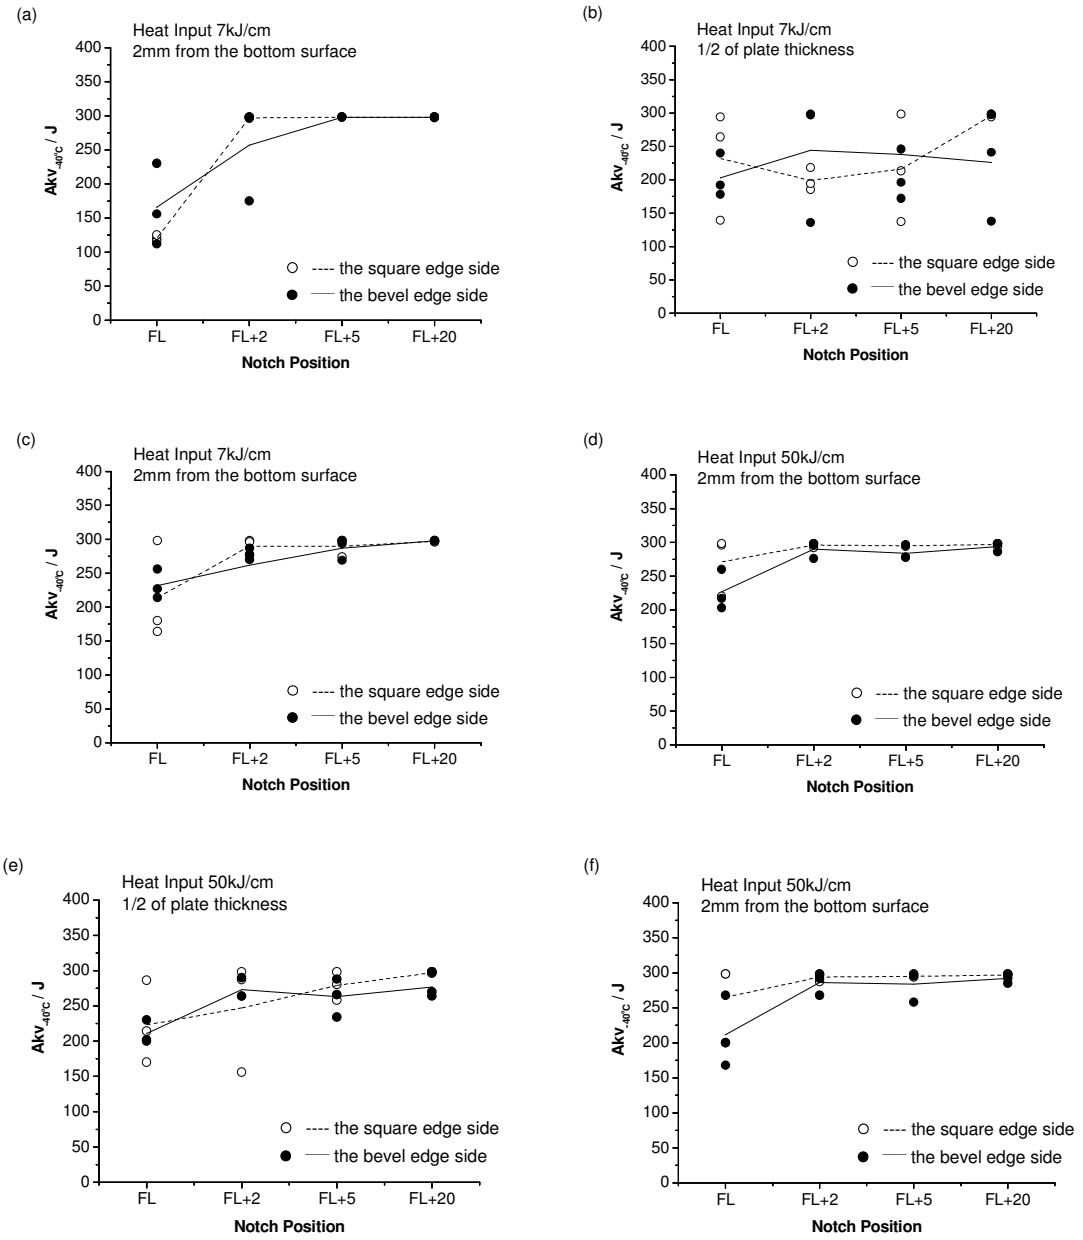

Fig. 6 K-groove SAW testing results

Crack Tip Opening Displacement Tests. Table3 shows the testing results of CTOD tests at -10 ℃for the welded joints in accordance with BS7448. The dimensions of the testing sample were 58×58×400mm and 7kJ/cm and 50kJ/cm heat input were respectively applied when making the welds. The crack orientation were along the weld direction and were located at 2mm inner the weld metal (WM) from straight edge of the fusion line (FL), grain coarsened HAZ (GCHAZ) and the subcritical HAZ/intercritical HAZ boundary (SCHAZ+ICHAC). The CTOD δ c values obtain for both welding conditions prove to be well competent with the requirement.

TABLE 3 The CTOD testing results

Crack position	δ_c /mm	
	7kJ/cm heat input	50kJ/cm heat input
WM-2mm	0.46, 0.43, 0.42	0.35, 0.32, 0.30
GCHAZ	0.43, 0.40, 0.37	0.35, 0.38, 0.33
SCHAZ+ICHAC	0.38, 0.42, 0.40	0.31, 0.37, 0.36

Conclusion

The 60mm thick E550 steel plate processed by TMCP and tempering heat treated was successfully developed with good mechanical properties, weldability and CTOD performance. The steel plate is characterized with fine bainite structures. Carbides and cabonitrides together play an important role in fine grain structure and high density dislocations which are in turn propitious to the plate strength and toughness. Precipitates in nano size that distribute inside the substructure and at the grain boundary are benefit to improve the steel plate weldability and CTOD property.

Keywords: Ferric oxide, nanoparticles, hydrothermal stripping, bauxite

Abstract. A novel of hydrothermal stripping technique is developed to synthesize nano-particles of ferric oxide from iron-loaded organic phase by ammonia. The iron-loaded organic phase was prepared by extracting simulated bauxite hydrochloric acid leaching liquors with N235 and then the iron is stripped by heating the organic phase up to 180°C to precipitate as ferric oxide. XRD patterns exhibits that the ferric oxide is composed of α-Fe_2O_3 and TEM images reveals that the particles of crystalline hematite powders are homogenous with quasi-spherical fine crystallites and its primary particles are about 150 nm. This process is a proof of concept for the removal and precipitation of iron from bauxite hydrochloric acid leaching liquors.

Introduction

To recover aluminium hydrometallurgically from bauxite, which contains Al, Fe and Ca and requires a step to separation iron–aluminium .Many processes are known for the removal of Fe^{3+} from aqueous solutions [1, 2]. The processes generally are comprised of precipitation, solvent extraction, ion exchange, and other techniques. Solvent extraction is one of the most widely methods that is used to the separation of metal ions from different sources [3-5]. Ferric oxide (Fe_2O_3) is functional materials for various applications (magnetic materials, catalytic materials, pigments, coatings, gas sensors, etc.) [6-8]. The hydrothermal stripping process [9,10], in which metal-containing species are hydrolyzed and precipitated directly from the loaded cation exchange solvent extractants, is still differ from hydrolysis, and clearly shows promise for synthesizing oxide ceramic powders for high-performance applications [11-16] .In this study, we developed a method for synthesizing Fe_2O_3 nanoparticles by stripping from iron-loaded organic phase which was prepared by extracting simulated bauxite hydrochloric acid leaching liquors with N235.

Experimental

A typical simulated liquor, which contained 15 g/L Fe^{3+}, 32 g/L Al^{3+}, 75 g/L Ca^{2+} and 3 M HCl (free acid, M: mol/L), was prepared. The simulated bauxite hydrochloric acid leaching liquors were used to prepare the aqueous phases. All other chemicals were of reagent grade. The various volume ratios of N235 and simulated liquor were taken in a reagent bottle and stirred with fixed speed (200 r/min) at room temperature. After mechanical stirring, the phases were separated to obtain iron-loaded organic phase. In each stripping experiment, at first put 40 mL of organic phase, 20 mL of ammoniacal water into the autoclave of 100 mL capacity, seal it, heat to the experimental

temperature, and take this instant as the starting time, then take a series of samples at timed intervals. The content of iron in the organic phase was determined by chemical titration method. The whole Process for Fe recovery (A) and preparation of crystalline hematite (B) was illustrated as follows (Fig.1). The crystal phase structure of ferric oxide was investigated using an X-ray diffractometer (XRD) (BDX-3300 made by Peking University Instrument Co., China). A Transmission Electron Microscope (TEM) (100CX-II made by JEOL, Tokyo, Japan) was used to characterize the ferric oxide powders with respect to their particle size and shape.

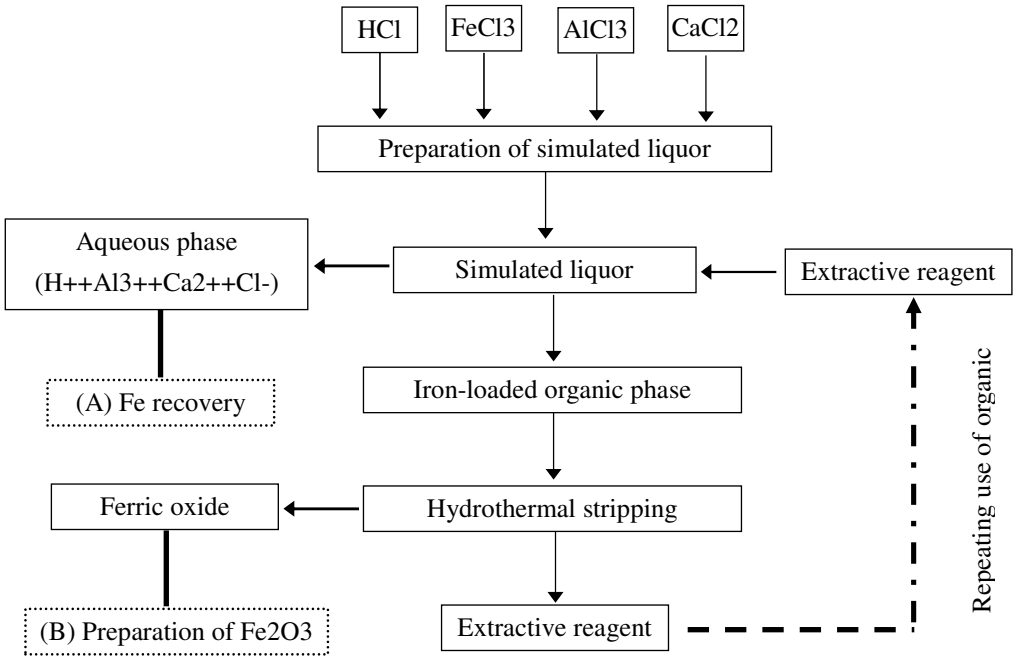

Fig.1 The whole experimental programme

Results and Discussion

Preparation of Crystalline Hematite Powder

The experimental results of stripping iron-loaded organic phase with ammoniacal water are given in Tables 1. It can be seen from Table 1 that the pure crystalline hematite was obtained with ammoniac water phase and at higher temperature (180°C or 200°C).

The percentage of stripping Fe is over 90% after hydrothermal stripping of 40 minutes at 180°C. There is hardly any Fe in the organic phase after hydrothermal stripping of 1.0 hour at 180°C.The size of α-Fe_2O_3 powders will large with the time on the extent of stripping in the same conditions.

Table 1 EXPERIMENTAL RESULTS OF STRIPPING IRON-LOADED ORGANIC PHASE BY AMMONIAC WATER

Ammoniac Water phase*	ratio O:W	Stripping Temperature[°C]	Stripping Time[h]	Sample		
				Color	Component	
Pure water	2:1	130	1.0	No hematite		
Pure water	2:1	180	1.0	Green	Mixture	
1:10	2:1	180	1.0	Red	α-Fe2O3	1#
1:5	2:1	180	1.0	Red	α-Fe2O3	2#
1:1	2:1	180	2.0	Red	α-Fe2O3	3#
1:1	2:1	200	2.0	Red	α-Fe2O3	4#

*The different ratio of ammoniac water phase was obtained by mixing NH3·H2O with water.

XRD of Crystalline Hematite Powder

X-ray diffraction analysis (XRD) of powders was conducted on a Rigaku Dmax X-ray diffractometer. The XRD shown in Fig.2 reveals the crystalline hematite powder obtained by the technique of hydrothermal stripping was well crystallized and composed of α-Fe_2O_3.

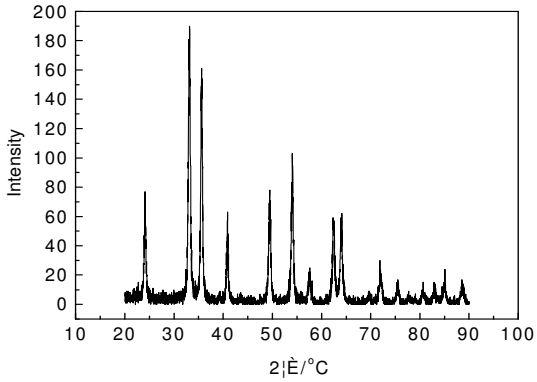

Fig.2 X-ray powder diffraction patterns for the samples 2# in Table 1.

TEM of Crystalline Hematite Powder

A transmission electron microscope (TEM) model H-8100IV was employed to characterize the morphology and the particle size of the powders. Some TEM images at different conditions are shown in Fig.3 reveal that the particles of crystalline hematite powders are homogenous in their shape, with quasi-spherical fine crystallites with an average diameter of sub-micron grade. It can be seen from Fig.3 that the Fe_2O_3 particles sizes were influenced by stripping temperature and time.

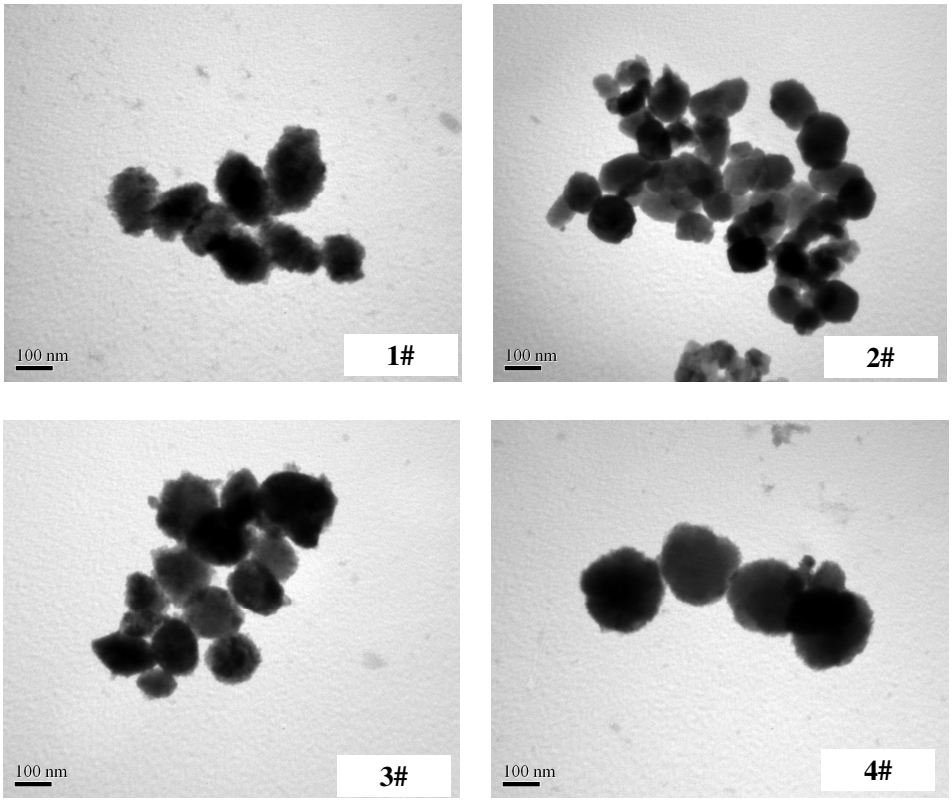

Fig.3 TEM Images of Oxide Particle Prepared by Hydrothermal Stripping

Analysis of the Composition of Crystalline Hematite Powder

The composition of crystalline hematite powder was shown in Table 2. It is can be seen from Table 2 that the iron oxide powder synthesized by hydrothermal stripping route has higher purity.

Table 2 ANALYSIS OF THE COMPOSITION OF THE IRON OXIDE POWDER

Composition of powder, w%			
Fe2O3	Al2O3	Ca	Cl and others
98.97	0.862	0.1615	0.0065

Conclusion

N235 can effectively remove Fe from Al + Fe + Ca liquors. Moreover, The iron-loaded organic phase can be prepared by extracting simulated bauxite hydrochloric acid leaching liquors with N235. The ferric oxide nanoparticles were successfully synthesized via a hydrothermal stripping route which strip ferric ion from iron-loaded organic phase by ammoniacal water. The XRD patterns and TEM images of ferric oxide reveal that the powders are composed of spherical a-Fe_2O_3 with a narrow and uniform size distribution. The experimental results indicated that the Fe_2O_3 nanoparticles sizes were influenced by the stripping temperature and time. The fact that the organic phase and water phase can be reused here means that this route is a green synthesis method.

Keywords: Heat treatment, gray and nodular cast iron, dissolution of graphite, corrosion rate

Abstract: In this work, the influence of heat treatment process and quenching in different quenchant media of medium carbon steel, gray and nodular cast iron with ferrite matrix on the hardness, ductility and corrosion rate of has been investigated. During this type of operations, the specimens were Austenizing at 900ºC for one hour. Therefore, the specimens were quenched in different kind of oil as quenched medium (oil 20-50, oil 40, oil 90, and water as reference). The hardness , impact energy to measure the ductility, corrosion rate and microstructures were studied. From result of steel 0.47% carbon was clear increasing in hardness and decreasing in ductility with close varying values in oil quenchant kind comparing with as received specimen and water quenched one, corrosion rate decreased with heat treatment and quenching process due to formation of single face instead of double phase before heat treatment process which created galvanic cell. For gray and nodular cast iron it is noticeable that no changing in microstructure within heating for one hour at 900ºC because the matrix in both cast iron types is ferrite, therefore no changing in mechanical properties under heat treatment process with time of one hour which is not sufficient to decomposition of graphite, but with comparison the hardness of gray cast iron is more than nodular one due to distribution of graphite flacks which increase the hardness and decrease the ductility as well as increasesing the corrosion rate compared with nodular cast iron. Microstructure of both types of cast iron have been studied after subjected the specimens to heat treatment at 1000ºC and for 10 hours, the microstructures shown clear diffusion of some carbon in ferrite matrix around the graphite phase and under quenched some of martensite formed.

Introduction

One reason for the versatility of metallic materials lies in the wide range of mechanical properties they possess, which are accessible to management by various means. Steel is an alloy of iron and carbon. Steel with low carbon content has the same properties as iron, soft but easily formed. As carbon content increases, the metal becomes harder and stronger but less ductile and more difficult to weld. Higher carbon content lowers steel melting point and its temperature resistance in general[1]. Medium carbon steel is steel with 0.3 to 0.7%C and approximately 0.8%Mn which are used in the production of machinery parts such as nuts and bolts, shafts and gears[2]. Plain-carbon steels and cast irons are heated to austenitizing temperatures and then rapidly cooled (quenched) in water, brine, or oil to the critical temperature [3-4]. The critical temperature is dependent on the carbon content, but as a general rule is lower as the carbon content increases [3-5]. This results in a martensitic structure; a form of steel or cast iron that possesses a super-saturated carbon content in a deformed body-centered cubic (bcc) crystalline structure, properly termed body-centered tetragonal (bct). This crystalline structure has a very high amount of internal stress [6]. Due to internal stress quenched steel and ductile cast iron is extremely hard but brittle, usually too brittle for practical purposes [6-7]. These internal stresses cause stress cracks on the surface [7].

Experimental Procedure

Materials

Materials use in this study are medium carbon steel, gray and nodular cast iron with ferrite matrix, oil 20-50, oil 40, oil 90,olive oil and water as quenchant medium. The chemical composition of steel and two types of cast iron is shown in Table 1.

Table 1, Chemical compositions of materials specimens samples.

Element	*%C*	*%Si*	*%Mn*	*%P*	*%S*	*%Mg*	*%Al*	*%V*	*%Ti*
Medium carbon steel	0.47	0.26	0.145	0.017	0.012	-	0.012	0.035	0.32
Gray cast iron	2.7-4	1.8-3	0.2	0.07	0.2	0.09	-	-	-
Nodular cast iron	3.79	2.1	0.3	0.1	0.043	0.044	-	-	-

Hardening process

The specimens were initially normalized, followed by austenizing at 900ºC for 60 minutes and then quenched in oil 20-50, oil 40, oil 90, and water.

Result and Discussion

Hardness Result

Hardness values for medium carbon steel and two types of cast iron are shown in Fig. 1.

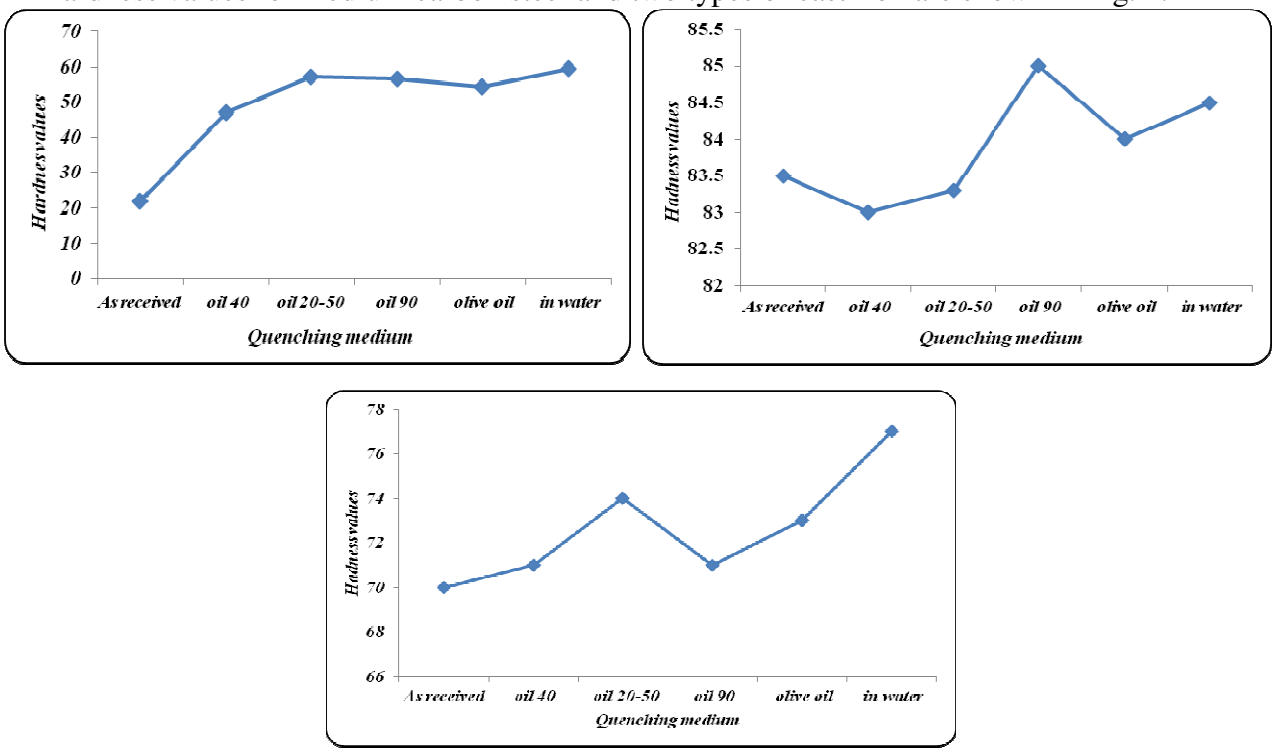

Fig. 1, Show the hardness of 0.47% carbon, gray and nodular cast iron steel respectively in quenching mediums

Corrosion rate values

Corrosion rate values for medium carbon steel and two types of cast iron are shown in Fig. 2.

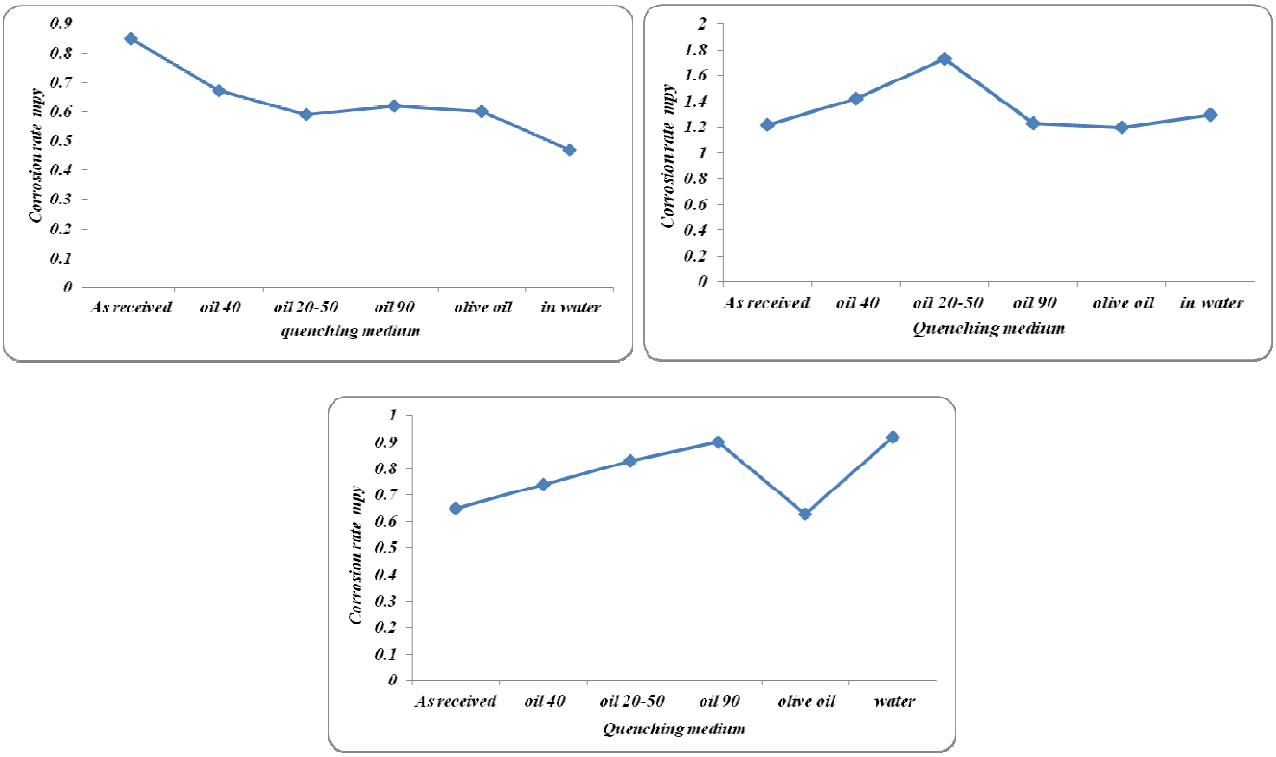

Fig. 2, Show the corrosion rate of 0.47% carbon, gray and nodular cast iron steel respectively

Microstructure

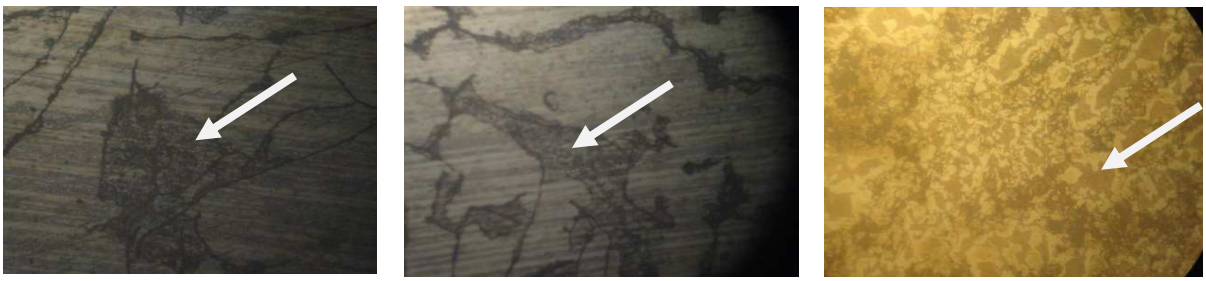

Fig. 4, Microstructure gray cast iron after 10 hour in austenite area at 1000oC and quenched in water

Microstructure of nodular cast iron after 10 hours at 1000^0C then quenching oil and water

Fig. 5, Microstructure nodular cast iron after ten hour in austenite area at 1000oC and quenched in water

Discussion

Fig. 1, Shows the affect of hardening of steel 0.47% carbon, gray and nodular cast iron in different quenched medium, from the results obtained, the hardness value of medium carbon steel specimens increased after quenching in all the mediums. The quenched specimens in the different oils types have a lower hardness values as compared to water. This may be attributed to the fact that water have higher cooling rate than different oil types. Water quenched produced the highest hardness value and most oil kinds or degrees looks get close hardness values. The hardness values for gray cast iron, hardness values obtained looks in same range its between 83.5 to 85 R/B because the microstructure is graphite flacks and ferrite matrix, so heating up to 900ºC for one hour then quenching doesn't change the microstructure also the hardness values of nodular cast iron have hardness in range close about 70 to 74.5 R/B, there is no big changing in hardness value because the microstructure doesn't change after quenching from one hour heating at 900ºC, but it's clear the hardness value of gray cast iron higher than in nodular cast iron do to different in microstructure in both case and area of ferrite which is bigger in nodular that make it more ductile than gray cast iron. Fig. 2, Shows the corrosion rate of steel 0.47% carbon , from result obtained the as received sample have higher corrosion rate due to galvanic corrosion between pearlite and ferrite which acts as cathode and anode respectively, also due to ratio of area for pearlite and ferrite. Corrosion rate will be increased with increases of cathodic and decreases of anodic area, with martensite structure obtained the corrosion rate will be decreased due to one phase martensite structure even thought stresses present. The corrosion rate for both gray and nodular cast iron respectively, shown the rate of corrosion rate of gray is higher than in nodular cast iron because the distribution of graphite with ferrite matrix, in gray cast iron the distribution of flaks that is acting as cathode to ferrite make galvanic cell is higher than shape of graphite as nodular with more big area of anode which is ferrite. Fig. 3, Shows the microstructure of steel 0.47% carbon , as received, oil quenching and water quenching, the microstructure changed from ferrite and pearlite as received sample to martensite structure after quenching which is improve the hardness value but decreases the ductile, for gray and nodular cast iron quenching in water after one hour austenizing doesn't affect in microstructure. Fig. 4 and 5, Shows the graphite decomposition process in both gray and nodular cast iron after ten hour austenizing time at 1000^0C, as arrow shown in the Figures also martensite can be seen near the flakes and nodular graphite's with ferrite matrix .

Conclusion

- Medium carbon steel can be heat treated to improved strength and hardness with sacrificed of ductility .
- Water quenching steel will produced higher hardness than different kinds of oil quenched medium.
- Medium carbon steel exposed to corrosion under many factors specially due to multiphase at room temperature more than after heat treatment and quenching even with stressed martensite structure which produced after quenching.
- Improvement of mechanical properties of both gray and nodular cast iron with ferrite matrix couldn't be achieved with heating at austenite area for one hour then quenching but have to give more time to allow some decomposition of graphite .
- Decomposition of graphite will be around graphite itself with more austenizing time, the ferrite matrix couldn't be changed to pearlite one within 1ten hours treated.
- Strength and hardness in gray cast iron is more than nodular cast iron but the ductility is opposite due to ferrite area.
- The corrosion rate in gray cast iron with ferrite matrix is higher than nodular cast iron with ferrite matrix due to galvanic cell which created from layer structure in gray cast iron.

Keywords: Ti-Ni-Cu alloy; melt spinning; fracture morphology; tensile curve.

Abstract. Microstructure and mechanical properties of $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon fabricated by melt spinning were investigated by X-ray diffraction (XRD), transmission electron microscopy (TEM) and tensile tests. Some B19 martensite crystalline with (011) compound twin was embedded in the mainly amorphous ribbon, while the ribbon annealed at 450℃ for 1 h is at fully martensitic state. Annealing process alter the preferential orientation from (022)-B19 to (111)-B19. Tensile fracture stresses of as-spun ribbon and the annealed ribbon are 1257 MPa and 250 MPa, respectively. The tensile fracture morphology of as-spun ribbon shows typical vein fringe while that of the annealed ribbon reveals fine but depth-inhomogeneous dimples. After tensile deformation, the annealed ribbon exhibits typical martensitic detwinning behavior accompanying with the strain contrast.

Introduction

TiNi-based shape memory alloys is well known for the unique nature such as shape memory properties and superelasticity. Addition of Cu substituting Ni decreases the transformation hysteresis as well as reducing the sensitivity of the transformation temperatures to composition changes [1-2]. Besides for Ti-Ni-Cu sputtered thin film, Ti-Ni-Cu ribbons fabricated by melt spinning technique can be as candidate materials for sensors or actuators in micro-miniature systems [3]. The unique microstructure, transformation characteristics and mechanical properties of Ti-Ni-Cu ribbons can be introduced by the technique compared with that in a bulk Ti-Ni-Cu alloy [4]. The above-mentioned properties are affected not only by annealing condition but also by the composition of the alloys [5]. Previous work [6] shows the effect of annealing process on the transformation characteristics of Ti-rich Ti-Ni-Cu ribbon. However, no systematic experimental has been performed on the microstructure and mechanical properties of Ti-rich Ti-Ni-Cu ribbon. In the present study, the microstructure and tensile behavior of Ti-rich Ti-Ni-Cu ribbon were investigated by using X-ray diffraction (XRD), transmission electron microscope (TEM) and tensile test.

Experimental

Initially mainly amorphous $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbons were prepared by single-roller melt-spinning technique. The surface speed of the wheel is 37 m/s. The ribbon is about 35 μm in thickness and 1.7 mm in width. In order to be fully crystallized, the ribbon was heated at 450℃ for 1 h followed by water quenching to room temperature (RT). The martensitic transformation finish temperature (M_f) of the annealed ribbon measured by DSC (TA-Q100) is 50℃. The tensile test was performed at RGD-5 type electronical tensile testing machine. The gauge length is 50 mm and the tensile rate is 2 mm/min. Crystal structure was characterized by using XRD with Cu Kα radiation. TEM studies have been

carried out on Hitachi H-800 microscope operated at 150 kV. Fracture morphology of the ribbon was characterized by EMPA of a JCXA-733 instrument.

Microstructure of $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon

Fig. 1 shows the XRD pattern of as-spun ribbon. A diffuse and low intensity was observed revealing that as-spun ribbon is mainly amorphous. Only a few weak diffraction peaks can be found, being indexed as (022) reflections from B19 martensite. Typical TEM bright field micrograph of $Ti_{51.5}Ni_{25}Cu_{23.5}$ as-spun ribbon in Fig. 2(a) and its corresponding SAD pattern (Fig. 2b) confirms amorphous microstructure of the ribbon. The microstructures of the as-spun ribbons consist of mainly amorphous and a small amount of crystalline particles.

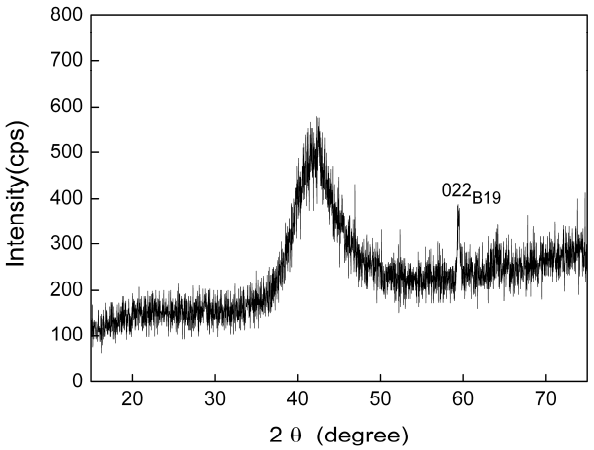

Fig. 1. X-ray diffraction pattern of $Ti_{51.5}Ni_{25}Cu_{23.5}$ as-spun ribbon.

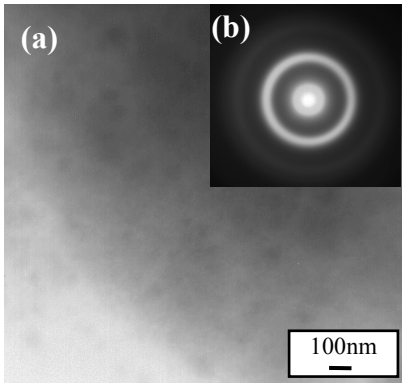

Fig. 2. TEM image (a) and a corresponding SAD pattern (b) of the as-spun ribbon.

Fig. 3 shows bright field micrographs of the B19 martensite in the as-spun ribbon and the corresponding SAD patterns. Fig. 3(a) shows the martensite morphology with preferential orientation. Electron diffraction pattern (Fig. 3b) indicates that the substructures of the martensite variants are dominantly (011) compound twin. The incident electron beam parallels to the $[100]_{M,T}$ zone orientation. Here M and T represent matrix and twin, respectively. TEM observations (Fig. 2 and Fig. 3) indicate non-equilibrium characteristics of as-spun ribbon [7].

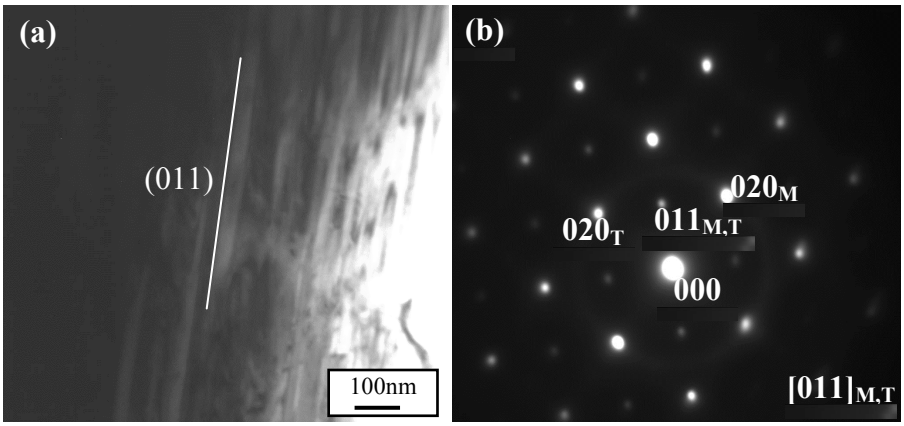

Fig. 3. TEM micrograph of B19 martensite (a) and its corresponding SAD patterns (b) in $Ti_{51.5}Ni_{25}Cu_{23.5}$ as-spun ribbon. Subscripts M and T indicate matrix and twin for martensite, respectively.

Fig. 4 shows the XRD pattern of the ribbon annealed at 450℃ for 1 h. All diffraction peaks only corresponding to B19 martensite are found, indicating the ribbon is fully crystallized. The lattice parameters of the B19 martensite are found to be: a = 0.2903 nm, b = 0.4296 nm and c = 0.4518 nm. Comparing the intensity of (111)-B19 with that of other crystal planes in B19 martensite, it is found

that a strong (111)-B19 texture is developed in the annealed ribbon. From Fig. 1 and Fig. 4, it indicated that annealing process can alter the preferential orientation from (022)-B19 to (111)-B19.

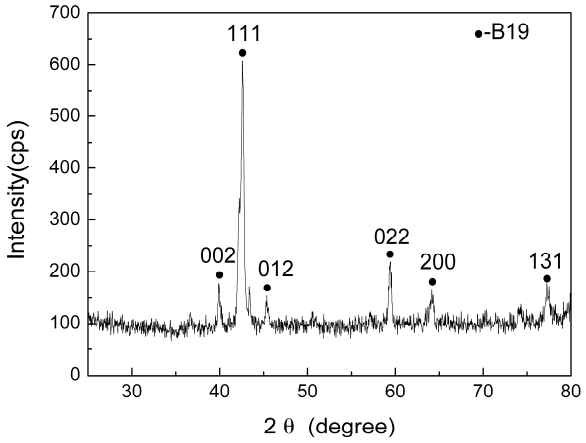

Fig. 4. XRD pattern of the $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon annealed at 450℃ for 1 h.

Fig. 5 shows TEM micrographs of the annealed ribbons at 450℃ for 1 h before and after tensile test. Fig. 5(a) is a bright field image, in which the size of the grains varies from about 600 nm to 1.3 μm. Only one pair of twinned martensite variants can be seen in most of these grains and the twin boundaries are straight and well-defined. The characteristics of Ti-Ni-Cu ribbon is different from that of a triangular self-accommodated microstructure with several martensite plates coexisting in one grain in the binary Ti-Ni alloy and Ti-Ni-Cu ternary bulk materials [8-9].

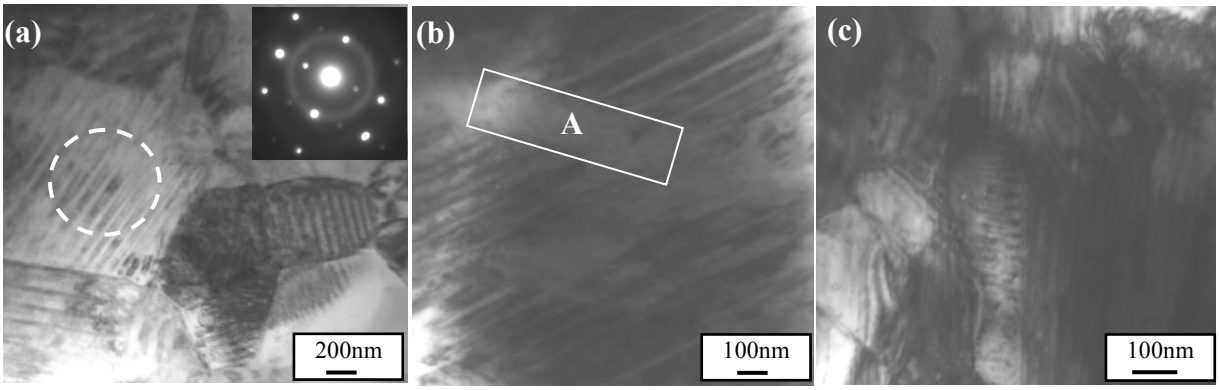

Fig. 5. Typical BF micrographs in TEM observations of $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon annealed at 450℃ for 1 h before (a) and after (b-c) tensile tests.

After the tensile deformation, the martensite morphology is still single-pair marentsite mostly. XRD analysis (Fig. 4) and the value of M_f (50℃) indicated that the annealed ribbon before tensile test is in the fully martensitic state at RT. It may exhibit the reorientation behavior or detwinning behavior of martensite variants when applied with tensile stress. Fig. 5(b) shows the detwinning behavior in one martensite variant. The substructural boundaries of the martensite variant are not well-defined, being destroyed or blurred as marked by area A. It is due to the detwinning behavior of martensite variants induced by local severe plastic deformation under the applied tensile stress. The width of rectangle is about 200 nm and the previous preferential orientation of martensite is vanishing. Clear strain contrast is observed between the parts of twinning and detwinning inside one martensite variant. Fig. 5(c) shows the complex contrast and high density of irregular structured grain boundaries resulting from the overlapping of martensite orientation, strain and moiré fringe contrast [10].

Tensile behavior of $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon

Fig. 6 shows the stress-strain curves of $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon at RT. The curve of the as-spun ribbon (Fig. 6a) shows the fully elastic until fracture without plastically deformation. Its ultimate fracture stress and strain are 1068 MPa and 3.7%, respectively. The tensile response of the ribbon annealed at 450℃ for 1 h is shown in Fig. 6(b). This curve can be divided into three stages. The first linear stage corresponds to the elastic deformation of the martensite phase. The Young's modulus of the annealed ribbon is about 12.5 GPa, being much smaller than that of Ti-Ni wire [11]. The large difference in elastic modulus between binary Ti-Ni and ternary Ti-Ni-Cu is likely due to Cu addition leading to a reduction in the atomic binding force [12]. The second stage corresponds to the rearrangement of the martensite variants. The third linear stage corresponds to the elastic deformation of the reoriented martensite. The fracture stress and fracture strain of the annealed sample are about 216 MPa and 2.7% respectively, which is smaller than that of as-spun ribbon.

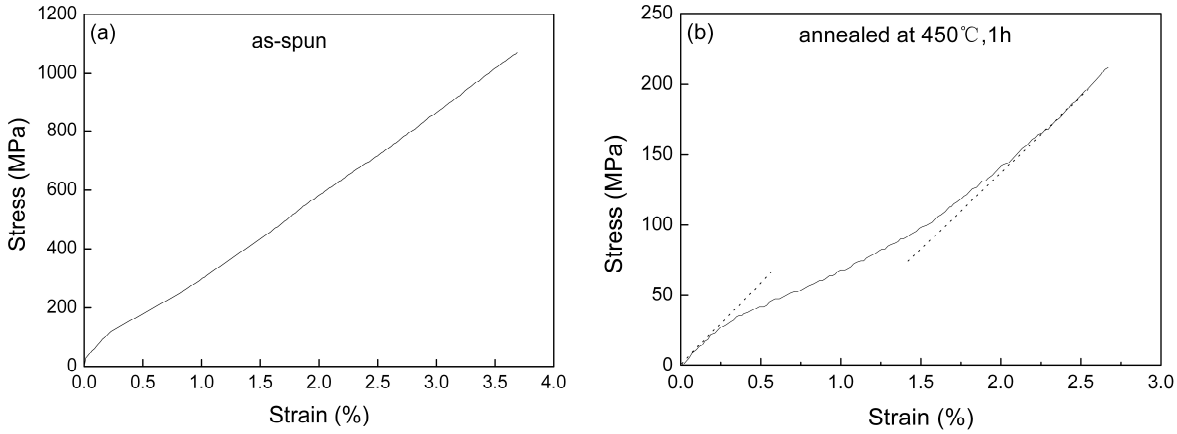

Fig. 6. Stress-strain curves of $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon (a) as-spun (b) annealed at 450℃ for 1 h.

Fig. 7 shows the typical fracture morphology for $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon. The typical vein fringes and smooth amorphous featureless zone as shown in Fig. 7(a) indicated that the as-spun ribbon is mainly amorphous. The observation is consistent with that of TEM micrograph in Fig. 2 and tensile curve in Fig. 6(a). The vein fringe is generally regarded as an indication that local shear bands expanded in softening fracture surface [13]. A small amount of particles resulting from the melting liquid drop were embedded among the vein fringes. When the ribbon is annealed at 450℃ for 1 h, the fracture morphology as shown in Fig. 7(b) is greatly different from that of as-spun ribbon. The tensile fracture surface is composed of fine but depth-inhomogeneous dimples originating from the nucleation, growth and aggregation up to the fracture of micro-holes.
aggregation up to the fracture of micro-holes.

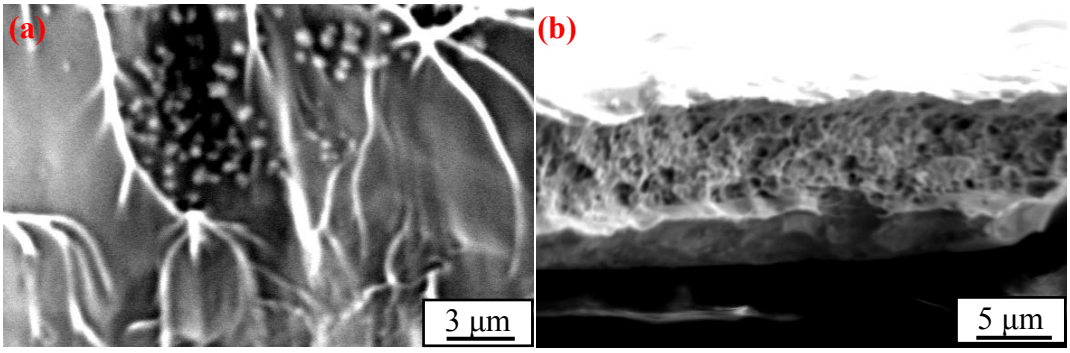

Fig. 7. Tensile fracture morphologies of $Ti_{51.5}Ni_{25}Cu_{23.5}$ ribbon: (a) as-spun, (b) annealed at 450℃ for 1 h.

Summary

As-spun $Ti_{51.5}Ni_{25}Cu_{23.5}$ alloy ribbon is mainly amorphous with the fracture morphology of vein fringe. Some B19 martensite crystalline grains with (011) compound twin were embedded in the ribbon. The ribbon annealed at 450℃ for 1 h is at fully martensitic state and its fracture morphology shows fine and depth-inhomogeneous dimple. Annealing process alter the martensite preferential orientation from (022)-B19 to (111)-B19. Tensile fracture stresses of as-spun ribbon and the annealed ribbon are 1257 MPa and 250 MPa respectively, while the fracture strains of them are 3.7% and 2.7%, respectively. Stress-strain curve of the as-spun ribbon is simple elastic deformation, while that of the annealed ribbon was composed of three stages. TEM observations of the annealed ribbon after tensile test show typical martensitic detwinning behavior.

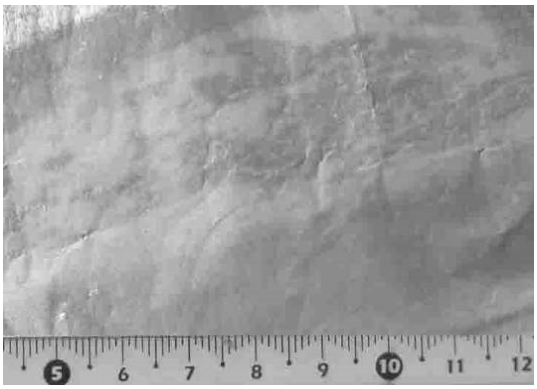
Keywords: C70250 alloy; Copper alloy strip; Oxide skin defects

Abstract. The oxide skin defect during hot rolling process for Cu-Ni-Si alloy strip was investigated. Oxide skin defects were analyzed by means of alloy elements detection and microstructures characterization. The characterization and test results showed that high temperature oxidation and silicon segregation are the main causes of the oxide skin defect. Pilot scale tests indicated that hot processing temperature for C70250 alloy should be lower than 950°C. Reducing atmosphere is recommended during the thermal treatment of Cu-Ni-Si alloys.

Introduction

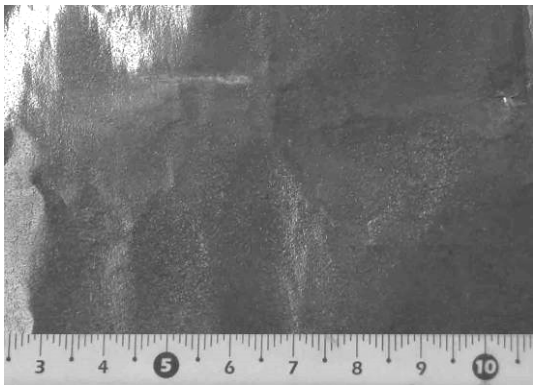
As the second generation of lead frame material [1,2], the consumption demand of Cu-Ni-Si alloy strip keep growth steadily. Plenty of theoretical researches on Cu-Ni-Si alloy have been done in colleges and research institutes [3-11]. However, few works has been carried out in industrial production. Many domestic copper processing enterprises [12], such as Chinalco Luoyang Copper Co., Ltd, Xingye Copper Co., Ltd, et al, have carried out a series of researches, and are developing their abilities of Cu-Ni-Si alloy strip production.

In the present work, Oxide skin defects after hot rolled process were investigated. Helped by alloy elements measuring and microstructures characterization, the main cause of oxide skin defect was analyzed. The heating process of hot rolling was also optimized. A technical problem of strip processing was solved.



Experimental

The C70250 alloy ingot was heated up to 950±20°C for 3~5h in the chamber resistance furnace, hot rolled to 5mm and cold rolled to 1.5mm. Hot rolling was carried out on the three-roller irreversible rolling mill. The roller size is Φ250×500mm and the draught pressure is 200t. The maximum size of nip cross-section is 75×300mm^2. Cold rolling was carried out on the four-roller reversible cold-rolling mill, and the roller size is Φ200 × 500 mm. Draught pressure is 300t. The cross-section ranges of the strip sizes are 75~0.15×400mm^2.



Microstructure and energy dispersive spectrometer (EDS) were analyzed by JEOL scanning electron microscope. The composition of the casting alloy was tested by Inductively Coupled Plasma (ICP) analysis instrument.

Microstructures Characterization and Composition Detection of Oxide Skin

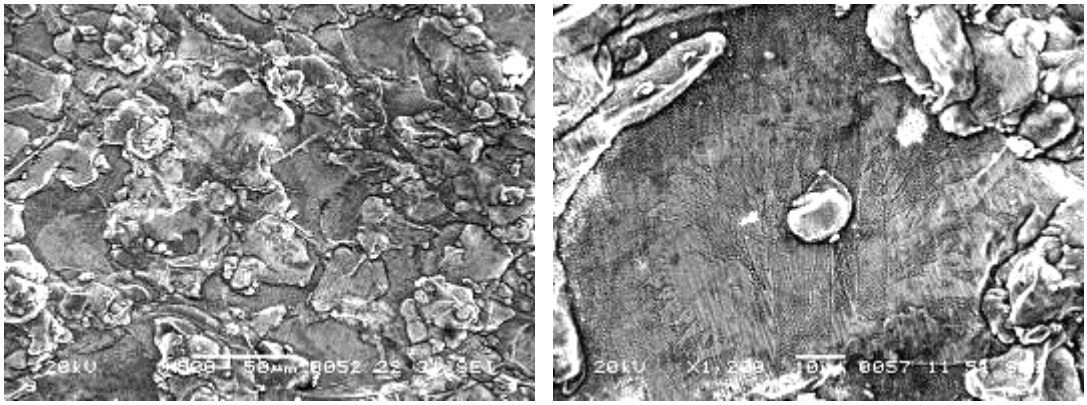
Oxide skin defects appear on the strip surface in the pilot scale test. Local area of the alloy plate slab appeared oxide skin defects during hot rolling, and the oxide skin defects became more obvious after solution treatment. Large scale oxide skin defects appeared on the C70250 strip surface after the first pass rolling. The oxide skin defects could be striped homogeneously, the morphology of oxide skin is shown in Fig.1.

(a) Inner surface of oxide skin defect is wine

(b) Outer surface of oxide skin defect is purple brown

Fig. 1 Macro-morphology of Oxide Skin Defect for C70250 Rolled Strips

The thickness of oxide skin defects is about 0.3~0.4mm. Inner surface of the oxide skin appears dull red color (fig 1(a)), and the outer surface is purple brown (fig 1(b)).



Microstructure Characterization

Microstructure of the oxide skin defects on the Cu-Ni-Si alloy strip after hot rolled is shown in Fig.2. Scanning electron microscopy experiments indicated that the surface distribution of oxide skin defects is no-uniform (Fig.2 (a)). According to the test result, the oxide and precipitated phases tend to appear on the salient area, the flat area is the matrix (Fig.2 (b)).

Selected Area Energy Spectrum Analysis

The micro-topography and selected area energy spectrum analysis results in different parts of oxide skin defect are shown in Fig.3 and table 1.

Energy spectrum analysis results indicated that there were silicon segregations in local area of oxide skin defects. The content of silicon is between 2.2%~5.3%, which is between five to ten times higher than the average content of silicon (0.5%). Qualitative data results indicated that oxide skin defects were very serious.

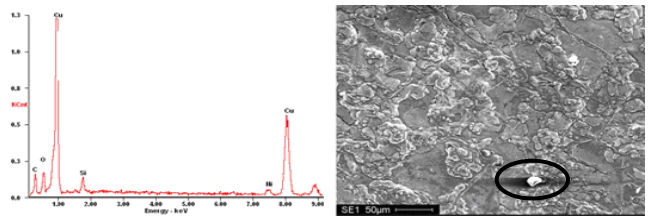
Element	O	Si	Ni	Cu
Wt [%]	$4.5^{+1.67}_{-1.69}$	$3.7^{+1.52}_{-1.53}$	$3.8^{+1.15}_{-0.55}$	$86.0^{+4.7}_{-14.3}$



(a) Morphology of local oxide area and EDS

(b) Morphology of local oxide and silicon segregation and EDS

(c) Morphology of local oxide area and EDS

(d) Morphology of local oxide, silicon segregation and carbon segregation and EDS

Fig. 3 Energy Spectrum Analysis of Oxide Skin for Rolled Strip of Cu-Ni-Si Alloy

ICP Results

Alloy composition of the oxide skin was then analyzed carefully. ICP results indicated that nickel content is 2.69 wt. % and the silicon content is 0.45wt. %. The content of nickel and silicon was close to the matrix content. No silicon segregation was found between matrix and the oxide skin itself.

Analysis and Discussions

Qualitative data results indicated that no silicon segregation was found between matrix and the oxide skin surface, but the silicon segregation happened in some local area of the matrix surface. The silicon segregation was relatively serious, and its content is up to 2.2%~5.3%. Overburning evidence was found in the local area by the microstructure observation measure. The characterization and test results showed that high temperature oxidation and silicon segregation are the main reasons leading to the oxide skin defect.

Excessive heating temperature leads to silicon segregation on the surface of Cu-Ni-Si alloy strip. High heating-up temperature also cause oxidation. Meanwhile, the breaking of the precipitated phases, during the deformation process, weakens the bonding force between the surface and the matrix.

Due to unbefitting high temperature, the surface of Cu-Ni-Si alloy strip was seriously oxidated (EDS qualitative data results shown that oxygen content is about 10~20%), which weakens the bonding strength between the oxide skin and the matrix. Oxide skin could be peeled off with the increase of the plastic deformation rate. Carbon content was relatively high in some local area. It's because that high holding temperature lead to carbon diffusion under carbon protection. Pilot scale tests indicated that employing proper holding temperature (≤950°C) could avoid oxide skin defects during rolling process.

Conclusions

The characterization and test results indicate that high temperature oxidation and silicon segregation are the main reasons of oxide skin defects of Cu-Ni-Si alloy strip.

Heating temperature of C70250 alloy should be lower than 950°C during hot rolling and solution treatment.

Pilot scale tests indicated that proper holding temperature and reducing atmosphere could effectively prevent the oxidation of Cu-Ni-Si strip, which can avoid large-scale oxide skin defects during rolling process.

Keywords: High alloy medium-upper carbon steel, Austenite catalytic, Catalytic temperature, Transformation, Cryogenic treatment, Precipitation hardening, Tempering hardness

Abstract: The processing of austenite catalytic cryogenic treatment of two components of Cr-W-Mo-V high alloy medium-upper carbon steels and the effect on the retained austenite transformation and tempering hardness were studied in this paper. The results show that, the effect of austenite catalytic cryogenic treatment of Cr-W-Mo-V high alloy medium-upper carbon steel is better than that of direct cryogenic treatment after quenching, and the content of residual austenite reduced to below 5%, and the hardness improved by 1.5HRC than that of conventional quenching and tempering. The retained austenite catalytic temperature of Cr-W-Mo-V high alloy medium-upper carbon steel merely is higher than 10℃~20℃ of the temperature for the highest tempering hardness. Catalytic temperature Tc can be determined by experimental method of conventional quenching and tempering of the steel, in which the microstructure feature is precipitation of M_3C carbide particle of 0.01μm～0.03μm in martensite matrix, and the content of retained austenite decreases evidently. By cryogenic treatment after the austenite catalyzed the retained austenite of quenching are transformed into more martensite, and in the subsequent tempering processing the original quenching martensite and the martensite from retained austenite transformation almost will form synchronous precipitation hardening. Thus the tempering hardness improves evidently as well.

Introduction

Has showed that, conventional quenching and cryogenic treatment of tool and die steels can promote the decomposition of retained austenite to martensite transformation and precipitation of ultrafine carbides on large amount of dispersed carbides in the martensite matrix[1-3]. It has become an advanced technology of quality guarantee and upgrade for the tool and die of traditional products. However, in the actual production the tool and die often occurs brittle fracture by direct cryogenic treatment after conventional quenching. And the cryogenic treatment is must in good time after quenching as to avoiding stabilization of the retained austenite for long time stopping, so that is resulting in frequent startup and shutdown of cryogenic processing equipment and resulting in energy waste. Earlier studies have found, the tempering of high speed steel at higher temperatures for short time after quenching, which takes catalytic effect on the quenching retained austenite decomposition[4]. We envision using this principle, the austenitic catalytic treatment of high alloy steel after conventional quenching and then cryogenic treatment can overcome the drawbacks of directly cryogenic treatment after conventional quenching. In this paper the processing of austenite catalytic cryogenic treatment of two components of Cr-W-Mo-V high alloy medium-upper carbon steels and the effect on the retained austenite transformation and tempering hardness are studied, at the same time, in which is contrasted to that of direct cryogenic treatment after quenching and conventional quenching and tempering. And by analysis of phase structure and microstructure the outcome of effect and the mechanism of the phase transformation are discussed.

Experimental materials and method

The composition of two experimental materials was shown in Table 1, which are two kinds of new steels for making tool with thin edge. Experimental materials were melted in 0.5t variable frequency induction furnace adding electro-dregs remelting furnace. After forging and rolling, the steels were processed to 58mm ×11 mm×11 mm samples by incision machining.

TABLE 1 CHEMICAL COMPOSITION OF TWO EXPERIMENTAL STEELS (WT.%)

	C	Si	Mn	Cr	W	Mo	V	Ni
7S	0.69	0.52	0.45	6.98	3.22	1.53	1.45	0.32
6S	0.66	0.62	0.55	6.34	2.26	1.04	0.75	0.25

The experiments of conventional quenching and tempering treatment were performed using KSJ-5kw electric furnace, and the temperatures of conventional heat treatment are reasonable in the light of production process[5]. Cryogenic treatment is using cryogenic tank of the self-made liquid nitrogen vaporization together with the workpieces, and after quickly cooling to -60℃ from room temperature the cryogenic rate is 2℃/min and the returning rate to room temperature is 10℃/min. The hardness was mensurated using 150DT-HR sclerometer, and an average value of the hardness was accounted adopting six testing points or more. The phases present and retained austenite were analyzed using X-ray diffractometer D/max-3A, and carbide phases were analyzed by extraction powder. The microstructure was investigated using scanning electron microscope XL30.

Experimental processes and results

Processes and technical parameters

The experimental processes of two steels and the temperature and holding time of their technics are listed in Table 2. No.1 process is containing of austenitic catalytic cryogenic treatment, the whole process is consist of heating at high temperature and quenching cooling to room temperature and to conducting an austenitic catalytic treatment, and then in conducting the cryogenic treatment and finally tempering treatment 2 times. No.2 process is the quenching cooling to room temperature and then in conducting the cryogenic treatment, and last tempering treatment 2 times. No.3 process is the conventional quenching and tempering treatment. No.2 and No.3 processes are used as contrasting with No.1. And the temperatures of annealing and quenching are the best values of two steels commonly used[5]. The temperature of austenitic catalytic is higher than 20℃ comparing to temperature of the highest hardness of secondary hardening, and the cryogenic treatment at -120℃ is used currently in our production. Final tempering temperature of No1 process is the temperature of highest hardness during secondary hardening. But final tempering temperatures of No2 and No3 processes are higher than 20℃ comparing to corresponding temperatures of the highest hardness, which are commonly used of temperatures in production for the sake to reduce the amount of residual austenite. All values of holding time are correct not only by the study proved and also commonly used in the production.

TABLE 2 EXPERIMENTAL PROCESSES AND TEMPERATURE (℃) AND HOLDING TIME(HOUR) OF TWO STEELS

	No	Annealing	Quenching	Catalytic	Cryogenic	Tempering	Tempering
7S	1	840×4	1080×0.4	540×0.8	-120×0.5	520×2.5	520×2.5
	2	840×4	1080×0.4	not	-120×0.5	540×2.5	540×2.5
	3	840×4	1080×0.4	not	not	540×2.5	540×2.5
6S	1	840×4	1050×0.4	530×0.8	-120×0.5	510×2.5	510×2.5
	2	840×4	1050×0.4	not	-120×0.5	520×2.5	520×2.5
	3	840×4	1050×0.4	not	not	520×2.5	520×2.5

Selection of austenitic catalytic temperature and holding time

Catalytic temperature is related with both the steel composition and quenching temperature. The higher temperature will reduce the subsequent tempering hardness during secondary hardening. The lower than catalytic temperature not only to pall on the catalytic role, and will enhance the thermal stability of retained austenite. The method for determining the catalytic temperature Tc is through the conventional quenching and tempering experiments with cryogenic treatment effect on retained austenite. The experiments show that, the retained austenite catalytic temperature of Cr-W-Mo-V high alloy medium-upper carbon steel is higher than 10℃~20℃ of temperature of the highest tempering hardness. And retained austenite catalytic temperature of high speed steel is higher than 30℃~40℃ of temperature corresponding to the highest tempering hardness[4], which may be related to higher thermal stability of retained austenite with high carbon and alloys. Figure 1 shows selection of the retained austenite catalytic temperatures Tc by tempering curves of two steels, and two temperatures were severally selected 20℃ higher then temperatures Th of the maximum hardness. Namely, Th of 7S steel is 520℃ so Tc is 540℃, and Th of 6S steel is 510℃ so Tc is 530℃. Holding 1.5 hours at the tempering temperature, the tempering hardness is not less than 1HRC of highest hardness, and the microstructure features are appearing precipitation particle of M_3C type of carbides in size of about 0.01μm～0.03μm on martensite matrix and the amount of retained austenite reduced obviously. Hence these criterions can be used as catalytic temperature selection.

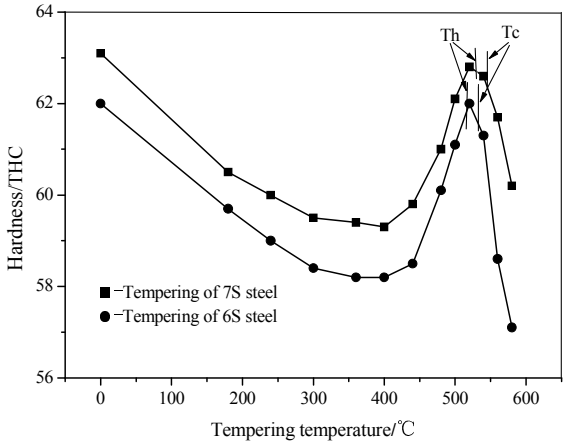

Fig.1 Temperature selection of austenitic catalytic by tempering curve

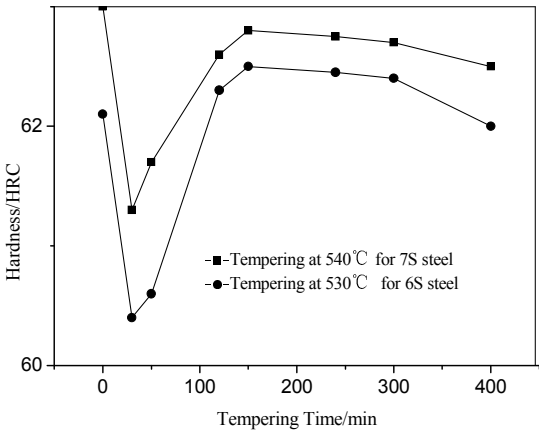

Fig.2 Tempering hardness change with tempering time

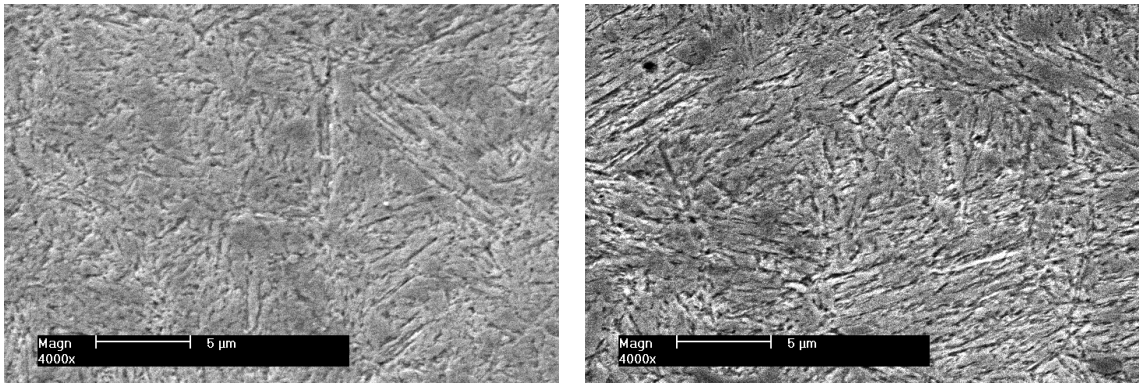
Figure 2 is isothermal tempering hardness change of two steels at Tc with tempering time. Figure 2 shows, in tempering for 30 minutes at the austenite catalytic temperature the hardness reduces to lowest. The main reason for the hardness decline in this stage is separating of C atoms oneself from the martensite rapidly. The hardness only slightly elevates until holding 1 hour, at the moment the precipitation of initial M_3C type of dispersed carbide with phase relationship of the matrix begins, and at the same time the transformation of retained austenite into martensite begins as well as beginning of precipitation of M_3C type carbide[6]. When more than 1 hour the dispersed alloy carbides will precipitate to cause precipitation hardening and hardness increased sharply, that in final tempering for longer times there is too large of size difference of precipitated carbides of new martensite from the retained austenite transformation and precipitated carbides of the original martensite by the continued to grow up. Accordingly, the precipitation hardening is not synchronous, It will not help improve the final tempering hardness, therefore, in the actual austenite catalytic processing the holding time is 0.8 hours.

Experimental results and comparison

The effect of austenite catalytic cryogenic treatment on retained austenite and hardness and their contrasts are listed in Table 3. Can be seen from table 3, the amount of retained austenite of two steel after quenching is ~ 40.3 and ~ 36.2 and hardness is HRC63.1 and 62.1 respectively. By No1



processing the amount of retained austenite of austenitic catalytic is ~ 28.6 and ~ 25.3, and the amount of retained austenite continuing cryogenic treatment is ~ 8.6 and ~ 7.5, and then after final tempering for 2 times the amount of residual austenite is ~ 4.7 and ~ 4.2 and hardness is HRC64.3 and 63.7 respectively. The contrast to results of the tempering for 2 times, the amount of residual austenite of No.1 processing is lowest and the hardness is highest. The effect is better than that of No.2 processing, the amount of residual austenite is reduced to close to 1/2 and the hardness is increased by 0.5HRC, and the effect is a lot of improving than that of No.3 processing obviously, and the amount of residual austenite is reduced to about 1/3 and hardness is increased by about 1.5HRC.

TABLE 3 EFFECT OF AUSTENITE CATALYTIC CRYOGENIC TREATMENT ON RETAINED AUSTENITE* AND HARDNESS

	No	Quenched		Catalytic	Cryogenic	Tempered in twice	
		retained γ′/%	hardness/HRC	retained γ′/%	retained γ′/%	residual γ′/%	hardness/HRC

Microstructure of two steels tempered by austenite catalytic cryogenic treatment and after tempering 2 times is shown in Figure 3. Although the microstructure of study with transmission electron microscopy after cryogenic treatment has a lot of microscopic characteristics[3,7], and by scanning electron microscopy and optical microscopy those microscopic features are not seen nearly. However, the specimen in the erosion under the same conditions, the microstructure after austenite catalytic cryogenic treatment to observe using scanning electron microscope is etched deeper than that of without cryogenic treatment.

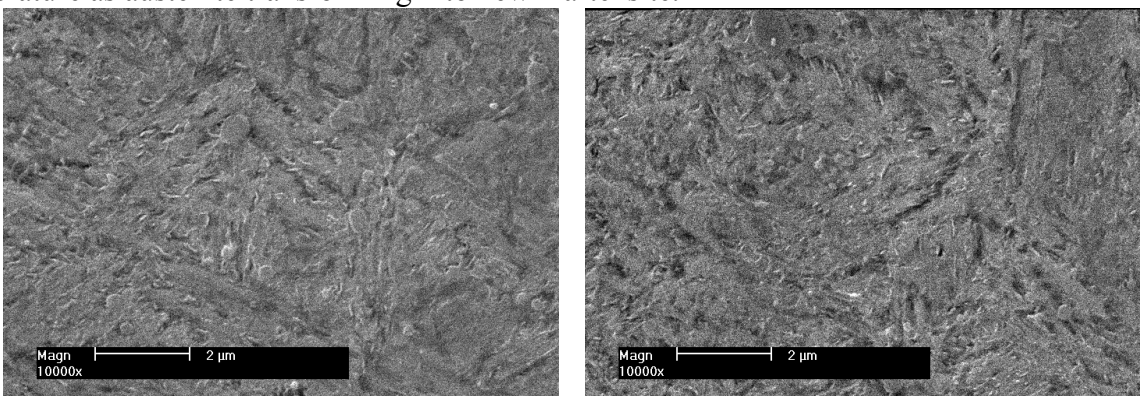

Fig.3 Microstructure of two steels tempered by catalytic cryogenic treatment

Analysis and discussion

Austenite catalytic treatment is tempering processing for short time. In order to analyze the effect on transformation, the samples of austenitic catalytic treatment for 1.5 hours were studied owing to observe clearly using scanning electron microscope and X ray phase analysis, it can estimate the transformation and precipitation of the earlier stage. Figure 4 is the microstructure of two steels treated at catalytic temperature for 1.5 hours. Figure 4 shows, in the quenched martensite the precipitation of more dot and tiny strip carbides is observed, which size is about 0.01μm～0.03μm and the precipitation of tiny dot carbides in primary austenite is observed too.

Table 4 is carbide phase analysis of two steels and calculated equilibrium phases of their tempered, and Figure 5 is the result of analysis carbides phase of two steels by carbides extraction. Can see, in addition to the existence of stable carbides the metastable phase of M_3C type also

appears, which is agreement with tempering precipitation regularity[8]. Figure 6 shows the variation of the amount of retained austenite of two steels tempered at different temperature for 1.5 hours, can see, the amount of retained austenite decreases sharply during tempering at austenite catalytic temperature as austenite transforming into new martensite.

Fig.5 X-ray spectrum of carbides of two steels tempered

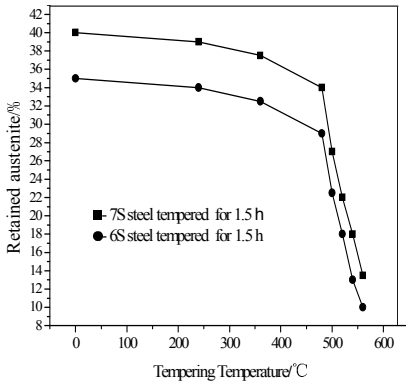

Fig.6 Retained austenite with tempering temperature

In the catalytic temperature the disordered distribution of dislocations by rearranging will become to effective distribution of nucleation, the vacancies and the air mass of solute atoms formation also are removed. The C content in retained austenite is reduced as a result of a small amount of precipitation of dot carbide at this temperature and the temperature of retained austenite transformation to martensite rises as well, it is easy of the retained austenite to transform into martensite[4]. Can be inferred, the tempering transformation at austenite catalytic temperature from 0.8 hours to 1.5 hours is continuous processing, in tempering at the austenite catalytic temperature for short time the precipitation size of carbide particle merely is more fine. Therefore, it can effectively promote the transformation of retained austenite after joining the cryogenic treatment, and the effect of final tempering is better than that of direct cryogenic after quenching. Of course, the experimental method and result also are determining of suitable catalytic temperature for Tc.

The carbides type of this kind of steels after annealing or quenching is agreement with equilibrium phase form, but the metastable phase appears after tempering, i.e.during tempering the first precipitation of M_3C type carbide from quenching martensitic or martensite of retained austenite transformation appears in early. Similarly, in austenite catalytic treatment the first precipitation of M_3C type carbide occurs as well, subsequently, in the continuous tempering or

secondary tempering the M_3C type carbide will anew dissolve and change direction to M_6C and $M_{23}C_6$ forming usually in the M_3C boundary or in situ, that is beginning of precipitation hardening acutely(see Fig.2). Accordingly, in pre catalytic processing the transformation of retained austenite has been made much into martensite, and sequentially in cryogenic processing the transformation of retained austenite has been made more into martensite. In the last tempering processing the original quenching martensite and the martensite from retained austenite transformation almost will synchronously form the precipitation hardening. In other words, the precipitation hardening will be increases as more of particles at the tempering temperature, so it can remarkably improve the tempering hardness[9]. And tempering temperature of the highest hardness is slightly lower, that or called secondary hardening peak left shift[7]. The final tempering hardness of direct cryogenic treatment after quenching increases only 0.5~ 0.8HRC in the same tempering conditions, this is because of the microstructure characteristics of cryogenic treatment by largely eliminated in final tempering processing at high temperature for high alloy steel.

Conclusion

(1) The effect of austenite catalytic cryogenic treatment of Cr-W-Mo-V high alloy medium-upper carbon steel is better than that of direct cryogenic treatment after quenching. The content of residual austenite reduced to below 5% and hardness is increased by 0.5HRC. And the effect is obviously improved much compared to that of the conventional quenching and tempering and the hardness is increased by about 1.5HRC.

(2) The temperature of retained austenite catalytic of Cr-W-Mo-V high alloy medium-upper carbon steel is merely higher than 10℃~20℃ of temperature of the highest tempering hardness. Catalytic temperature Tc can be determined by experimental method of conventional quenching and tempering, and the microstructure feature appears 0.01μm～0.03μm M_3C type carbide in martensite matrix precipitation, and the amount of retained austenite decreases evidently.

(3) As the retained austenite are transformed more into martensite by austenitic cryogenic cryogenic treatment after quenching, so original quenching martensite and martensitic of retained austenite transformation can form almost synchronous precipitation hardening.

Key words: non-quenched and tempered steel; dynamic recrystallization; forging technology;

Abstract: The effect of forging process on microstructure and performance of V-Ti, V-Nb-Ti non-quenched and tempered microalloying steel was investigated in this study. By comparing thecharacteristics between V-Ti and V-Nb-Ti microalloyed non-quenched and tempered steels by the forging process,the machinsm of micro-alloy technology and forging process for dynamic recrystallization and microstructure refinement was investigated. It revealed that addition of Nb in micro-alloying steel can increase significantly non-recrystallization temperature during forging process, and enhance the V (C, N) precipitation strengthening effect of V-Ti microalloyed non-quenched and tempered steels. V-Nb-Ti microalloying technology and controlling forging temperature in non-recrystallization region, can refine grain size, promote proeutectoid ferrite emerging and pearlite morphology alienating. By controlling final forging temperature in non-recrystallization region, the strength and toughness of V-Nb-Ti micro-alloy non-quenched and tempered steels can be improved.

Introduction

Microalloyed non-quenched and tempered steel developed with worldwilde energy shortage is an energy efficient steel. Comparing to the traditional alloy structural steel which needs high temperature quenching and tempering heat treatment, it have some advantages such as simple production process, higher material utilization rate, enhanced quality of parts, lower energy consumption and manufacturing cost, so it obtains a wide range of applications. At present, this kind of steel is widely used from the car industry to construction, heavy machinery, high pressure pipelines, bridges, and other fields [1,2].

Non-quenched and tempered steel is essential a kind of mechanical structural steel, requiring a good mechanical property as quenched and tempered steel. For the quenched state of the mechanical structural steel, its rolling (forging) process is only an intermediate product, so it has little effect on the performance of products. The final mechanical properties of parts mainly depend on quenching and tempering process. For non-quenched and tempered steel, the rolling (forging) and cooling is the final production process, so the heating temperature, final rolling (forging) temperature and cooling after deformation have a significant influence on the mechanical properties of final product. Microalloying technology, controlled forging and cooling process are the key way to achieve high strength and toughness [3-5]. Generally, the non-quenched and tempered steel supplied by the domestic market have poor impact resistance. Therefore, in this paper, the V-Nb microalloying non-quenched and tempered steel was investigated, with a view to improving the strength level greatly and enhance the impact properties simultaneously.

Experimental Materials and Methods

The tested material is a rod of non-quenched and tempered steel with diameter of 80mm, belonging to ferrite-pearlite type forging non-quenched and tempered steel, main chemical composition of which is shown in Table 1. The rod of non-quenched and tempered steel for experiments was prepared by controlled rolling and cooling in forging workshop. The controlled rolling and cooling process are as follows: the work-piece was reheated at 1130℃, followed by initial forging at 1050℃, and the final forging was carried out at 850℃, 900℃, 950℃ and 1000℃, and bars with final size of Φ25×500mm were obtained. After forging, the bars were air cooled with rate of about 1.5℃/s to 650℃, followed by air cooling to room temperature.

The tensile specimens (5mm diameter and 65mm gauge length) and U-notch impact test specimens (10mm width, 55mm length and 10 thickness) were machined from the rods according to the GB6397-1986, GB/T229-1994. The mechanical tests was used to determine tensile strength (Rm), yield strength (Rp0.2), percentage elongation (A) after fracture, the percentage reduction (Z) of fracture section and impact absorbed energy (AKU2). Microstructure analysis of the tested material was performed by employing optical microscopy, scanning electron microscopy and transmission electron microscopy.

TABLE 1 CHEMICAL COMPOSITIONS OF THE EXPERIMENTAL V-TI, V-TI-NB STEELS (WT,%)

Steels	C	Si	Mn	S	P	V
V-Ti	0.39	0.60	1.45	≤0.03	≤0.03	0.12
V -Nb-Ti	0.38	0.62	1.44	≤0.03	≤0.03	0.078
Steels	Cr	Ni	Ti	Nb	O	N
V-Ti	0.3	--	0.016	--	--	0.0058
V -Nb-Ti	0.3	--	0.016	0.025	--	0.0092

Results and Discussion

Mechanical Properties

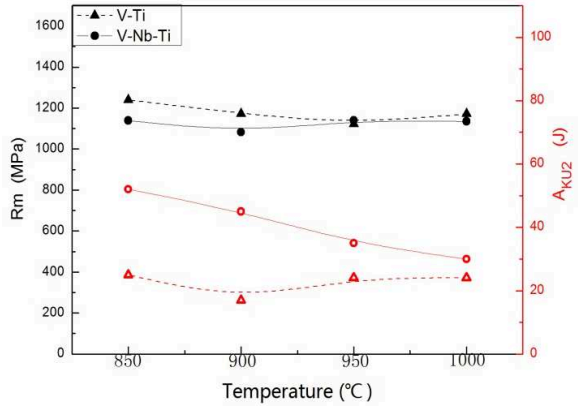

Fig. 1 Mechanical properties of steels with different final forging temperature

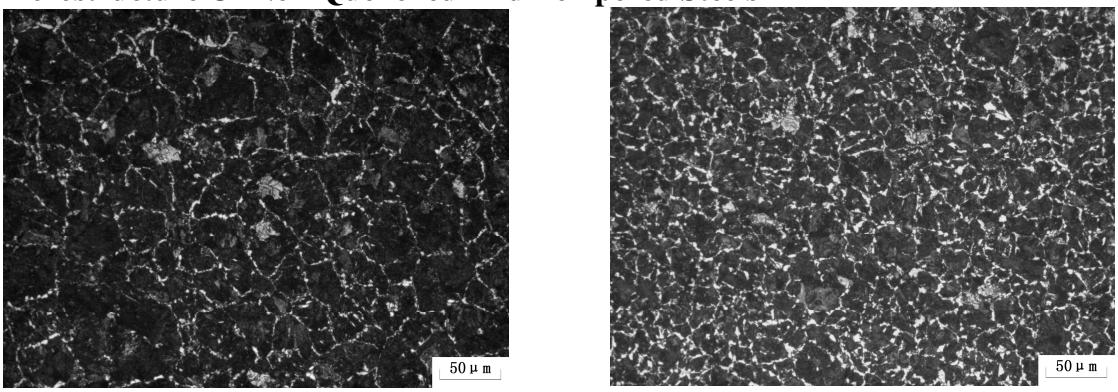

TABLE 2 THE MECHANICAL PROPERTIES OF V-TI AND V-NB-TI MICROALLOYING STEELS AT 850℃

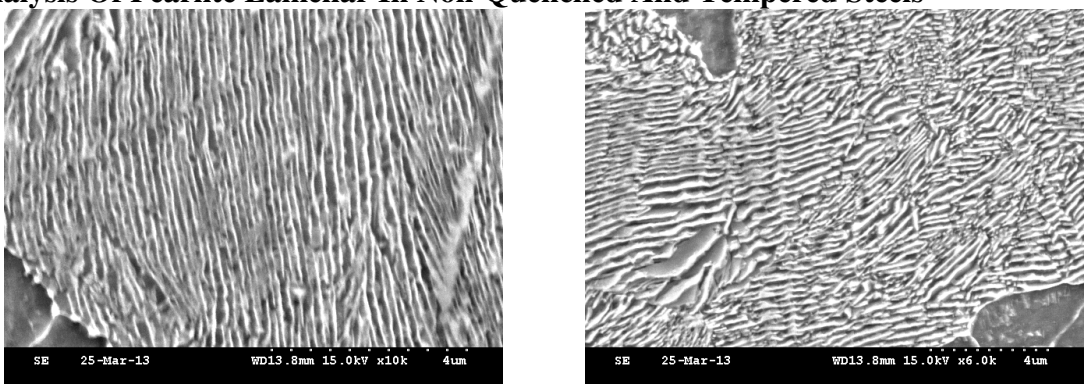
steels	Rm/(MPa)	Rp0.2/（MPa）	A/(%)	Z/(%)	AKU2/(J)
V-Ti	1240	695	14	19	25
V-Nb-Ti	1139	655	13.5	31	52

The mechanical properties of the V-Ti microalloyed steel exhibits a slight change with decreasing of final forging temperature, as indicated in Figure1 and Table2. Their tensile strength fluctuated at about 1150 Mpa, and impact energy at about 20J. The tensile strength of V-Nb-Ti micro-alloy steel went up and down a little with the final forging temperature dropping, indicating an inconspicuous

change. But the impact absorbing energy increased from 30J to 52J with the final forging temperature decreasing, and reached the highest value at 850℃. It is suggested that the strength of the V-Nb-Ti micro-alloy steel reached 1100 MPa level that is close to V-Ti microalloyed steel, and the impact toughness was also promoted greatly. At the same time it can be found that rolling at low temperature in non-recrystallization zone would improve the toughness of the V-Nb-Ti micro alloyed steel.

The Microstructure Of Non-Quenched And Tempered Steels



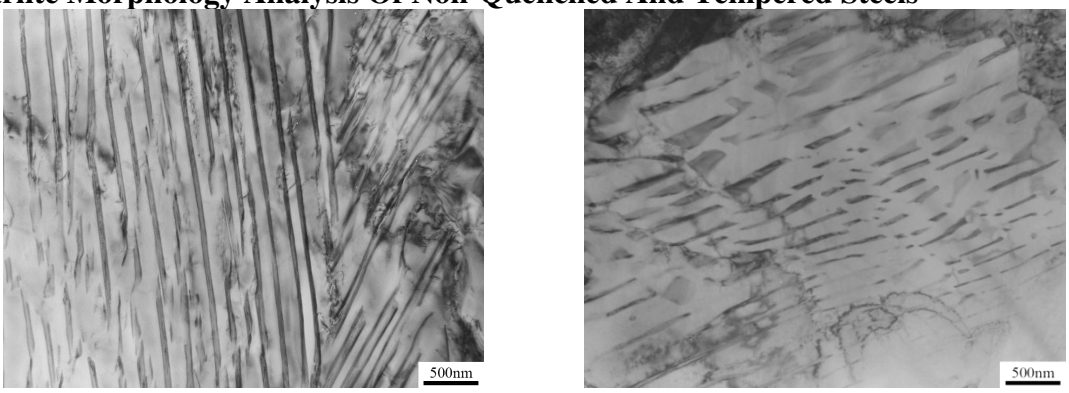
（a）V-Ti (b) V-Nb-Ti

Fig.2 Microstructure of non-quenched and tempered steels at 850℃

It can be observed from Figure 2 that the pearlite structure of V-Nb-Ti microalloyed steels after forging is tinier than that of the V-Ti microalloyed steel. And ferrite content reached 19%, which is the main reason that V-Nb-Ti microalloyed non-quenched and tempered steel has high impact toughness. Because the NbC precipitation in V-Nb microalloyed steel can prevented the austenite recrystallization at final forging stage, and raise obviously finish recrystallization temperature (950 ℃), shorten the time of dynamic recrystallization [6]. V-Nb-Ti microalloyed technology reduces the transformation temperature of austenite to ferrite, and the effect of grain refining can be achieved. The steel were rolled at the temperature range (850℃~900℃)of non-recrystallization region, and the austenite grains were elongated and refined after deformation. Warm rolling increases significantly the dislocation density and stored energy of deformation in the non-quenched and tempered steel. The V-Nb-Ti composite technology promoted the formation of the V(C, N) particles which precipitated along the grain boundary and dislocation line, and promote nucleation and growth of proeutectoid ferrite on VN particles [7, 8].

Rolling at non-recrystallization region of V-Nb non-quenched and tempered steel can promote effectively the homogeneous distributing and refinement of proeutectoid ferrite grain. Therefore, in the V-Nb micro alloyed steel there is a lot of intra-granular ferrite, which break up bulky pearlite group and refined grain. The formations of sufficient intra-granular ferrite form and microstructure refinement are main reasons that V-Nb microalloyed steel has high impact toughness [9, 10].

The Analysis Of Pearlite Lamellar In Non-Quenched And Tempered Steels



（a）V-Ti (b) V-Nb-Ti

Fig.3 Pearlite morphology of non-quenched and tempered steels at 850℃

Figure 3 shows the influence of forging process on the pearlite morphology of the V-Ti and V-Nb-Ti non-quenched and tempered steel. The figure clearly shows the distinction of pearlite layer between V-Ti and V-Nb-Ti microalloyed steels. The pearlite lamellar of V-Ti steels parallelly arranged, while the V-Nb microalloyed pearlitic arranged as short broken and disorders crowding, and part of them granulated spherically. Because V-Nb-Ti composite microalloying technology reduces the ferrite-pearlite phase transformation temperature and finer pearlite lamella can be obtained at low temperature. The average thickness of cementite layer of V-Ti steels was reduced from 42nm to 27nm, and the lamellar spacing was refined from 110nm to 85nm. The fine and blunt pearlite which disorderly distributed in the V-Nb-Ti steels can improve the toughness and strength [11].

The Pearlite Morphology Analysis Of Non-Quenched And Tempered Steels

（a）V-Ti (b) V-Nb-Ti

Fig.4 TEM micrograph of pearlite

The TEM micrograph of pearlite lamella in the V-Ti, V-Nb-Ti microalloyed steels after forging at 850℃ was presented in figure 4. It shows that the niobium has four effects for steel that preventing recrystallization, grain refinement, reducing pearlite lamellar spacing by the controlling phase transition and precipitation strengthening [12-15]. By using the V-Nb-Ti microalloying technology and taking full advantage of the low temperature forging at non-recrystallization zone, grain refinement can be achieved. Through V-Nb-Ti microalloying technology and controlled rolling technology, the long cementite lamellar during cooling transition process was broken. And the micrograph of short flake or abnormal globurizing, order-disorder transformation and narrow lamellar spacing can be obtained, which improve the toughness of non-quenched and tempered steel without the loss of strength.

The V-Nb composite microalloying steel after rolling exhibit bent, broken and spheroidizing cementite lamellae. At the same time, pearlite appear abnormal form, neat microstructure was arranged into chaos, the aspect ratio of cementite decreased significantly and cementite lamellar nodulizing for non-quenched and tempered steel, and good strength and toughness was obtained.

Conclusions

（1）V-Nb microalloying technology raised the dynamic recrystallization finish temperature, and expanded the recrystallization region of V-Ti non-quenched and tempered steel.The steel was firstly rolled in the dynamic recrystallization region, followed by rolling at low temperature (850℃) in the non-dynamic recrystallization region. And thus the boundaries of fine austenite were elongated, which increased the total effect area of the austenite grain boundary, increasing deformation energy storage and the nucleation position of ferrite phase transformation after deformation. So fine ferrite-pearlite structure can be obtained.

(2) The pearlite obtained after rolling at low temperature in non-recrystallization region, its micrograph changed significantly. Unlike V-Ti microalloyed steels, the cementite piece in pearlite of V-Nb steel is not parallelly arranged, but disordered obviously. Bent, broken and spherical pearlite lamella was observed. The aspect ratio of cementite decreased significantly and granulated, which improves strength and toughness of the V-Nb microalloyed steels.

(3) A small amount addition of Nb in V-Ti non-quenched and tempered steel can promote the precipitation of V, by which grain refinement, wide non-recrystallization region, precipitation strengthening and organization refinement can be achieved. Through V-Nb microalloying technology and rolling at low temperature in non-recrystallization zone, globular pearlite lamella was obtained. The aspect ratio of cementite reduced significantly, which improves the strength and impact toughness of non-quenched and tempered steel. V-Nb microalloying technology optimized the performance of non-quenched and tempered steel, and overcomes the shortcoming of V-Ti non-quenched and tempered steel that strength is high, bu toughness is insufficient.

Key words: Aging; Precipitation; M_7C_3 Carbide; Coarsening

Abstract: The precipitation behavior of carbides in Fe-5.78Cr-0.35C (wt.%) alloy during aging at 850℃ was studied. The type, particle size and distribution of carbides were determined and measured by the combination of HRTEM (High Resolution Transmission Electron Microscope), XRD (X-Ray Diffraction) and quantitative metallography technique. Results show that the type of carbides was M_7C_3 and the obvious coarsening of carbides was observed during aging. In addition, the thermodynamic and kinetic calculation using Thermo-Calc software was conducted to study the precipitation of carbides. The stable phase in the alloy aging at 850℃ was M_7C_3 carbide and austenite which is in accordance with experimental results. According to Ostwald coarsening mechanism, the average interfacial energy between γ phase and M_7C_3 carbide was calculated as 0.7 $J \cdot m^{-2}$. Then the precipitation behavior of carbides in Fe-5.78Cr-0.35C alloy during aging was well predicted.

Introduction

To understand the evolution of morphology, size, distribution and volume fraction of precipitates which have strong effects on the mechanical properties of steel materials during aging is quite important[1,2]. The precipitation behavior of carbides in a ternary Fe-Cr-C alloy during aging was experimentally studied in the present work. In addition, thermodynamic and kinetic calculations were also conducted using Thermo-Calc software. With the combination of experimental study and calculation, the precipitation behavior of carbides during aging can be predicted.

Experimental Material and Method

99.98wt.% Cr, 99.998wt.% Fe and Fe-1wt.% C alloy was electric arc and induction melted into the ingot. The composition of the ingot was measured to be Fe-5.78 wt.%Cr-0.35 wt.%C. The ingot was capsuled in a vacuum quartz tube under the pressure below 10^{-2}Pa and homogenized at 1000 ℃ for 100h. The specimens with size of 10mm×10mm×3mm were cut from the ingot and capsuled in a vacuum quartz tube. The specimens were solid-solution treated at 1100℃ for 20h before quenching into water. Then the specimens were capsuled respectively and aged at 850 ℃ for 10min, 1h, 5h, 30h and 100h.

The heat-treated specimens were mechanically polished and etched in 4% nitric acid alcohol to observe the metallographic microstructure.

The carbides precipitating during aging were obtained by chemical extraction in phosphoric acid (2:1) at room temperature[3]. Carbides powder was filtered using micro-porous membrane with 0.15 μm aperture and dried. A D/MAX-2500 X-ray diffractometer using Cu Kα radiation, at a

scanning speed of 5° /min, with scanning angle of 20°~100°(2θ) and operating at 40kV and 40mA was used to determine the type of precipitates.

Samples for TEM observation were obtained by carbon replica technique. Heat-treated specimens were mechanically polished and etched. A layer of carbon was deposited on the etched specimen and then etched in 8% nitric acid alcohol for seconds until the replica began to lift. The specimen was slid into distilled water and the replicas were collected by a copper net. The microscopy work was performed with the JEM-2010F instrument and operating at 200kV accelerating voltage. Precipitates were identified by a combination of electron diffraction patterns and EDS analysis. Morphology of carbides[4] were also observed,.

To determine the size distribution of precipitates, about 300 particles were photographed and measured for each sample. Measurements were conducted by using Image J analysis software.

Experimental Results

XRD results as shown in Fig.1 indicate that the precipitates are all M_7C_3 type carbide when aged for 10min, 1h, 5h, 30h and 100 h.

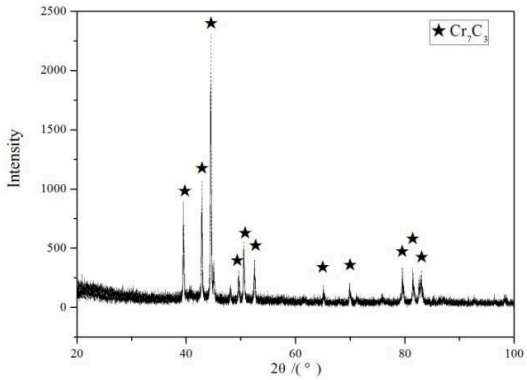

Fig.1 XRD patterns of precipitates in specimens aged at 850℃ for 10min, 1h, 5h, 30h and 100 h

TEM images of precipitates with diffraction pattern and EDS analysis in Fe-5.78 wt.%Cr-0.35 wt.%C (wt.%) alloy after aging at 850℃ for 100h was shown in Fig.2. Diffraction pattern of spherical and rod-like precipitates shows the type of carbides as M_7C_3.

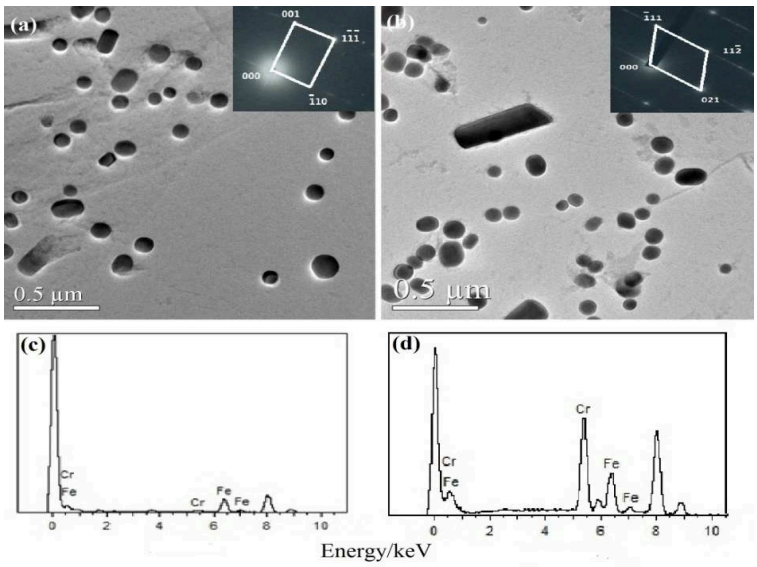

Fig.2 TEM micrographs with diffraction patterns and EDS analyais of (a,c) spherical precipitates and (b,d)rod-shaped precipitates

The analytical process to determine the size and distribution of precipitates was shown in Fig.3. Incomplete particles on the boundaries were not counted. 300 particles were counted to obtain the average particle size of precipitates. Mean radius of carbides after aging at 850℃ for 10min, 1h, 5h, 30h and 100h was 31.79nm, 34.18nm, 42.25nm, 48.36nm and 57.82nm respectively. The size distribution under each heat-treatment condition was shown in Fig.4.

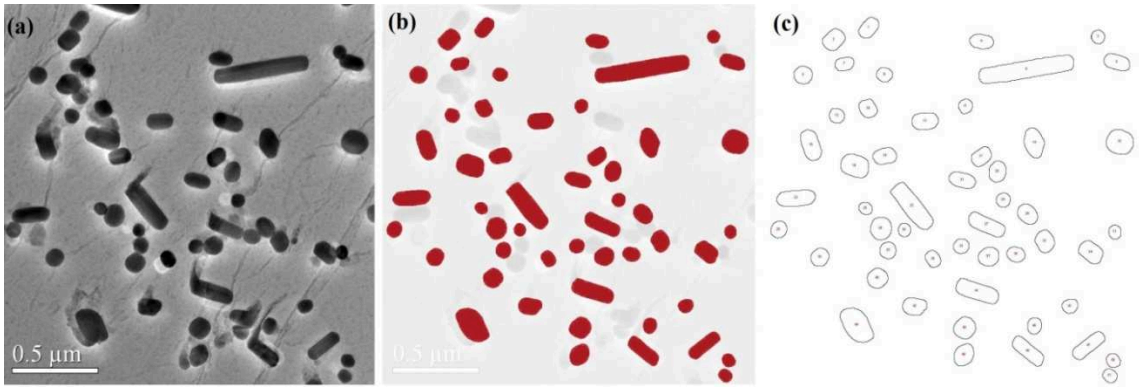

Fig.3 Schematic diagrams of the analytical process to determine the size and distribution of M_7C_3 carbides

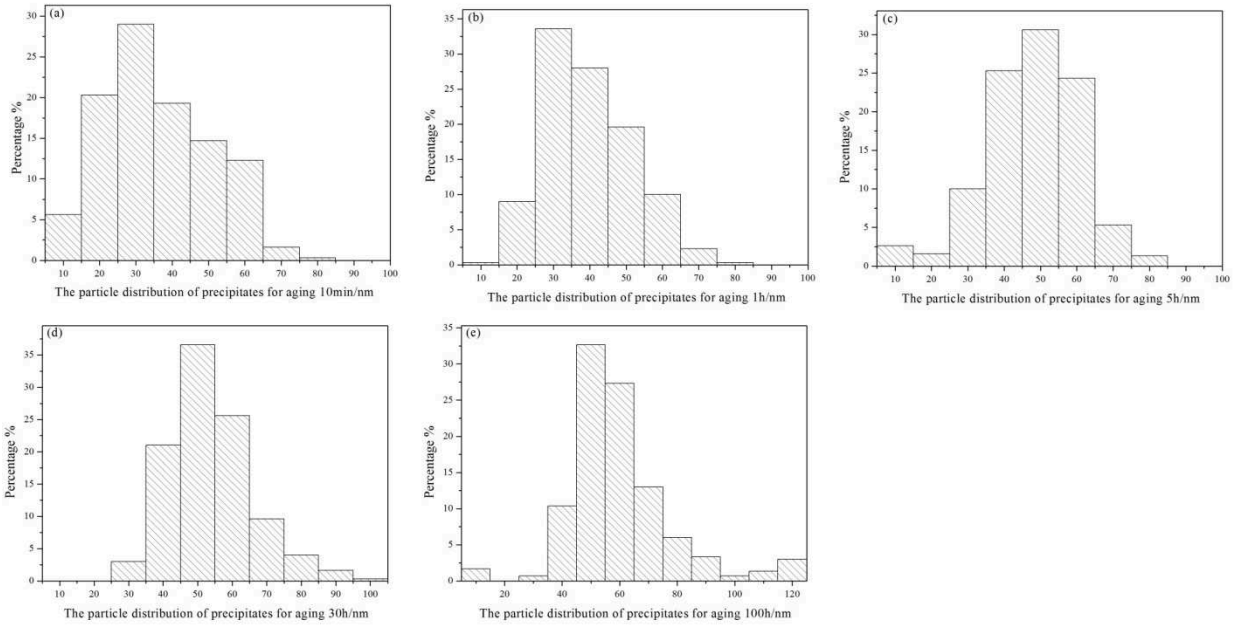

Fig.4 Size distribution of M_7C_3 carbides in specimens aged at 850℃ for (a) 10min, (b) 1h, (c) 5h, (d) 30h and (e) 100h, respectively

Discussion

The equilibrium phases of the Fe-5.78Cr-0.35C alloy aged at 850℃ consist of austenitic(denoted as FCC_A1#1) and M_7C_3 carbide according to the phase diagram calculated by Thermo-Calc Ⓢ [5] software as shown in Fig.5(a). Thus the carbide type precipitated in Fe-5.78Cr-0.35C alloy during aging at 850℃ was well predicted.

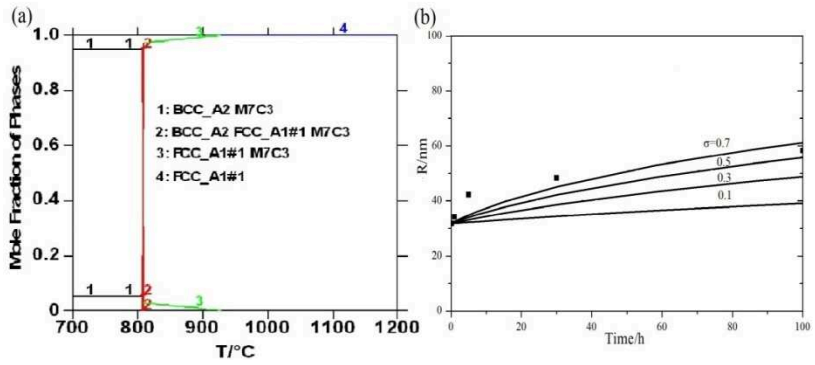

Fig.5 (a)Mole fraction of equilibrium phases as a function of aging time and (b) comparison between the experimental data with calculated coarsening of M_7C_3 carbides in Fe-5.78Cr-0.35C alloy aged at 850 ℃

As well known, the coarsening model Oswald ripening was adopted in DICTRA[5]. It uses the assumption that coarsening of a system can be described by performing calculations on a single particle of maximum size at the centre of a spherical cell. It is assumed that the particle size distribution obeys the Lifshitz-Slyozov-Wagner distribution, i. e.the maximum particle size is 1. 5 times the average size of the precipitates. Based on coarsening model, simulations were performed with thermodynamic database TCFE6 and the mobility database MOB2. Results were shown in Fig.5(b) in comparison with the measured average radius represented by symbols. Since the interfacial energy varies between 0.1 -1.0 $J.m^{-2}$ as a rule of thumb[6,7], value of σ changing from 0.1 to 0.7 $J.m^{-2}$ with a step of 0.2 $J.m^{-2}$ is used for simulation. Simulation of coarsening of M_7C_3 carbides in austenite at 850 °C with the interfacial energy of 0.7 $J.m^{-2}$fits the experimental data well.

Conclusions

(1) The equilibrium phases of Fe-5.78Cr-0.35C alloy aged at 850℃ consist of austenite and M_7C_3 carbide.

(2) The obvious coarsening of carbides was observed during aging at 850℃. The average particle radius of M_7C_3 carbides was equivalent to 31.79nm, 34.18nm, 42.25nm, 48.36nm, 57.82nm when aged at 850℃ for 10min, 1h, 5h, 30h, 100h, respectively.

(3) Precipitation behavior of M_7C_3 carbides in an Fe-5.78Cr-0.35C alloy can be simulated by Thermo-Calc software. Interfacial energy of M_7C_3/austenite interface is 0.7$J.m^{-2}$ for the coarsening of M_7C_3 carbide at 850℃.

Keywords: Titanium concentrate; Molten salt electrolysis; Temperature; TiFe; $TiFe_2$; Diffusion

Abstract. Ti-Fe alloy was prepared by electroanalysis using titanium concentrate as the cathode at 3.1V in $CaCl_2$ molten salt. The temperature is respectively 850℃ and 900℃. The comparison of the results under different temperature shows that the temperature has a significant influence on the diffusion process and the electrolytic products. At 850 ℃, the final electrolytic product is the $TiFe_2$ and Ti discrete ball-type structure with the particle size of 1 μm, while at 900 ℃ the final product is the TiFe space net structure with the particle size of 3 μm.

Introduction

Titanium alloy, as a kind of important functional material, has received the widespread attention. In recent years, there are studies and reports about the performance and magnetism of hydrogen storage of the ferro-titanium [1-5]. The method of preparing the ferro-titanium with the mixture of TiO_2 and Fe_2O_3 by electrolytic method is a kind of green metallurgy technology, which has advantages of short process, low energy consumption and low pollution. This method has been reported a lot [6, 7], but little research about the influence of temperature on electrochemical results has not been reported. This paper takes titanium concentrate's cathode as the cathode, with electrolysis voltage of 3.1V, the electrolytic experiments was carried out respectively under the condition of 850℃ and 900 ℃ , and the phase and structure of the electrolytic products are analyzed.

Experiments

Titanium concentrate, the starting material, was separated from tailings, which was the product from beneficiation of vanadium-bearing titanomagnetite. The main phase is $FeTiO_3$ and there is also a small amount of Si, Ca, Al, Mn, V, S, P and other elements. Table 1 is the element analysis of titanium concentrate

Titanium concentrate cathode was prepared by melting method under the protection of the Ar gas. $CaCl_2$ molten salt was used as the electrolyte, which was dried in an oven at 150 ℃. To reduce its moisture content and impurities, $CaCl_2$ was needed to pre-electrolysed at 600℃ for 2 h. The electro-deoxidation experiments were carried out in graphite crucible at atmosphere pressure, and the crucible was dried at 150℃ before the experiments. $FeTiO_3$ was used as the working electrode, a graphite rod was used as the counter electrode, and the graphite crucible was used as the reference electrode. The electrolytic temperature is respectively 850℃ and 900℃and the voltage was increased to 3.1 V.

After electrolysis, the pellet and the graphite rod were removed from the electrolyte and cooled to room temperature in the furnace. The pellet sample was put into distilled water for 12 h and then cleaned by Q2200E ultrasonic cleaner to remove the electrolyte. The morphology and elements distribution were observed by SEM (scanning electron microscopy) and phase composition was analyzed by XRD (Rigak D/Max-2500). Diffraction parameters were as follows: Scanning angle 2 θ was 20°~90°. Scanning speed was 1.2 °/min. Tube voltage was 40 KV. Tube current was 150 mA.

TABLE 1 ELEMENT ANALYSIS OF TITANIUM CONCENTRATE

Element	O	Fe	Ti	Mg	Si	Ca	Al	Mn	S	P

Results and Discussion

Phase and Appearance of the Cathode of the Titanium Concentrate

Fig. 1 and 2 is the XRD pattern and SEM of titanium concentrate cathode, respectively. Fig. 2 shows that the titanium concentrate cathode has a compact structure after solidification by melting. The phase composition of titanium concentrate cathode is the same as the raw ore after melting, showed by XRD, which is $FeTiO_3$.

At the same time, the presence of $CaSiO_3$ is detected and the diffraction peak of compounds of other elements is not obvious.

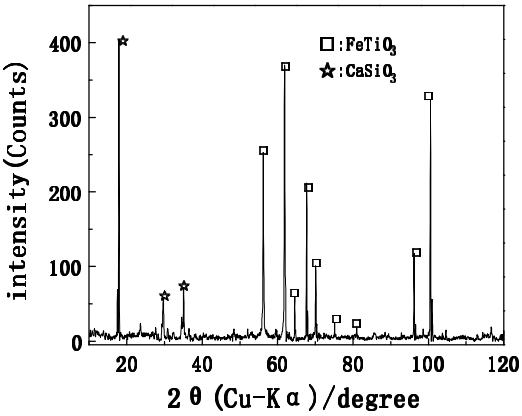

Fig. 1 XRD pattern of molten-solidified cathode

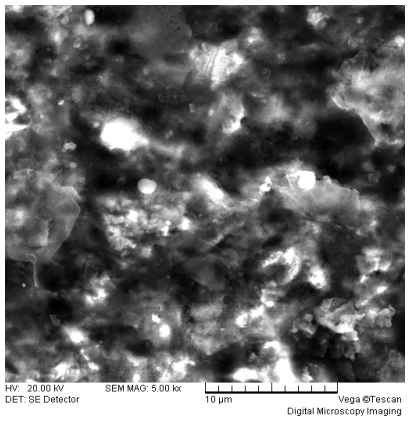

Fig. 2 SEM image of sample

The Analysis of the Electrolytic Product at 850℃

The titanium concentrate cathode was electrolysed in $CaCl_2$ molten salt at 850 °C for 0.5h, 10h and 48h, respectively. Fig. 3-5 are XRD pattern for the titanium concentrate at different electrolytic timescathode. It can be seen that the electrolytic products on cathode has a distinct difference. The main phases are Fe, $CaTiO_3$, $Ti2O_3$ and TiO when the electrolytic time is 0.5 h. when the electrolytic time is extend to 10 h, the phases are mainly $TiFe_2$ and Ti, the diffraction peak of TiFe is not obvious. With increasing the electrolytic time to 48 h, the main reaction product is TiFe and the diffraction peaks of $TiFe_2$ and Ti decrease significantly. It can also be seen that from Fig. 6 that there is an obvious change for the morphology of electrolytic product. The appearance of the cathode changes from the compact structure at the beginning into the discrete spherical structure of the particle size of 1 μm.

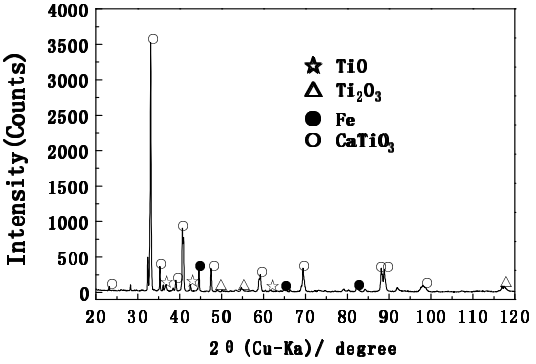

Fig. 3 XRD pattern of sample electrolyzed after 0.5h at 850℃

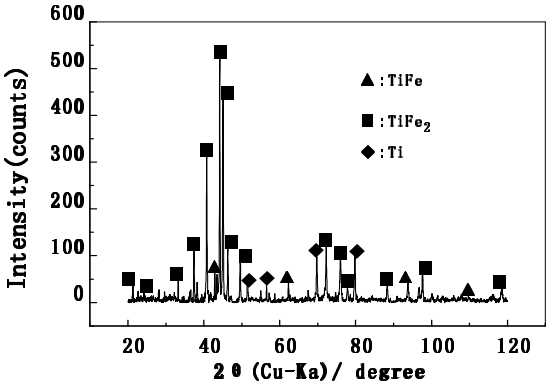

Fig. 4 XRD pattern of sample electrolyzed after 10h at 850℃

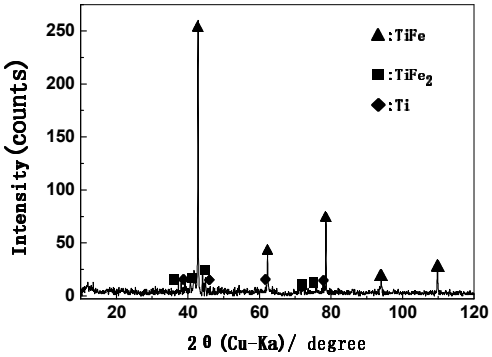

Fig. 5 XRD pattern of sample electrolyzed after 48h at 850℃

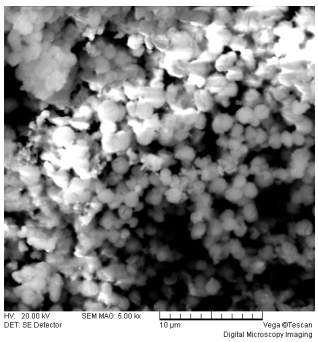

Fig. 6 SEM image of sample electrolyzed after 48h at 850℃（×5000）

The Analysis Of The Electrolytic Product At 900℃

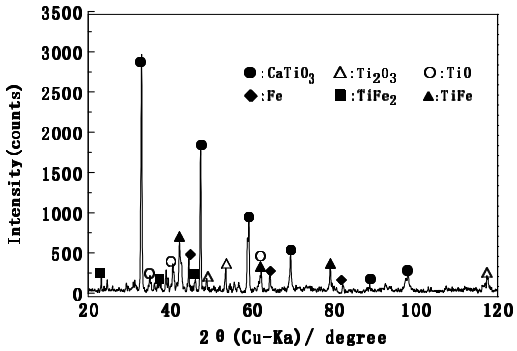

Fig. 7 XRD pattern of sample electrolyzed after 0.5h at 900℃

Under the same conditions, the electrolysis experiment for different electrolytic time at 900℃ is carried out. Fig. 7-9 are XRD pattern for the titanium concentrate at different electrolytic times at 900 ℃ It can be seen that the morphology of the electrolytic product at 900℃ is obviously different from that at 850℃.The particle size increases from 1 μm at 850℃ to 3 μm at 900℃. The appearanceof product changes from discrete spherical structure at 850℃ to spatial reticulated structure and there is significant consolidation phenomenon between particles. By XRD analysis, it can be seen that there are also Fe, $CaTiO_3$, Ti_2O_3, TiO and other intermediates in the electrolytic specimen reacting for 0.5h and there is also existence of $TiFe_2$ and TiFe phase. When the electrolytic time is 10h, the main product is TiFe and a certain amount of $TiFe_2$ at the same time. With increasing the electrolytic time to 48h, the main phases in the electrolytic sample is TiFe and the diffraction peak of $TiFe_2$ is weak. Because the TiFe alloy is formed by mutual diffusion process of $TiFe_2$ and Ti, thusthe existence of $TiFe_2$ is a intermediate process.

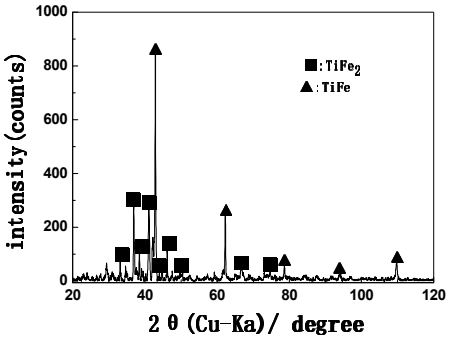

Fig. 8 XRD pattern of sample electrolyzed after 10hours

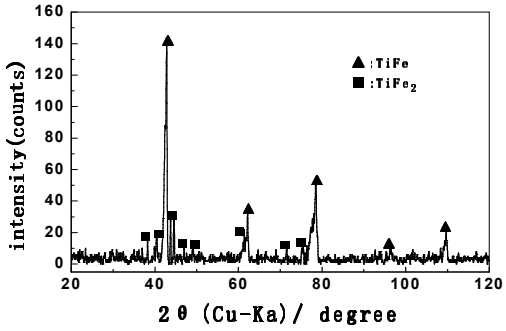

Fig. 9 XRD pattern of sample electrolyzed after 48hours

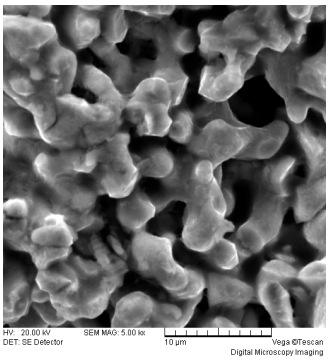

Fig. 10 SEM image of sample electrolyzed after 48h at 900℃（×5000）

Analysis On The Influence Of Temperature On The Electrolytic Product

Relevant electrode reactions in the electrolytic process are as follows:

$$FeTiO_3 + 2e = Fe + TiO_2 + O^{2-} \quad (1)$$

$$Ca^{2+} + TiO_2 + O^{2-} = CaTiO_3 \quad (2)$$

$$2CaTiO_3 + 2e = Ti_2O_3 + 2Ca^{2+} + 3O^{2-} \quad (3)$$

$$2TiO_2 + 2e = Ti_2O_3 + O^{2-} \quad (4)$$

$$2Ti_2O_3 + 2e = 2TiO + O^{2-} \quad (5)$$

$$TiO + 2e = Ti + O^{2-} \quad (6)$$

$$2Fe + TiO + 2e = TiFe_2 + O^{2-} \quad (7)$$

$$Fe + TiO + 2e = TiFe + O^{2-} \quad (8)$$

$$TiFe_2 + TiO + 2e = 2TiFe + O^{2-} \quad (9)$$

The thermodynamics for the electrolytic process is calculated by calculation. The gibbs free energy ΔG within the range of 0~1000℃ for different reactions can be obtained. According to the chemical thermodynamics ($\triangle_r G_m = -zFE$), the theory decomposition voltage of each reaction can be calculated, showed in Fig. 11. It is shown that the theoretical decomposition voltage of FeO is lower than TiO_2, so the Fe is prior to be reduced. The XRD analysis results of 0.5 h after electrolysis under the condition of 850℃ shows that there is the existence of the elemental Fe, and Ti exists in the form of suboxide of perovskite and titanium. The reduction of Ti is from + 4 to + 3 and then to + 2 and finally reduce to reduction process step by step of Ti. Perovskite only exists in the reaction area on the surface of cathode, the compact cathode structure prevents the diffusion of Ca_2+ in the molten salt inside the cathode, so there is no intermediate of $CaTiO_3$ in the electroreduction process inside the cathode.

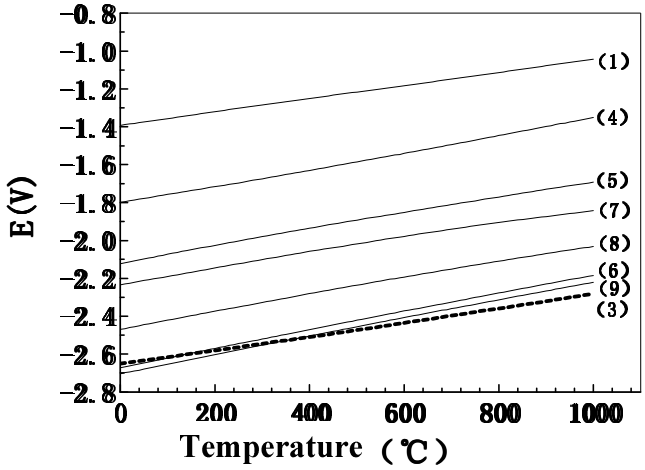

Fig.11 Theoretical decomposition voltage of electrode reaction at 0~1000℃

At the high temperature, the formation of $TiFe_2$ and TiFe alloy by Ti and Fe is a spontaneous process. It can be found from Fig. 11 that the theoretical decomposition voltage of forming $TiFe_2$ and TiFe is lower than that of Ti. Therefore, in thermodynamics, the process of forming $TiFe_2$ and TiFe is more easily than reduction to metallic titanium, thus, there is no simple substance Ti in the early stage of the reaction.

And the electrolysis voltage to form $TiFe_2$ is lower than to form TiFe and the structure is more stable, so in the alloying process, $TiFe_2$ is given priority to produce. However, the process of reduction and alloying of Ti in the $TiFe_2$ particles needs higher electrolytic voltage than that for directly producing the elemental Ti and through thermodynamic calculation, it can be known that the process where Ti combines with $TiFe_2$ to generate TiFe is a spontaneous process. Therefore, when Fe to produce $TiFe_2$ is exhausted, Ti will be electrolyzed and reduced in the elemental form, this result is same as the analysis result of XRD produced by electrolysis for 10 h under the condition of 850℃, with the extension of reaction time, the diffusion is further strengthened and this is same as the electrolytic products after 48h.

Compared with the result at 850℃, the phase and structure of the electrolytic product under the condition of 900℃ is obviously different, indicating the temperature has a significant influence on the process of preparation of titanium alloy by electrolytic titanium concentrate. Under this experimental condition, the priority of each electrode reaction has not changed, so the electrolytic mechanism has not changed. However, the increasing of temperature improves the electrolytic speed and the diffusion ability of Fe, Ti, O and other atoms. Under the condition of 850℃, after electrolysis for 0.5h, t Fe is reducted partially. When temperature is 900℃, after electrolysis for 0.5h, the phase of $TiFe_2$ and TiFe are also existed, which indicating the improvement of temperature is advantageous to the electrolytic process. In the comparison of feature of the product under different temperatures, it can be found that, from the discrete spherical structure at 850℃ to the space mesh structure at 900℃, the increase of electrolytic temperature significantly improves the diffusion ability of Fe and Ti atoms. As under the experimental condition, the process where Ti and TiFe2 combine to generate TiFe is a spontaneous process, combining the results of electrolysis for 48h at 850℃ and 900℃, it shows the mutual diffusion of Ti and $TiFe_2$ eventually generates the TiFe alloy and the temperature is very important for the mutual diffusion of alloying process.

$$FeTiO_3 \Rightarrow Fe+TiO_x \Rightarrow TiFe_2+TiO_x \Rightarrow TiFe_2+Ti \Rightarrow TiFe$$

Fig. 12 Schematic of electro-deoxidization process of titanium concentrates

Conclusions

1) Ti-Fe alloy can be prepared by electroanalysis using titanium concentrate as the cathode at 3.1V in $CaCl_2$ molten salt when the electrolytic time above 850℃. the direct electrolytic products are $TiFe_2$ and Ti.

2) The formation of TiFe alloy by Ti and $TiFe_2$ is a non-spontaneous process in thermodynamics. TiFe alloy is produced by the mutual diffusion between $TiFe_2$ and Ti.

3) The increasing of temperature promotes the mutual diffusion process of $TiFe_2$ and Ti and is favorable for the formation of TiFe alloy.

Keywords: Molten salt electrolysis; Ilmenite concentrate; Ferro-titanium; TiFe; $TiFe_2$

Abstract. Ti-Fe alloy is prepared by the electrolytic reduction of titanium concentrate in molten $CaCl_2$ under argon atmosphere. The formation mechanism of Ti-Fe alloy is discussed. The impact of electrolytic time on product is studied when electrolytic voltage is 3.1V and electrolytic temperature is 900℃. Results show that Ti-Fe alloy with uniform composition can be obtained by this method. The deoxidize product is iron and TiFe alloy by order. The reduction of Ti is a multi-step process and the intermediate products include $CaTiO_3$,TiO_2, Ti_2O_3, TiO,Fe, $TiFe_2$.

Introduction

Titanium ore resources in China are mainly distributed in Guangdong, Guangxi, Hainan, Hebei and Panzhihua. The TiO_2 grade of titanium concentrate is generally 45%~60%. As a typical hydrogen storage material, Ti-Fe alloy has attracted more attention [1] and how to directly use Chinese rich resources to prepare ferrotitanium is an exploratory work with vital significance.

Since the preparation of metallic titanium can be carried out through the technology of molten salt electrolysis deoxidization [2,3] with TiO_2, this technology has aroused extensive attention in the industry. The researchers have extracted metals or alloys successfully by FFC technology,such as Nb_3Sn[4], Ti-10W [5], Nb [6], Tb_2Fe_{17} [7], Cr [8], Ni-Ti [9], Mg-Zr [10], Co-Cr [11], V-Ti [12], TiFe [13-14] , and also built model of molten salt electrolysis oxide [15] etc.. The cathode reported in literature is mainly metal oxide. The little research on preparing metal or alloy is directly from ore. The author directly adopted the titanium concentrate from Panzhihua region in China as the materials to prepare Ti-Fe alloy through molten salt electrolysis, which possessing the certain significance in the aspects of economic cost and environmental pollution.

Experiments

Titanium concentrate with an average 75 μm particle size was selected as the starting material. The main phase is $FeTiO_3$. Table 1 is the element analysis of titanium concentrate

Titanium concentrate cathode was prepared by melting method under the protection of the Ar gas. $CaCl_2$ molten salt was used as the electrolyte, which was dried in an oven at 150℃. To reduce its moisture content and impurities, $CaCl_2$ was needed to pre-electrolysed at 600℃ for 2h. The electro-deoxidation experiments were carried out in graphite crucible at atmosphere pressure, and the crucible was dried at 150℃ before the experiments. $FeTiO_3$ was used as the working electrode, a graphite rod was used as the counter electrode, and the graphite crucible was used as the reference electrode. The electrolytic temperature is respectively 850℃ and 900℃and the voltage was increased to 3.1 V.

After electrolysis, the pellet and the graphite rod were removed from the electrolyte and cooled to room temperature in the furnace. The pellet sample was put into distilled water for 12 h and then cleaned by Q2200E ultrasonic cleaner to remove the electrolyte. The morphology and elements distribution were observed by SEM (scanning electron microscopy) and phase composition was analyzed by XRD (Rigak D/Max-2500). Diffraction parameters were as follows: Scanning angle 2 θ was 20°~90°. Scanning speed was 1.2 ° /min. Tube voltage was 40 KV. Tube current was 150 m A.

Results and discussion

A. Morphology and phase composition of titanium concentrate before and after electrolysis

Fig. 2 and 3 are SEM of the sample before and after electrolysis. Before electrolysis, the titanium concentrate presents a compact crystalline state structure. When cathode was electrolyzed at $CaCl_2$ molten salt 48 h, the cathode forms space reticular structure with 3 μm particles. The morphology of the sample changed significantly after electrolysis. Fig. 4 and 5 are XRD profile of the sample before and after electrolysis. We can see from Fig. 4 that the key composition of cathode phase of the preparative titanium concentrate through fusion and solidification is $FeTiO_3$. The oxidization of titanium concentrate can be avoided with protection of Ar. While $CaSiO_3$ detected in the phase may be the result of beneficiation of fusion and solidification of calcium metasilicate contained in the raw ores. XRD and EDS analysis has been conducted for the samples through 48-hour electrolysis. The XRD analysis found that ferrotitanium and a small quantity of elemental titanium and $TiFe_2$ alloy. EDS analysis reveals Ti:Fe (atomic ratio)=1.09 (table 2), showing that ferrotitanium can be prepared through molten salt electrolysis titanium concentrate and atomic ratio of Ti and Fe stays the same as that of raw materials. As ferrotitanium generates through inter-diffusion of $TiFe_2$ and Ti, the main product is TiFe after complete electrolytic reduction of titanium concentrate and alloy phase is very homogeneous and there are a few $TiFe_2$ and elemental Ti.

B. Phase analysis on cathode surface at earlier stage of electrolysis

In order to deeply analyze the electrolytic reduction of titanium concentrate, under the condition of 3.1V voltage and 900℃ electrolysis temperature, XRD analysis on the surface of samples with 10 min and 30 min of electrolytic time and diffraction profile is shown in Fig. 6. As shown in the Fig., new phases including Fe, $CaTiO_3$, Ti_2O_3 and TiO were generated on the cathode surface and the original phase $FeTiO_3$ disappeared. Due to the reduction potential of Fe is lower than that of Ti, metallic iron and TiO_2 and O^{2-}. TiO_2 were generated on cathode surface and then combined with CaO in the fused salt to produce the intermediate product $CaTiO_3$. $CaCl_2$ has extremely strong hydroscopicity and CaO are formed by the hydrolyzation of $CaCl_2$. With the processing of reaction, the intermediate product $CaTiO_3$ will generate suboxides Ti_2O_3 and TiO of Ti after further electroreduction and Ti and Fe will combine to generate $TiFe_2$ and TiFe. O^{2-} moves toward the anode through electric field action and performs electrode reaction on the anode to emit O^{2-} The involved electrode reactions are as follows.The thoretical electrolytic voltage of the related reaction are also listed when the temperature is 900℃.

$$FeTiO_3 + 2e = Fe + TiO_2 + O^{2-} \quad (1)$$

E1=-1.07813V

$$Ca^{2+} + TiO_2 + O^{2-} = CaTiO_3 \quad (2)$$

$$2CaTiO_3 + 2e = Ti_2O_3 + 2Ca^{2+} + 3O^{2-} \quad (3)$$

E3=-2.32034V

$$2Ti_2O_3 + 2e = 2TiO + O^{2-} \quad (4)$$

E4=-1.73098V

$$TiO + 2e = Ti + O^{2-} \quad (5)$$

E5=-2.23089V

$$2Fe + Ti = TiFe_2 \quad (6)$$

$$TiFe_2 + Ti = 2TiFe \quad (7)$$

$$2O^{2-} + 4e = O_2 \quad (8)$$

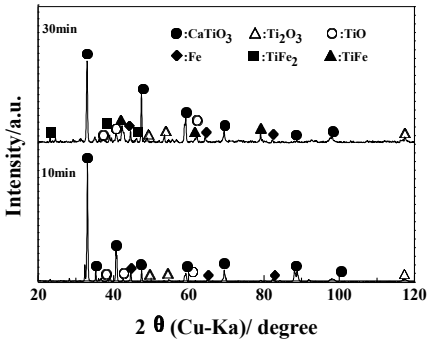

Fig. 6 Surface XRD after 10-min and 30-min electrolysis

C. Phase analysis of cathode at metaphase of electrolysis

Under the same experiment conditions, the sample section with 1h, 8h and 20h electrolytic time were analyzed. it is found that there are obvious reduzate layers between the interior of cathode and the exterior contacted with $CaCl_2$ molten salt(Fig. 7). XRD pattern of cathode section is shown in Fig. 8, which showing that the main product are TiO_2, Ti_2O_3, TiO, $TiFe_2$ With the processing of electrolysis, the reaction region moves toward the center of sample and the mass of intermediate products decrease as well until disappear. With increasing of electrolytic time, mass of TiFe product increases continuously. It can be found from Fig. 8 that X-ray diffraction peak of TiFe phase strengthens increasingly. However, the unreacted $FeTiO_3$ phase does not exist in the sample center at different reaction times. Therefore, there is strong X-ray diffraction peak of $FeTiO_3$ phase in the result of XRD analysis. $CaTiO_3$ phase does not exist in the phase because the compact cathode structure restrict the diffusion of Ca^{2+} inward the cathode in $CaCl_2$ molten salt. The intermediate product $CaTiO_3$ does not formed during electrolytic reduction inside the cathode, which resulting in difference of intermediate products inside the cathode and its surface as the reactions described in formula (2) and (3) do not happened and the chemical reaction described in (9) happens:

$$2TiO_2 + 2e = Ti_2O_3 + O^{2-} \tag{9}$$

E9=-1.39893

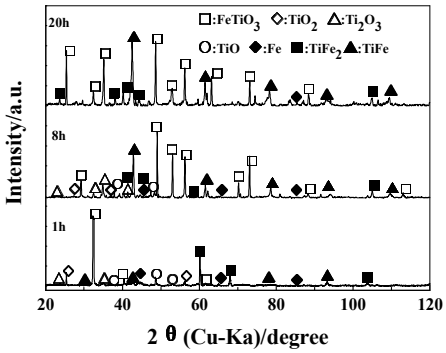

Fig. 8 XRD of cathode section of sample after 1-hour, 8-hour and 20-hour electrolysis

D. Mechanism analysis of process of electrolysis and deoxidization and alloying of titanium concentrate

Due to the complicated compositions of titanium concentrate, the deoxidization is a complex reaction process which not only refers to electrochemical reduction process and chemical reaction but also involves diffusion course of oxygen ion in solid phase and the diffusion and migration of oxygen ion in fused salt. The electrolysis reaction starts from cathode surface. $CaTiO_3$ was formed from Fe, O^{2-} , TiO_2 and CaO. $CaCl_2$ has strong hydroscopicity and the CaO contained in molten salt is mainly due to the hydrolysate of $CaCl_2$. With proceeding of electrolytic reaction, $CaTiO_3$ is electrolyzed to generate the suboxides of Ti, which are Ti_2O_3 and TiO. TiO is further electrolyzed and reduced and to generate TiFe and $TiFe_2$ alloy with Fe through alloying process. O^{2-} moves toward the anode through

molten salt and emits oxygen in anode. The compact cathode structure stops the diffusion of $CaCl_2$ toward inside. Due to the electrode reaction inside the cathode turns into the gradual reduction and alloying of $FeTiO_3$, so the intermediate product $CaTiO_3$ does not exist. According to the thermodynamics calculation, due to the deposition potential of Fe is lower than that of Ti, it will deposit firstly and the results of XRD analysis prove that Fe deposits at the beginning and Ti is reduced gradually, therefore reduction amount of Fe at reaction site will be higher than that of Ti. it can be seen from Fe-Ti phase diag that it is easy to form $TiFe_2$ alloy when the content of Fe is high. Formation of $TiFe_2$ alloy under high temperature is a spontaneous process, so it is easier to perform reduction of suboxide of Ti on Fe atom to form alloy than to form metal Ti. With proceeding of the reaction, Ti will be reduced continually and form TiFe alloy with $TiFe_2$ generated at earlier stage through interdiffusion. The structure of $FeTiO_3$ determines that the atomic ratio of Ti and Fe is 1:1 at micro level which will reduce the difficulty of interdiffusion greatly and avail formation of TiFe. As TiFe alloy generates through interdiffusion of $TiFe_2$ and Ti, the main product will be TiFe after complete electrolytic reduction of titanium concentrate and a small amount of elemental Ti and TiFe2 also exist.

The speed of preparation of TiFe alloy through electrolysis of titanium concentrate is generally decided by the following aspects: ① speed of migration of oxygen from reaction site to the cathode surface through product layer; ② speed of migration of oxygen ion from cathode outer layer surface to anode through electrolyte; ③ speed of electrolytic reduction on cathode; ④ reaction speed of Ti, Fe to form alloy. At the beginning of reaction, the cathode is a non-conductor, seriously impacting movement of electrons in cathode. The reaction will be hard to proceed without participance of electrons and electrolytic reaction is controlled by step ③. With proceeding of reaction, the thickness of product layer increases continually to improve the speed of electrolytic reduction. But the increasing of product layer thickness will increase the difficulty of oxygen migration at product layer. The homogeneity of Ti atom and Fe atom will cause high speed of diffusion and alloying process and the electrolytic reaction is controlled by step ① in fact.

$$FeTiO_3 \rightarrow \begin{matrix} Fe \\ + \\ TiO_{x(x=0\sim2)} \end{matrix} \rightarrow \begin{matrix} TiFe_2 \\ + \\ TiO_{x(x=0\sim2)} \end{matrix} \rightarrow TiFe$$

Fig. 9 Schematic diagram of electrolytic reduction of iron ore concentrate Conclusions

Conclusions

1) Ti-Fe alloy can be prepared by electroanalysis using titanium concentrate as the cathode at 3.1V in CaCl2 molten salt when the electrolytic time above 850℃. the direct electrolytic products are TiFe2 and Ti.

2) The formation of TiFe alloy by Ti and TiFe2 is a non-spontaneous process in thermodynamics. TiFe alloy is produced by the mutual diffusion between TiFe2 and Ti.

3) The increasing of temperature promotes the mutual diffusion process of TiFe2 and Ti and is favorable for the formation of TiFe alloy.

Keywords: atomic mobility; molar volume; Fe-Co alloy; fcc phase; EPMA; CALPHAD

Abstract: The diffusion-couple experiments have been performed at 1273 K and 1423 K in order to verify and bias the controversial interdiffusion data in the literature. In the meantime, the literature data on the lattice parameter have been assessed to obtain the molar volume of fcc Fe-Co phase, which was in turn fed into the Sauer-Freise equation to retrieve the interdiffusion coefficients from the EPMA (Electron Probe Micro-Analysis) measured diffusion profiles. The reliable experimental data on the diffusion coefficients for fcc Fe-Co phase have finally been used to assess the atomic mobility. A general agreement has been reached between the calculated and experimentally measured data.

Introduction

As well-known that the Fe-Co alloy is a kind of soft magnetic materials, and the Curie temperature and saturation magnetic flux density are the highest in all magnetic materials [1]. Moreover, Co-base alloys are found to offer great promise as candidates for the next-generation high-temperature materials [2].

In the study and design of these materials, diffusion analysis plays an important role in explaining the mechanisms of various reactions occurring in the condensed states. Various diffusion coefficients (i.e. self-, impurity-, intrinsic-, and inter-diffusion coefficients) are basic parameters when detailed analyses and simulations of complex diffusion-controlled transformations are performed. The quality of these simulations is largely dependents on the precision of both thermodynamic and diffusion data. The present work is a part of the efforts to systematically measure the diffusivities and establish an accurate diffusional mobility database.

The reason to choose the Fe-Co system in the present study is not only because of its technological importance, but also due to the controversial measurements of the diffusion coefficients for the fcc Fe-Co alloys in the literature. Accordingly, the aim of the present work is to verify the diffusion coefficient data by conducting diffusion couple experiments and the CALPHAD-type assessments.

Experimental Procedure

Diffusion Couple

Bulk Fe pieces (purity 99.999 wt.%) and Co plates (purity 99.99 wt.%) were used to fabricate the Fe-Co binary samples containing 58 at.% Co. It was prepared in an arc melting furnace under an argon atmosphere. The arc melting was repeated 5 times to attain a homogeneous composition. The

alloy ingots were hot-rolled into 6mm at 1373 K, and then the alloy ingots were solid-solution treated under vacuum in quartz tubes at 1273 K for 8 days followed by water-quenching. They were cut into bulk with approximate dimension of 7×7×6 mm^3. After grinding and polishing, two of them were bound together to form well-contacted diffusion couples. Then the couples were sealed in quartz tubes and placed in the furnace with specified temperature. Both diffusion couples made in this work and their diffusion conditions are listed in Table 1. After annealing, the couples were quenched in water to maintain the high-temperature microstructures and concentration. The diffusion couples were then cut parallel to the diffusion direction, grinded, and polished by standard metallographic techniques. The microstructure of diffusion zone was observed by scanning electron microscopy (SEM) and the local concentration was analyzed by electron probe microanalysis (EPMA, JXA-8530F, JEOL, Japan).

Table1. Diffusion couples and diffusion conditions involved in this work.

Phase	Diffusion-couple	Temperature (K)	Diffusion time
FCC	Pure Fe/pure Co	1423	23 hours
	Pure Fe/Fe-58 at.% Co	1273	7 days

Interdiffusion Coefficient

The interdiffusion coefficient $\tilde{D}$ was determined by using the Sauer-Freise method [3], i.e.

$$\tilde{D}\left(Y^*\right)=\frac{1}{2t\dfrac{d\left(Y/V_m\right)^*}{dz}}\left[\left(1-Y^*\right)\int_{-\infty}^{z^*}\frac{Y}{V_m}dz+Y^*\int_{z^*}^{\infty}\frac{\left(1-Y\right)}{V_m}dz\right] \tag{1}$$

where the normalized composition variable is $Y=\left(x_{Co}-x_{Co}^{-}\right)\Big/\left(x_{Co}^{+}-x_{Co}\right)$, x_{Co}^{-} and x_{Co}^{+} are the Co compositions of the left and right ends of the diffusion couple, z^* is the location of interest with the normalized composition Y^*, V_m is the molar volume of the alloys and t is the time for the diffusion experiment.

Modeling

Molar Volume

From Eq.1, it is evident that the molar volume of fcc Fe-Co phase is an important parameter. Usually the relation of the volume and composition is assumed to be linear, i.e. Vegard law. However, this is not the case for fcc Fe-Co alloys.

For a solid solution Fe_xCo_{1-x}, the molar volume V_m can be expressed as:

$$\begin{aligned} V_{\mathrm{m}} &= xV_{Fe}+\left(1-x\right)V_{Co}+V_m^E \\ &= xV_{Fe}+\left(1-x\right)V_{Co}+x\left(1-x\right)L \end{aligned} \tag{2}$$

where V_{Fe} and V_{Co} are the molar volume of pure Fe and pure Co. Their values have been assessed by Lu et al. [4] as a function of temperature. x is the mole fraction of Fe. V_m^E is the excess molar volume and the related L is regarded as the interaction parameter for the volume, and can be evaluated by fitting the experimental values of the lattice parameter. In the present work, L is assumed as a constant so the temperature variation of V_m is accounted for by the temperature dependences of V_{Fe} and V_{Co}.

Most experimental data related to volume are lattice parameters. For cubic crystals, the molar volume V_m can be computed from the lattice parameter by $V_m = N_A \frac{a^3}{\eta}$, where N_A is the Avogadro number, a is the lattice parameter, η equals to 4 for fcc phase.

Atomic Mobility and Diffusion Coefficient

According to Anderson and Ågren [5] and Jönsson [6], the atomic mobility of species B, i.e. M_B can be expressed as follows:

$$M_B = M_B^0 \exp\left(\frac{-Q_B}{RT}\right)\frac{1}{RT}{}^{mg}\Gamma = \exp\left(\frac{RT\ln M_B^0}{RT}\right)\exp\left(\frac{-Q_B}{RT}\right)\frac{1}{RT}{}^{mg}\Gamma \tag{3}$$

where M_B^0 is a frequency factor and Q_B is the activation energy. R is the gas constant, and ${}^{mg}\Gamma$ is a factor taken into consideration the ferromagnetic contribution to the diffusion coefficient. For non-bcc phases, the effect of ferromagnetic on diffusion can be ignored [7].

Following the phenomenological CALPHAD technique, a parameter Φ_B is composition dependent [6] and expressed by a Redlich-Kister polynomial,

$$\Phi_B = \sum_i x_i \Phi_B^i + \sum_i \sum_{j>i} x_i x_j \left[\sum_{r=0,1,2} {}^r\Phi_B^{i,j}\left(x_i - x_j\right)^r\right] \tag{4}$$

where Φ_B represents either the activation energy $-Q_B$ or the rescaled frequency factor $RT\ln M_B^0$, x_i and x_j are the mole fraction of species i and j, Φ_B^i is the value Φ_B of species B in pure species i, and ${}^r\Phi_B^{i,j}$ is the binary interaction parameters.

Assuming the mono-vacancy mechanism for diffusion and neglecting correlation factors [5], the tracer diffusivity D_B^* is related to the mobility M_B by the Einstein relation:

$$D_B^* = RTM_B \tag{5}$$

For a system of n members, the interdiffusion coefficient $\tilde{D}_{kj}^{n}$ can be expressed as:

$$\tilde{D}_{kj}^{n} = \sum_{i=1}^{n-1} (\delta_{ki} - x_k) x_i M_i \left(\frac{\partial \mu_i}{\partial x_j} - \frac{\partial \mu_i}{\partial x_n} \right) \quad (6)$$

where μ_i is the chemical potential of species i, the kronecker delta $\delta_{ki} = 1$ when $i = k$, and otherwise equal to 0.

The mobility parameters Φ_B^i and ${}^r\Phi_B^{i,j}$ can be evaluated by fitting the experimental values of the diffusion coefficients. When M_B is obtained, all diffusion coefficients can be calculated by, for example, Eq.5 and 6.

Optimization and Discussion

All the assessments of atomic mobility and molar volume were performed by using the PARROT module [8] in the thermodynamic-kinetic software package Thermo-Calc/DICTRA [9]. This module allows simultaneous numeric fittings of atomic mobility from experimentally determined diffusion coefficients.

Optimization of Molar Volume

The molar volume for pure fcc Fe and fcc Co were taken from the work by Lu et al [4]. In this work, the available lattice parameters from Ohnuma et al. [10] and Ellis and Greiner [11] were used to access the L parameter in Eq.2, which is 0.57 cm^3/mol. The variation of molar volume with the temperature is accounted for by the temperature dependent of pure Fe and Co. The Calculated V_m of fcc Fe-Co alloys are in fair agreement with the available experimental data, as shown in Fig. 1. The values of molar volume at 1423 K and 1273 K were used in retrieving the interdiffusion coefficients described from Eq.1.

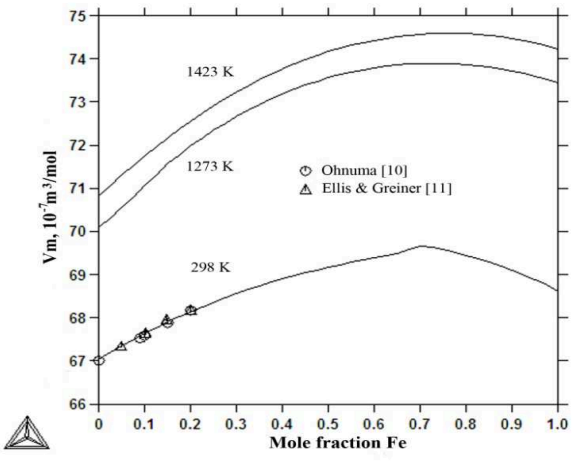

Fig. 1 The calculated V_m of fcc Fe-Co alloys compared with experimental data [10,11] at 298 K, 1273 K and 1423 K.

Optimization of Atomic Mobility

Cui et al. [12] have evaluated the atomic mobility for fcc phase of the Fe-Co system, and the thermodynamic data assessed by Guillermet [13] have been adopted. Recently the thermodynamic property of the Fe-Co system has been carefully reassessed by Ohnuma et al [10]. Therefore it is necessary to reassess the mobilities of the system.

The atomic mobilities for the self-diffusion of fcc Fe and fcc Co have been assessed by Jönsson [6] and Cui et al. [12], respectively. They were adopted in the present work. The impurity diffusion of Co was taken from the work by Badia and Vignes [14]. The assessments of other mobility parameters were carried out based on the measured diffusivities including impurity diffusivity and interdiffusion diffusivity. The results of the assessed mobilities are listed in Table 2.

In the section of follow, the results of the present assessment are discussed compared with experimental information.

TABLE 2. ASSESSED ATOMIC MOBILITIES FOR THE FCC PHASE OF FE-CO SYSTEM.

Mobility	Parameter (J/mol)	reference
Mobility of Fe		
Φ_{Fe}^{Fe}	$-286000-79.55\cdot T$	[6]
Φ_{Fe}^{Co}	$-259074-91.76\cdot T$	Present work
$\Phi_{Fe}^{Fe,Co}$	$-61000+48.96\cdot T$	Present work
Mobility of Co		
Φ_{Co}^{Co}	$-301654-70.10\cdot T$	[12]
Φ_{Co}^{Fe}	$-301900-76.58\cdot T$	[14]
$\Phi_{Co}^{Fe,Co}$	$+370000-255.08\cdot T$	Present work

Fig. 2 shows the calculated impurity diffusivity coefficient of Fe in fcc Co as a function of inverse temperature, compared with the experimental data from Badia and Vignes [15]. Fig. 3 shows the calculated tracer diffusivities of Co and Fe in the fcc Fe-Co alloys compared with the experimental data [16-18].

There are two sets of experimental data about the interdiffusion coefficients of fcc phase of Fe-Co system in the lecture, i.e. data from Badia and Vignes [15] and Hirano et al [19]. Cui et al. [12] has noticed that the data from Hirano et al. [19] were inconsistent with self- or impurity diffusion data and thus resulted an over complex variation of interdiffusion coefficients with composition. Therefore they have only used the data from Badia and Vignes [15] and obtained the mobilities satisfactorily. The experimental results in the present work confirm the bias of Cui et al. A comparison of the interdiffusion coefficients measured at about 1423 K by Badia and Vignes [15], Hirano et al. [19] and the present work is shown in Fig. 4. Data from Hirano et al. [19] are apparently too high and not used in the present assessment. As seen from Fig. 5, the calculated interdiffusion coefficients compare favorably with the selected experimental data.

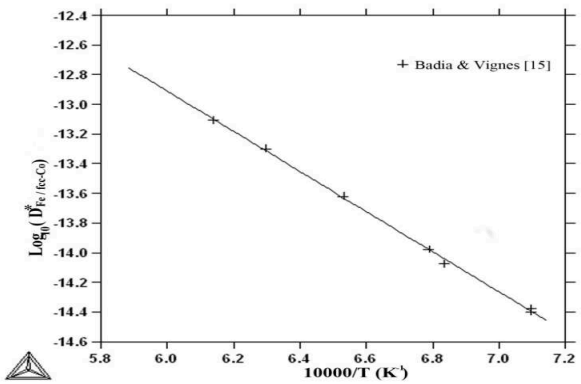

Fig. 2 Arrhenius plot of impurity diffusion coefficients of Fe in fcc Co in comparison with the experiment data [15].

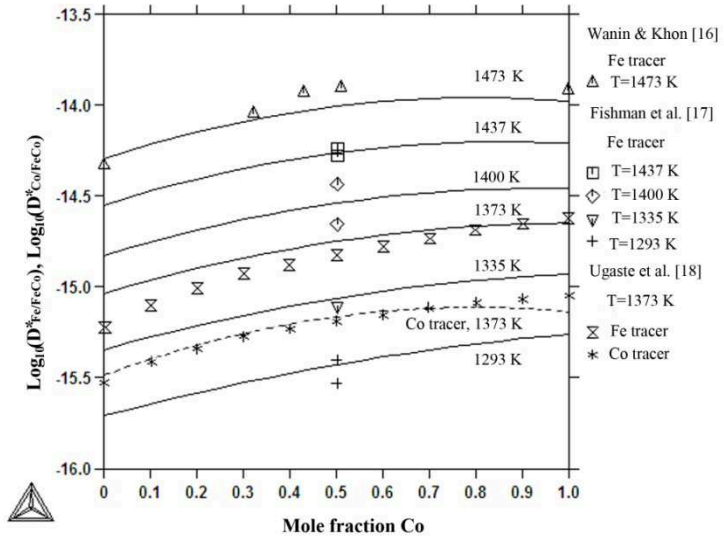

Fig. 3 Calculated tracer diffusivities of Fe (solid line) and Co (dashed line) for the fcc Fe-Co alloys compared with the experimental data [16-18].

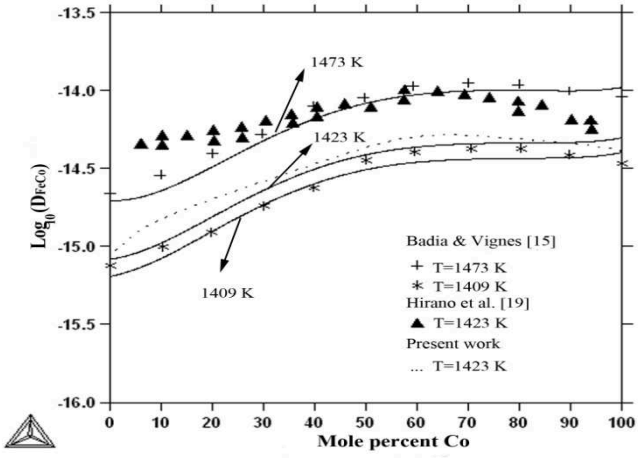

Fig. 4 Calculated interdiffusion coefficients compared with the data from Badia and Vignes [15], Hirano et al. [19] and the present work.

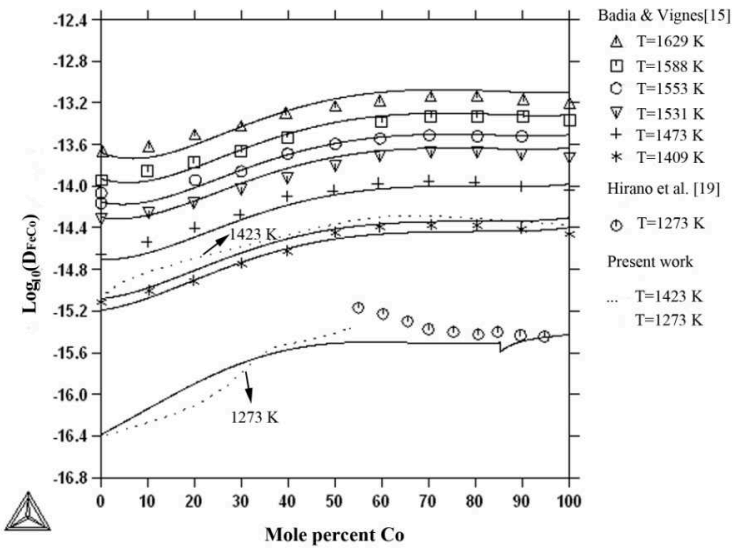

Fig. 5 Calculated interdiffusion coefficients for fcc Fe-Co phase at various experiment temperatures along with the experimental data from Badia and Vignes [15], Hirano et al. [19] and present work. Data from Hirano et al. [19] at high temperatures are proved to be doubtful and are thus not shown, while at 1273K and high Co compositions their data are acceptable.

Calculated Concentration Profile and EPMA Measurements

In order to verify the assessed atomic mobility, concentration profiles were simulated by the software package Thermo-Calc/DICTRA with the mobilities and diffusion-couple conditions as inputs. Fig. 6 shows the calculated concentration profiles compared with the present EPMA measurements. The agreement is fairly good.

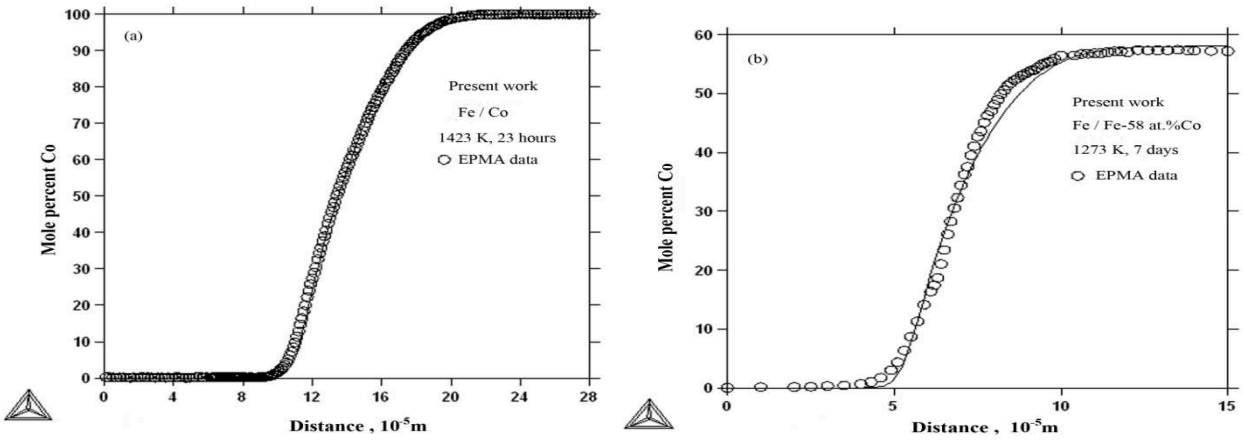

Fig. 6 Calculated concentration profiles of (a) the Fe/Co diffusion couple annealed at 1423 K for 23 hours (b) the Fe/Fe-58 at.% Co diffusion couple annealed at 1273 K for 7 days, compared with the present experimental data.

Summary

Experiments on the bulk Fe/Co and Fe/Fe-58 at.% Co diffusion couples at 1423 K and 1273 K have been performed, respectively. The experimental results have clarified the different interdiffusion data which are controversial in the literature. The molar volume has been assessed by using the available lattice parameter data. A general agreement has been reached between the

calculated and experimentally determined data. On the basis of the reliable data from the literature and the present work, a set of self-consistent atomic mobility of both Fe and Co for the fcc phase has been obtained. Its reliability has been varified by simulating the concentration profiles for the diffusion couples.

Keywords: molar volume; Ni-Cr-Mo; fcc phase; CALPHAD; first-principles calculations

Abstract: The molar volume of fcc phase in the Ni-Cr-Mo system has been evaluated by means of the CALPHAD approach based on experimental data from the literature. The molar volumes of the non-stable fcc Cr and Mo were determined by extrapolating volume data from several stable solid solutions combined with the first-principles calculation results. A set of parameters has been obtained and can give a reasonable description of most experimental data on molar volume.

Introduction

Ni-based alloys have remarkable high strength, high oxidation and corrosion resistance ability at high temperatures and have been used as ideal materials in many kinds of severe environments, such as jet engines, gas turbines, etc. The Ni-Cr-Mo ternary system has close relationship with many Ni-based alloys such as Alloy 22, Alloy 59 and C-4 and the thermodynamic data of this system have been studied by several investigators previous. The CALPHAD method is widely used to develop thermodynamic databases, while the volume data at atmospheric pressure are rarely obtained in a form of database for multicomponent systems. Volume, as a function of chemical composition, temperature and pressure, is a fundamental physical property and volume data has many practical applications. Volume databases can also be established by means of the CALPHAD approach.

In this work, the molar volume of fcc phase in the Ni-Cr-Mo system was assessed by means of the CALPHAD approach and the first-principles calculations. The required experimental data of lattice parameters were collected from the literature and converted to molar volumes.

Methodology

Volume Model for Solution Phases

Similar to the modeling of thermodynamics, the volume model can also be established by means of the CALPHAD method. In this work, we consider only the model and experimental data at the atmospheric pressure.

The molar volume of solution phases in A-B binary system can be expressed as:

$$V_m = (1-x)V_A + xV_B + x(1-x)L \tag{1}$$

where V_A and V_B are molar volumes of pure A and B, respectively. Their values for stable structures have been assessed by Lu et al. as a function of temperature and the elements related to this work are listed in Table 1 [1]. x is the mole fraction of B, and L is the binary interaction parameter which is usually a constant capable of describing most experimental data [2]. The ternary

interaction parameters can be added to fit experimental data when extending from binary to multi-component systems.

First-Principles Calculations (SQS-VASP)

At atmospheric pressure, both Cr and Mo are stable with bcc structure and non-stable in fcc structure. In the CALPHAD approach, the values of the molar volume for fcc Cr and Mo must be obtained in order to describe the volume for the fcc Ni-Cr-Mo phase. However, these values cannot be measured experimentally and it may not be feasible to use the first-principles calculated data for pure elements directly. So a conventional method is adopted by extrapolating linearly from the volume data of stable fcc solution phases to pure Cr or Mo. The problem is that the linear extrapolation may not be correct. To assist the extrapolation, the first-principles special quasirandom structure (SQS) calculations were performed for disordered fcc phases containing 50 at.% Cr or Mo.

We used a 16-atom SQS [3, 4] to represent the randomly disordered fcc structure. The advantage of the SQS approach is that it can adequately reproduce the statistics of a random alloy in a relatively small and thus computationally feasible supercell. For the generated SQS structures, first-principles calculations were performed using the plane wave method with projector augmented wave (PAW) pseudo-potentials [5], as implemented in the Vienna ab initio simulation package (VASP) [6]. We used the exchange-correlation functional within the generalized gradient approximation (GGA), as parameterized by Perdew, Burke, and Ernzerhof (PBE) [7]. The k-point meshes (10*8*6) for Brillouin zone sampling were constructed using the Monkhorst-Pack scheme.

The calculated volume data, together with the molar volumes of pure elements calculated by Wang et al. [8] (listed in Table 1) were assessed to obtain the L parameter in Eq.1. These data present a theoretical view of the relationship between volume and composition. If a linear relation holds, the extrapolation from the volume data of stable fcc solution phases to pure Cr or Mo is straightforward. Otherwise, the L parameter should be assessed by these theoretical data to fit the experimental data.

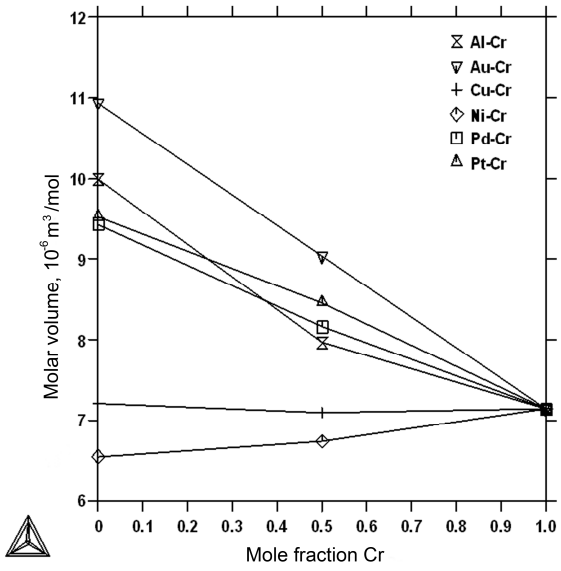

TABLE 1LATTICE PARAMETERS AND MOLAR VOLUMES OF PURE ELEMENTS IN THE FCC STRUCTURE.

Element	a (Å)		Vm (10^{-6} m^3 / mol) at T=298 K [1][a]

Results and Discussion

After collecting the experimental data extensively from the literature, and guided by the first-principles results, we used the PARROT module [9] in the Thermo-Calc software package [10] to assess the L parameters in Eq.1 as well as the molar volumes of fcc Cr and Mo. A set of model parameters which can represent most of the experimental data was obtained and listed in Table 2.

(a)

(b)

Fig. 1. Molar volume of the fcc X-Cr (X = Al, Au, Cu, Ni, Pd, Pt) phases. (a) First-principles calculated results. (b) Experimental data at 298.15 K.

Molar Volume of Fcc Cr

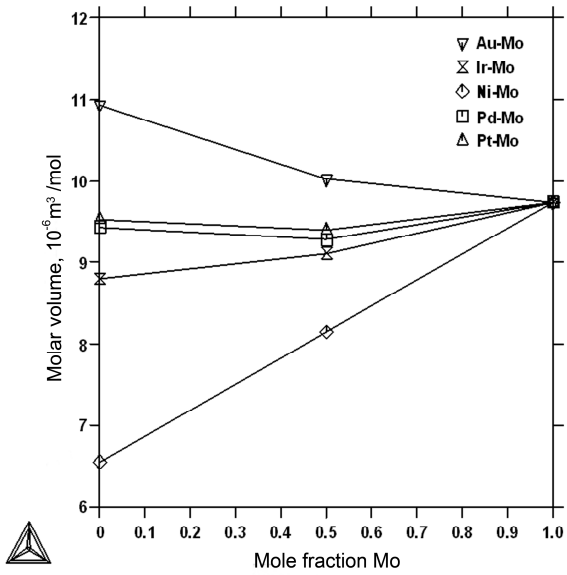
In the work, six binary systems related to fcc X-Cr phase were chosen, i.e. X = Al, Au, Cu, Ni, Pd and Pt. Their experimental data are shown in Fig. 1b. The fcc Pt-Cr solid solution shows linear behaviour up to about $x_{Cr} = 0.72$ and Ni-Cr up to about $x_{Cr} = 0.45$. The linear extrapolations lead to different values for fcc Cr. Considering the small theoretical value of L and the large composition extension of fcc Pt-Cr, the linear extrapolation is reasonable and the molar volume of fcc Cr is fixed to 7.5×10^{-6} m^3/mol. All parameters for other binary systems are assessed accordingly and listed in Table 2. It deserves mentioning that the theoretical L value for Au-Cr suggests a linear behavior which is consistent with the experimental data. However, due to the large deviation of volume for fcc Au between the first-principles calculations and experimental results, this linear relation for fcc Au-Cr is questionable.

TABLE 2 ASSESSED PARAMETERS (L IN EQ.1) FOR X-CR (X = AL, AU, CU, NI, PD, PT), X-MO(X = AU, IR, NI, PD, PT) BINARY SYSTEMS, AND THE NON-STABLE FCC CR-MO PHASE COMPARED WITH THOSE EVALUATED BASED ON THE FIRST-PRINCIPLES CALCULATION RESULTS.

System	L (10^{-6} m^3 / mol)	
	Based on the first-principles calculations	Based on the experimental data
Al-Cr	-2.40	-1.80
Au-Cr	-0.01[a]	2.10
Cu-Cr	-0.31	-0.35
Ni-Cr	-0.43	-0.32
Pd-Cr	-0.49[a]	1.25
Pt-Cr	0.53	0.00
Au-Mo	-1.27	-1.00
Ir-Mo	-0.62	-0.55
Ni-Mo	0.00	-0.65
Pd-Mo	-1.23	-0.85
Pt-Mo	-0.93	-0.80
Cr-Mo	0.30	-

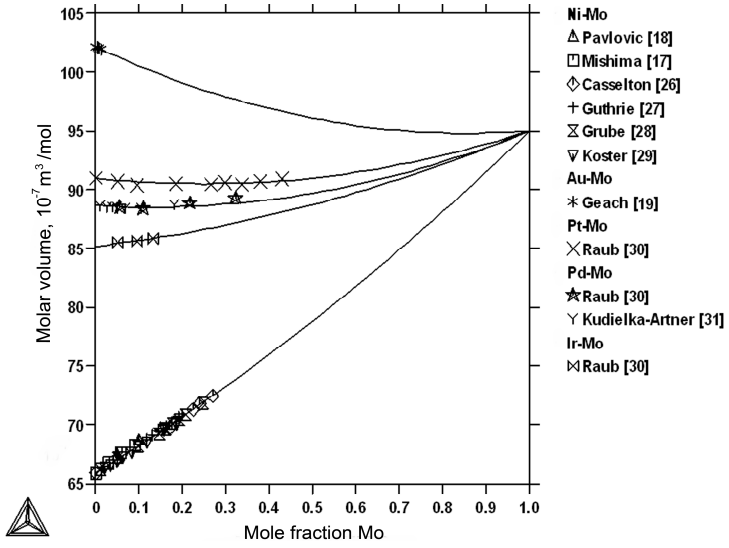
a: The relatively large deviations are considered to be the deviation between the first-principles calculations and experimental results for fcc Au and Pd. These data were not considered in the assessments.

Molar Volume of Fcc Mo



Five binary systems related to fcc X-Mo phase were chosen, i.e. X = Au, Ir, Ni, Pd, Pt. The experimental data are shown in Fig. 2b. For fcc Ni-Mo, the theoretical value of L is zero. The linear extrapolation Ni-Mo and Ir-Mo leads to 9.3×10^{-6} m^3/mol for fcc Mo. However, the experimental data of fcc Pt-Mo and Pd-Mo reveal non-linear behaviors and their distribution trends suggest the molar volume of fcc Mo should be larger than 9.3×10^{-6} m^3/mol. Considering the overall agreement between the theoretical data in Table 2 and the experimental data a value of 9.5×10^{-6} m^3/mol was finally fixed for fcc Mo.

Molar Volume of Fcc Phase in Ni-Cr-Mo System



After fixing the value of molar volume for fcc Cr and Mo, the volume of non-stable fcc Cr-Mo was determined by using the theoretical value of L directly. Then the ternary interaction parameter of the fcc Ni-Cr-Mo phase was assessed to be -2.0×10^{-6} m^3/mol based on the experimental data. The molar volume of the fcc phase in the Ni-Cr-Mo ternary system are shown in Fig. 3.

Summary

The values of molar volume for fcc Cr and fcc Mo have been determined and the molar volumes of several Cr or Mo relating fcc binary phases have been evaluated as well. The model parameters for molar volume of fcc phases in the Ni-Cr and Ni-Mo binary systems and Ni-Cr-Mo ternary system have been assessed and the obtained parameters can best describe the collected experimental data from the literature on molar volume. The first-principles calculations play an important role in the assessments.

Keywords: NiTi, pseudoelasticity, R-phase, phase transformation, heat treatment, shape memory alloy

Abstract: The pseudoelasticity (PE) and shape memory effect (SME) are the two main behaviors presented by the shape memory alloys (SMA's) and are associated respectively to mechanical and thermally induced martensitic transformations. The aim of this work is to investigate the effects of heat treatment temperature on the microstructure properties and phase transformation temperatures of a NiTi alloy with 57 w.t. % Ni. The X-ray diffraction (XRD) was carried out to obtain the phases present. The phase transformation temperatures were measured by differential scanning calorimetry (DSC). The alloy chemical composition and hardness were obtained by X-ray fluorescence (XRF), hardness (HRC) and microhardness (HV) tests, respectively. The analysis were performed in the state as received and after aging treatment at different temperatures between 350 °C and 600°C. The samples as received contained a fully austenitic microstructure at room temperature and the DSC analysis showed the presence of a phase transformation in multiple steps (B19'-R -B2). After aging at 350 °C the R phase was observed at room temperature with the austenite. With the aging treatment at 600 °C the R phase was solubilized and the alloy phase transformation occurred in a single step, ie, direct transformation ~~of~~ from austenite to martensite and vice versa. The transformation temperatures Af, As, Ms and Mf changed with the aging treatment temperatures.

INTRODUCTION

The Shape Memory Alloys (SMA's) are a group of metallic materials that are able to recover their original shapes (or develop considerable restitution forces when you restrict their recovery) through a field of temperature and/or stress, due to martensitic phase transformations

The SMA has the unique property of pseudoelasticity and/or shape memory effect. Both properties are directly associated to the martensite - austenite phase transformation. There are many alloys that have these properties (CuZnAl, CuAlNi, AuCd, NiTiNb and others), but the NiTi alloy exhibits excellent mechanical properties that have been used and investigatedfor decades [1].

The R phase is considered as a martensitic transformation because happens with the same mechanisms of this transformation [4]. The R phase could occur by three different forms: at first, when a specific concentration of Ni equiatomic is substituted for Fe or Al, or, when the Ni-Ti alloy with more than 50,5 at-% of Ni is aged at determined temperatures, where the Ni_4Ti_3 precipitates are formed, and at last, after cold work and subsequently heat treatment due to the reoriented dislocations structure [5].

In the case of a NiTi alloy the type of heat treatment chosen can change the transformation temperatures and the thermal hysteresis [6]. Another important effect of this kind of treatment is the possibility of solubilization of the R phase present in most of the NiTi alloys. The R phase occurs due to the presence of Ti_3Ni_4 precipitate in Ni rich alloys and can increase the size of the thermal hysteresis and the alloy hardness [4,7].

The aim of the present work is to investigate the influence of aging treatment in NiTi alloy in the transformation temperatures and thermal hysteresis and their effect on microstructure properties.

The aging temperatures considered are 350°C, 450°C, 550°C and 600°C followed ~~with~~ by quenching in water.

EXPERIMENTAL PROCEDURES

~~For~~ In the present study the samples were obtained of a NiTi bar with a diameter of 8mm and a nominal composition ranging from 54.5% to 57% of Ni. In order to know the correct composition of the received alloy, x-ray fluorescence procedure was carried out using an EDX-720. The Table 1 shows the acronym for each sample.

To perform the heat treatments a Nabertherm GmbH LHT 04/17 oven was used. The samples were heat treated at 350°C, 450°C, 550°C and 600°C for 30 minutes using a 7°C/min heating rate, and then all samples were water quenched at room temperature.

TABLE 1 - SAMPLES ACRONYM

Samples	
Acronym	**Treatment**
AR	As Received
Ag350	Aged at 350°C
Ag450	Aged at 450°C
Ag550	Aged at 550°C
Ag600	Aged at 600°C

The samples were cut in smaller sizes using a Struers Secotom 15 precision cut-off. To prevent any undesirable transformation or deformation, all the cutting procedures were done using a coolant and performed at a low velocity of 0,005mm/min. To prepare the samples for the metallographic analysis, the procedures described in the ASTM E-384 were used, and the procedures on ASTM E3 were selected in order to prepare them for the micro hardness (HV0,5) tests. Every sample was flattened, grinded and polished according to its own normative process. The Rockwell C (HRC) hardness tests were performed on an Identec Zwickroell durometer.

In order to obtain the phase transformation temperatures, the differential scanning calorimetry (DSC) method was carried out. The heating and cooling rates were of 10°C/min, going from the initial temperature of -100°C to the final temperature of 100°C. Before cooling to -100°C the samples were heated up to 100°C to guarantee full transformations. To perform the differential scanning calorimetry a Netzsch 200 F3 Maia was used. To determine the phases present on the alloy an Ultima IV X-ray diffractometer was usued.

RESULTS

X-ray Fluorescence

The chemical composition of the as received material is presented in the Table 2.

TABLE 2–CHEMICAL COMPOSITION OF AS RECEIVED NITI ALLOY.

	Component Elements (w.t.%)
Element	**XFR**
Ni	57.446
Ti	42.235
Ca	0.159
Fe	0.1
Ac	0.059

As seen on the Tab. 2, the studied material is rich in Ni element, this element tends to stabilized the austenitic phase and to introduce a R phase in it microstructure [5].

Hardness (HRC) and Microhardness (HV0,5)

Hardnes (HRC) and microhardness (HV0,5) were performed in the samples as received and after heat treatment, the results are showed in Figure 1.

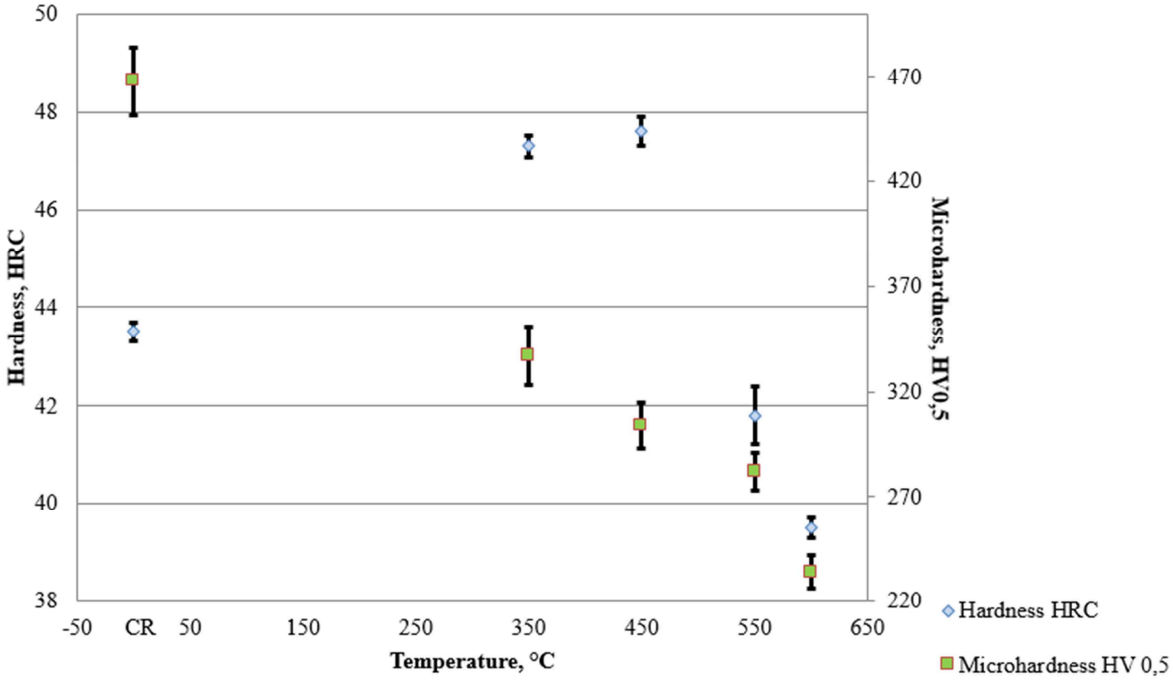

Figure 1: Hardness and microhardness results

The increased hardness found on the Ag350 and Ag450 is probably due to the increased amount of Ti_3Ni_4 precipitate and consequently the presence of R phase. The heat treatments at higher temperatures decrease the hardness, possibly due to the solubilization of precipitates and grain growth.

On the other hand, the microhardness values decreases with the increase of heat treatment temperature.

Themal analysis (DSC)

The Figure 2 shows the transformation temperatures of the sample as received. Upon heating there are two exothermic peaks between As (-41.2°C) and Af (-6.6°C). These peaks could be the transformation from the phase B19' (martensite) to phase R and from phase R to the final phase B2 (austenite). Upon cooling there are also two peaks, in this case endothermic peaks, the bigger one is the martensite start (-74.7°C) and martensite finish (-98°C) and the smaller peak is the R phase that starts at 11.5°C and ends at -60.2°C. So, looking at the temperature of phase transformations, Figure 2, is possible to say that the as received material is probably fully austenitic at room temperature.

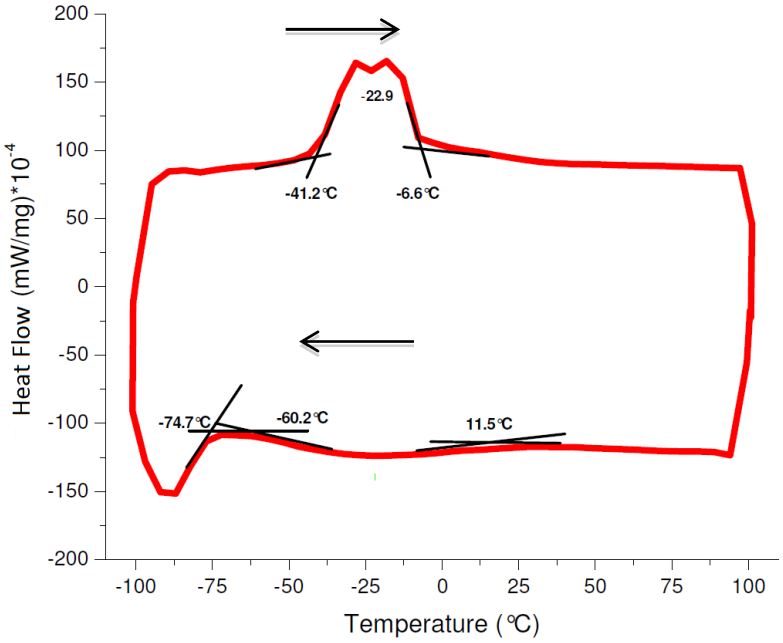

Figure 2 - Sample as received DSC

Figure 3 shows the transformation temperatures of the HT350 sample. In this case the total austenitic and martensitic transformations are again composed by two peaks. The austenite transformation goes from a martensitic phase to an R phase and later to an austenite phase, and the reverse transformation goes from an austenite phase to an R phase and later to a martensitic phase. Upon heating the R phase transformation starts at 5.6°C and ends at 49.53°C; upon cooling the transformation from austenite to the R phase starts at 42.35°C and ends at 23.75°C, and later the martensite transformation starts at -44.95°C and ends at -83.73°C. So, the HT350 sample presents an austenite and R phases at room temperature.

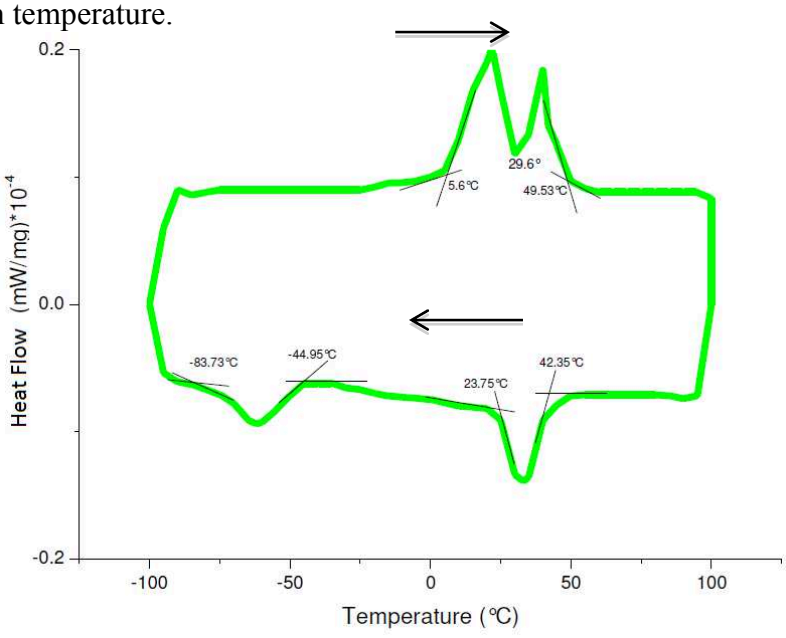

Figure 3 - HT350 sample DSC

Figure 4 shows the martensite to austenite transformation in a single stage for the HT600 sample. So, the R phase was probably solubilized during the heat treatment. From the DSC curve it is possible to find the As (-39.5°C) and Af (-0.9°C) temperatures and the martensite start (-35.4°C) and finish (-79.4°C) temperatures.

In aged Ni rich alloys the appearance of Ti_3Ni_4 precipitate [7] is expected. The R phase transformation appears due to the Ti_3Ni_4 precipitate formed in the B2 phase. Thus, one may state that the

HT350 samples had an increased amount of precipitate and the HT600 samples had most of this precipitate solubilized and the microstructure is fully austenitic at room temperature.

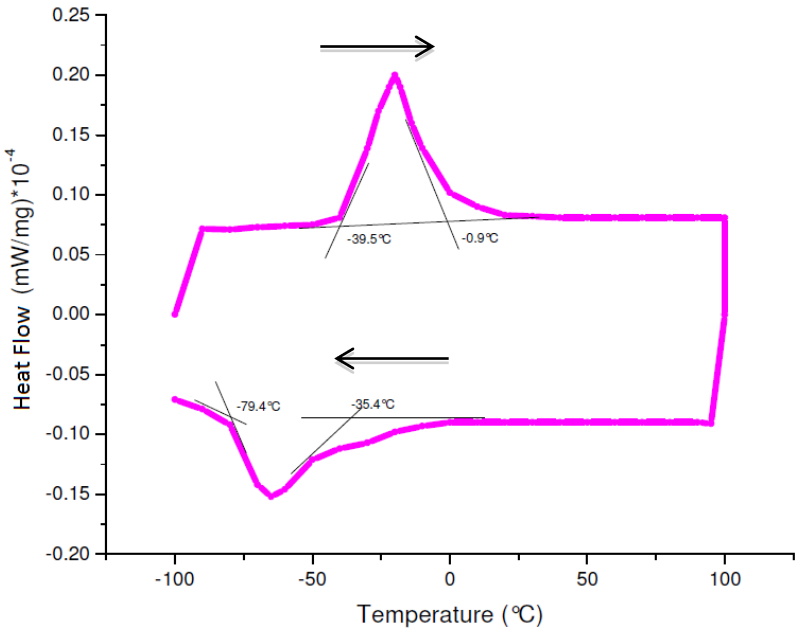

Figure 4 - HT600 sample DSC

To analyze the temperature range of transformation a thermal hysteresis was calculated for each sample, shown in Fig. 5. The thermal hysteresis is obtained calculating the difference between the medium point of the Af and As and the medium point of the Ms and Mf. The samples with 600°C heat treatment showed the lowest thermal hysteresis.

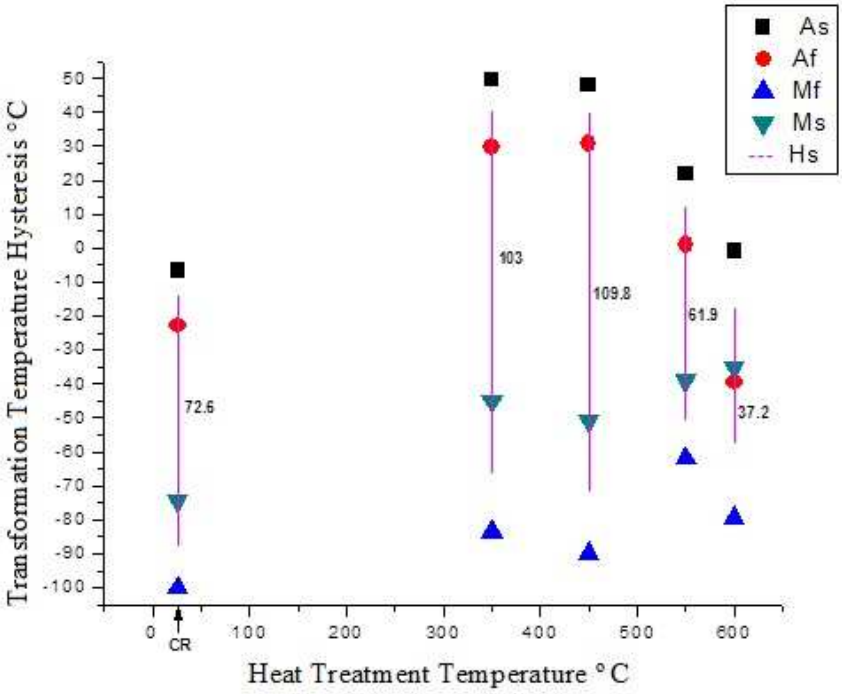

Figure 5 - Transformation temperatures hysteresis for tested samples

X- Microstructural analysis (XRD)

The microstructural analysis was based on a XRD measurement carried out to confirm the phases present at room temperature. The spectrums reported in Fig. 6 presented a high quantity of austenitic phase with B2 structure. It is confirmed by the more intensity diffraction picks that for the austenitic phase are around 42°, 60°, 92° and 108°. So, is possible to state the absence of martensitic phase induced for cut or sample preparation.

Comparing the results with both software Crystallographica Search Math and Crystallographic Data Bases of ICDD (The International Centre For Diffraction Data), the same picks are identified concluding that the main picks are the cubic system of B2 austenitic phase.

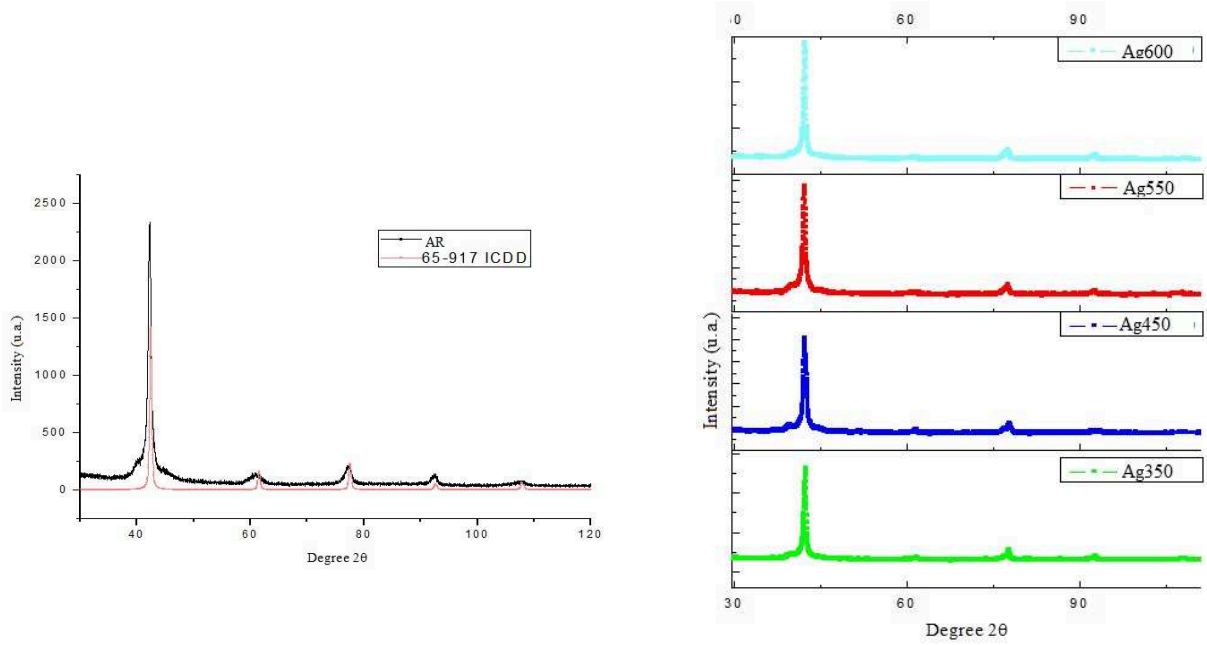

Figure 6 – XRD spectrum of the as received sample (a), and heat-treated samples (b).

Apparently, the XRD results showed in Fig. 6 do not present any variation due to heat treatment. However, if the main pick are zoomed (Fig. 7) one can observe the variations of the intensity as function of the heat treatments.

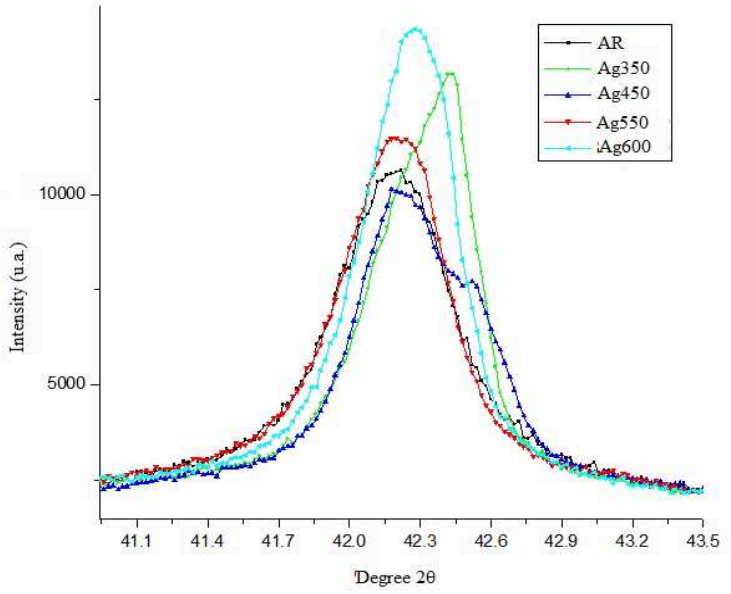

Figure 7 – Zoomed main diffraction pick for as received and heat-treated samples.

The trend of main diffraction picks indicates the presence of another phase that can be attributed to precipitates. According MAGELA (2010) the aging treatments induced the formation of R phase on NiTi alloys due to the heterogeneous composition in B2 matrix caused by the Ni_4Ti_3 precipitates. So, the R phase is a solution of precipitates in the matrix.

To identify the presence of other phase beyond the austenitic phase the deconvolution of the main pick (around 42 degree) are carried out for all samples and showed in Fig. 8. The deconvolution curves are obtained with the Fityk program using the Gaussian fitting.

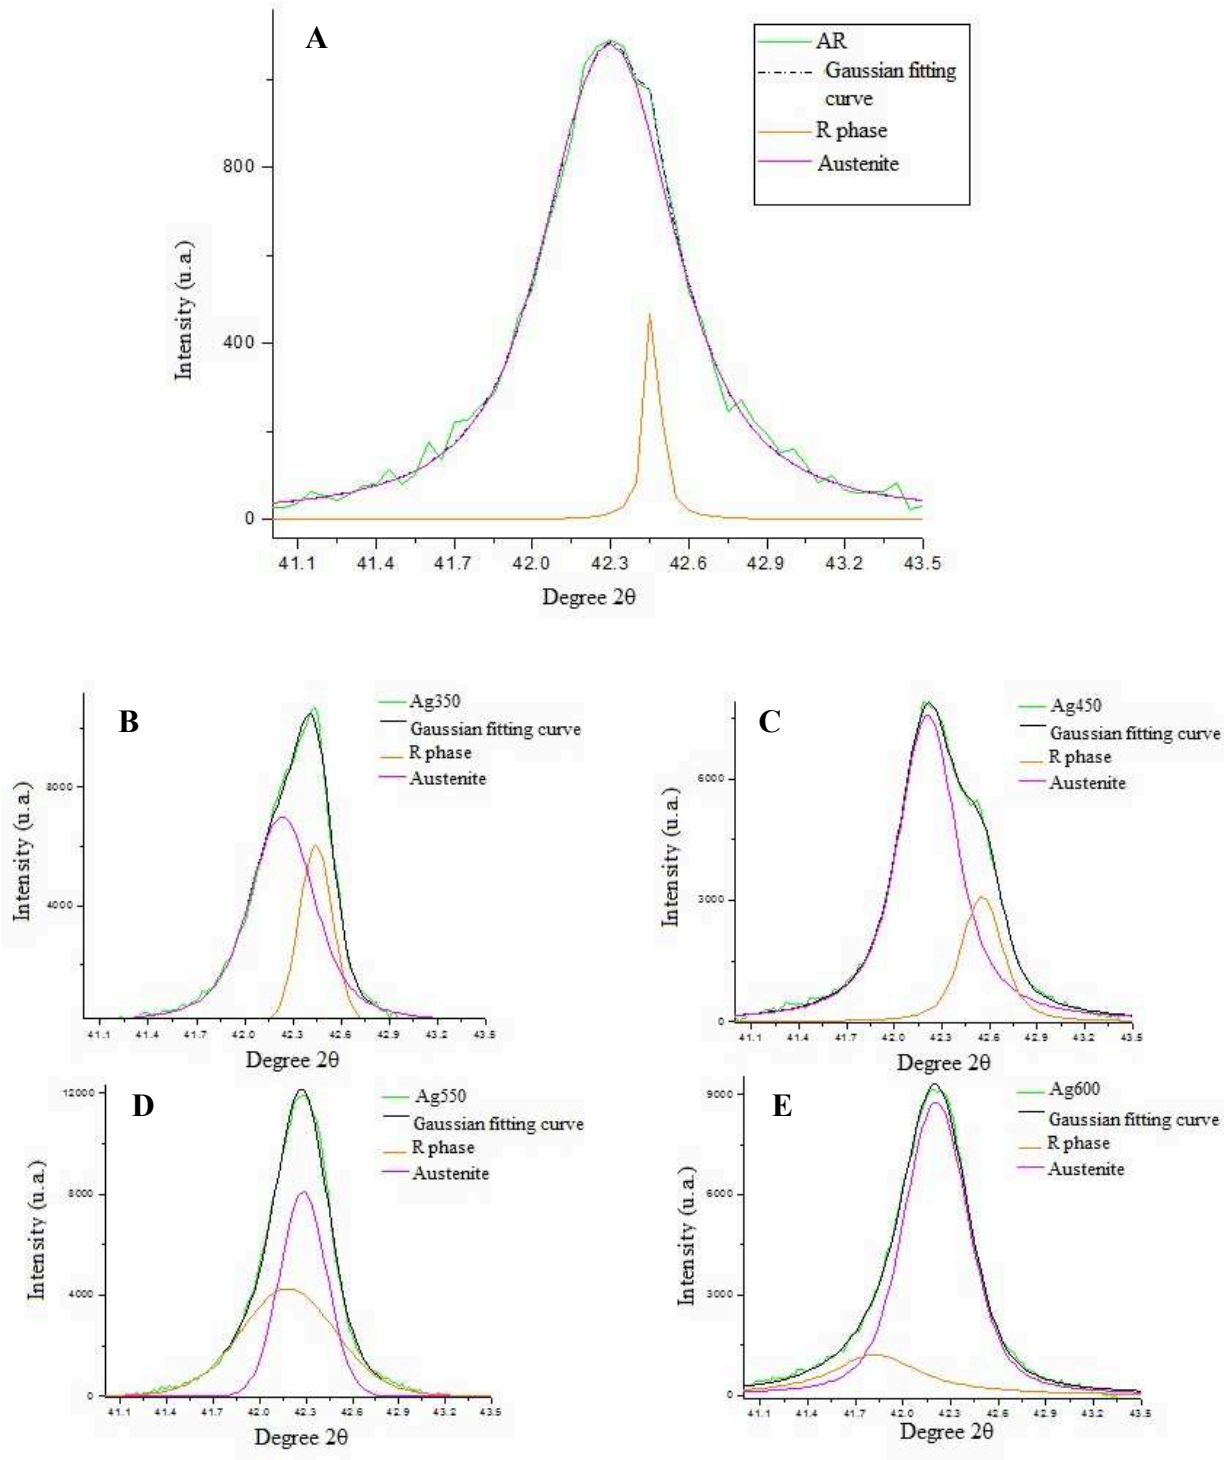

Figure 8 – Diffraction main pick deconvolution for: as received sample (a), Ag350 (b), Ag450 (c), Ag550 (d) and Ag600 (e).

The analysis of the pick deconvolution indicates the presence of R phase and its evolution with the heat treatment temperature. For the as received sample, Fig. 8a, it was observed a small amount of R phase with austenite B2 phase at room temperature. For the heat-treated samples, Fig. 8b to 8e, the R phase quantity changed with the heat treatment temperatures due to the variation of Ni_4Ti_3 precipitates. The pick intensity of this phase decreases with the increase of heat treatment temperature, at 350°C (Fig. 8b) the R phase is in more quantity that at 600°C (Fig. 8e) where this phase is almost totally solubilized.

CONCLUSIONS

From the analysis presented in this study it is possible to realize the influence of the aging at different temperatures on the microstructure of a NiTi shape memory alloys.

The DSC curves showed that different aging temperatures cause changing on phase transformation temperatures and different thermal hysteresis range. The heat treatment at 600°C didn't have an R phase and had a lower thermal hysteresis when compared to the samples as received and the samples treated at 300°C. The DSC also showed the difference found in the hardness tests, indicating that the R phase is present on the samples with more Ti_3Ni_4 precipitate. The deconvolution of XRD picks revealed the presence of R phase and austenite in all studied samples.

Comparing the results obtained by XRD and DSC analyzes it was possible to identify that both methods showed the phase presents in the matrix of the alloy. However, in the case of the as received and Ag600 conditions the DSC analyzes showed only the austenitic phase at room temperature, and the XRD analyzes identified a few quantity of R phase too.

Keywords: Al-Mg-Si-Zn alloy, pre-ageing, paint baking response, automotive panels

Abstract: In the present work, the microstructure and properties of a novel Al-0.90Mg-0.78Si alloy with Zn addition were investigated by electron back scattering diffraction (EBSD), high transmission electron microscopy (HREM), mechanical properties and Erichsen tests. The average grain size of the alloy after pre-ageing was about 20 μm. The yield strength and elongation of pre-aged alloy was 137 MPa and 30% respectively. The I_E value of the alloy was 8.6 mm. After paint baking at 170 °C for 30 min, the increment of yield strength was about 100 MPa. GP(II) zones were formed in the alloy during paint baking process through adding Zn, which should play a very important role for improving paint hardening response. GP(II) zones and η´ phases were formed after artificial ageing at 170 °C for 10 h.

Introduction

The growing demand for more fuel-efficient vehicles to reduce energy consumption and air pollution is a challenge for the automotive industry, aluminum usage in automobiles will be increased significantly in the near future. The characteristics of 6000 (Al-Mg-Si) series aluminum alloys, high strength stiffness to weight ratio, good formability, good corrosion resistance, recycling, and age-hardenable make it the ideal candidate to replace steel sheet in the car to respond the weight reduction demand within automotive industry [1,2]. Currently, the widely used 6000 series aluminum alloy was AA6016, AA6111 and AA6022 alloy. The formability of AA6016 alloy was excellent, yield strength of AA6111 alloy was higher after baking hardening with high Cu content. Corrosion resistance and formability of AA6022 alloy was good, the 6022-T4E29 was developed by Alcoa, and applied for a patent in 2000 [3], which was used in Ford Crow Victoria, Crand Marquis and Taurus/Sable.

Although 6000 series aluminum alloy was widely used in automotive skin panels, the formability of the alloys still does not meet the requirements of actual stamping, and bake hardening response exhibits inadequately after paint baking. Such as AA6016 alloy, yield strength was less than 200 MPa after paint baking, the formability of AA6111 alloy was bad with high Cu content, meanwhile the corrosion resistance was poor. The overall performances of AA6022 alloy was better, compared with AA6016 and AA6111 alloy. However, yield strength of the alloy was about 220 MPa after paint baking, the dent resistance was insufficient. Consequently, the present work investigated a novel Al-Mg-Si alloy used in automotive skin panels with Zn addition. The alloy shows excellent mechanical properties after ageing.

Experimental

The alloy was prepared from high-purity aluminum, magnesium, copper, Al-10Mn, Mg-30Zr and Al-14Si master alloys. The chemical composition of the ingots was 0.90wt% Mg, 0.78wt% Si, 0.20wt% Cu, 0.60wt% Zn, 0.098wt% Mn, 0.12wt% Zr, <0.01wt% Fe and balance Al. The ingot was homogenized at 430 °C for 10 h plus at 550 °C for 18 h, then hot-rolled and cold-rolled to 1-mm thick sheet, solution treated at 545 °C for 30 min, and immediately water quenched. The sheet was pre-aged at 140 °C for 5 min. In order to simulate the stamping of the sheet, the alloy was prestretched 2% after pre-ageing. The pre-stretched and without pre-stretched sheets were aged at 170 °C for 30 min, corresponding to paint baking process of automotive panels. The alloy was artificial aged at 170 °C for 10 h in order to further investigate the strengthening mechanism.

The microstructure of the alloy was investigated by electron back scattering diffraction (EBSD) and high resolution electron microscopy (HREM). EBSD measurements were performed on a field emission gun (FEG) scanning electron microscopy (SEM) JEOL JSM 7001 using a tilt of 70°, accelerating voltage of 20 kV and a step size of 1.5 μm. Samples for EBSD were electropolished in a 10% perchloric acid solution, at a voltage of 30 V for 15 s at room temperature. The precipitates were investigated by JEOL JEM-2010 high resolution electron microscope operated at 200 kV. The mechanical properties of the alloy were tested by WD 3100 testing machine. The I_E value of the alloy was measured by Zwick/Roell Bup600 Erichsen machine, and the size of samples was 90×90 mm.

Results and Discussions

Bake Hardening Response of the Alloy

The alloy used for automotive skin panels, should be easily deformed during stamping, and very difficult to deform after paint baking. Before stamping, the alloy was required low yield strength, preferably less than 140 MPa, and high formability (δ>25%) for obtaining complex automotive panels with high accuracy [4]. After paint baking, the alloy was required high yield strength for in-service dent resistance. The mechanical properties of the alloy are shown in Table 1. The increment of yield strength without pre-stretching is about 100 MPa, while the increment of yield strength with 2%+pre-stretching is about 130 MPa. Before stamping, elongation of the alloy was more than 25%, and yield strength is less than 140 MPa, and the I_E is 8.6 mm. After paint baking, the alloy exhibits high yield strength, namely excellent in-service dent resistance.

TABLE 1 MECHANICAL PROPERTIES OF THE ALLOY AFTER AGEING

Temper	R_m/MPa	$R_{p0.2}$/MPa	A/%	I_E/mm

EBSD Analysis of the Alloy after Pre-Ageing

The microstructure of the alloy after pre-ageing was investigated by EBSD. The measurement was on the TS plane of the alloy, the results are shown in Fig. 1. The size of grains is very small, and most of grains are equiaxed. The average grain size of the alloy is 20 μm. After pre-ageing, most of grain boundary is high-angle boundary, the fraction is 91.9%. The main grain orientation is cubic, which is useful for the alloy to stamping. The results indicate that perfect recrystallization is occurred after solution treated.

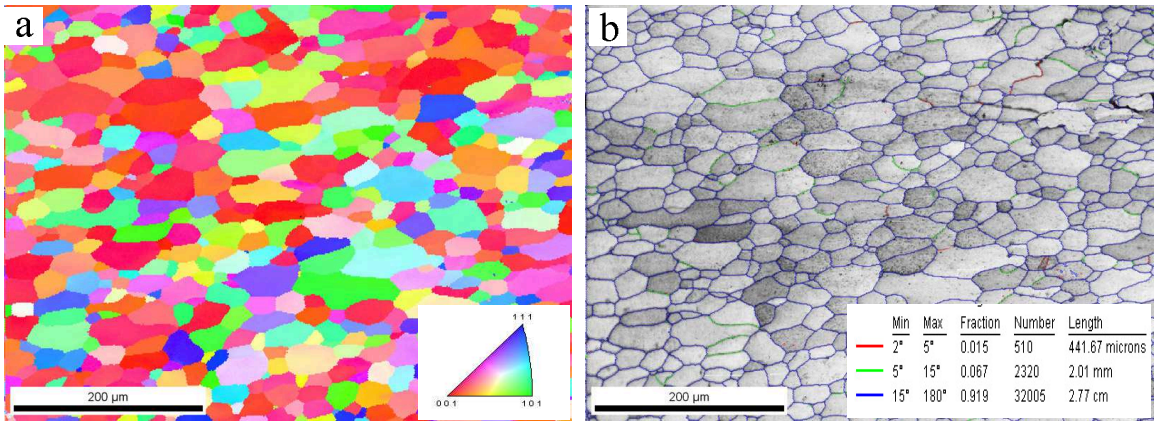

Fig.1 EBSD maps of the alloy after pre-ageing (a) grains orientation distribution and (b) image quality

Microstructure of the Alloy after Ageing

Fig. 2 shows HREM image and selected area electron diffraction (SAED) of the alloy after pre-ageing. HREM image indicates that the precipitates are approximately 2~4 nm and coherent with the matrix, justifying that the phase is GP zones, as shown in Fig. 2(a). SAED pattern shows neither extra reflection nor diffuse scattering, which suggests that the precipitates are fully coherent with matrix and do not have any distinct structure, the result obtained from SAED pattern was the same as the HREM image. GP zones make contributions to yield strength of the alloy, according to the Orowan strengthening mechanism [5]. There is on other phases are found after pre-ageing.

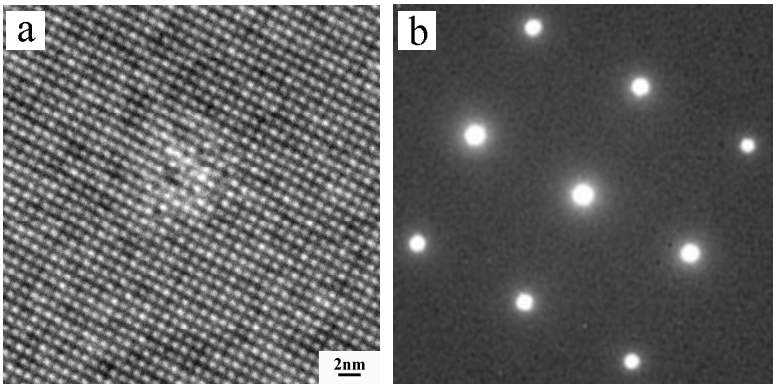

Fig. 2 HREM image (a) and SAED pattern (b) in $<001>_{Al}$ direction of the alloy after pre-ageing

Fig. 3 shows HREM images of the alloy after paint baking. In addition to GP zones, the other phase is precipitated, as observed in Fig. 3(a). The selected area diffraction pattern shows faint streaks along $[010]_{Al}$ and $[100]_{Al}$ due to the precipitates, called β" phases. In Al-Mg-Si alloys, the strengthening effect of β" phase was the best, more volume fraction of β" phase were needed, in order to improve bake hardening response of the alloy [6,7].

HREM image in $<011>_{Al}$ direction are shown in Fig. 3(b), the precipitates are identified as GP(II) zones, formed by adding Zn. The phase is 1-3 atom thick, about 6 nm wide, the habit plane is $\{111\}_{Al}$ [8]. In Al-Mg-Si-Zn alloys, Si postponed the formation of Mg/Zn clusters or GP zones at the early stage of artificial ageing, but the interaction between Mg, Si and Zn atoms was so weak, that Si atom unchanged the evolution of Mg/Zn clusters or GP zones. At the initial stage of artificial ageing, the precipitates including Mg and Si formed firstly, as observed in Fig. 2. After paint baking, GP(II) zones were formed. With the precipitation of GP zones, β" phases and GP(II) zones, the yield strength of the alloy increased apparently, seen in Table 1. The alloy exhibited rapid bake hardening response after artificial ageing at 170 °C for 30 min.

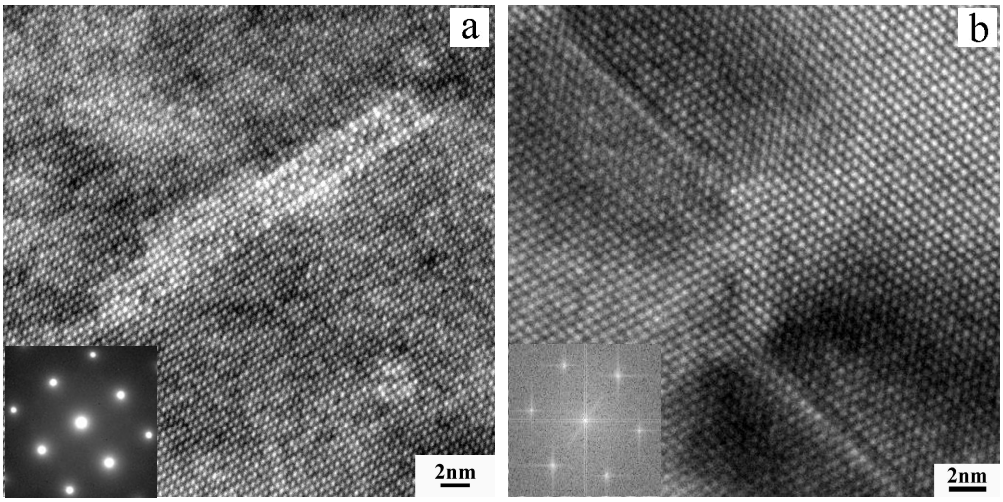

Fig. 4 HREM images in <001>$_{Al}$ (a) and <011>$_{Al}$ (b) directions of the alloy after paint baking

Microstructure in a Sample Aged for 10 h at 170 °C

In order to further investigate the precipitates that were formed owing to Zn addition, the alloy was artificial aged at 170 °C for 10 h, Fig. 5 shows the TEM micrograph of a sample aged at 170 °C for 10 h. The bright field image reveals strain contrast of needle-like precipitates oriented along $[100]_{Al}$ and $[010]_{Al}$ directions together with some fine dots. The needles are typically 20~60 nm long. Most of the dots should be the end-on sections of the needles along $[001]_{Al}$. The selected area electron diffraction pattern showed faint streaks along $[010]_{Al}$ and $[100]_{Al}$ due to the needle-like precipitates, this indicates that the precipitates are mainly β" phases.

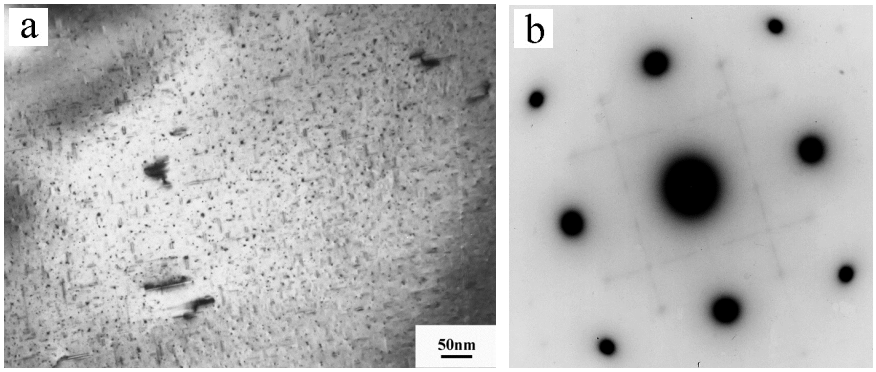

Fig. 5 BF image (a) and SAED pattern (b) in <001>Al direction of the alloy aged at 170 °C for 10 h

Fig. 6 reveals a different set of strong spots in <111>$_{Al}$ and <112>$_{Al}$ directions. The diffraction spots in Fig. 6(a) is slightly outside the $(\bar{4}22)/3$ positions, which indicates the phases is the GP(II) zones. The GP(II) zones are parallel to $\{111\}_{Al}$ plane of the alloy and fully coherent with matrix. The diffraction spots of η´ phases is at 1/3{220} and 2/3{220}, seen in Fig. 6(b), which is the same as the literature reported [9]. The η´ phases are semi-coherent with matrix, and compared with GP(II) zones, the size is larger.

As a result, only GP zones including Mg and Si atoms were formed after pre-ageing. β" phases were observed after paint baking, and GP(II) zones were also precipitated owing to Zn addition. After ageing at 170 ºC for 10 h, in addition to GP zones and β" phases, GP(II) zones η' phases were found.

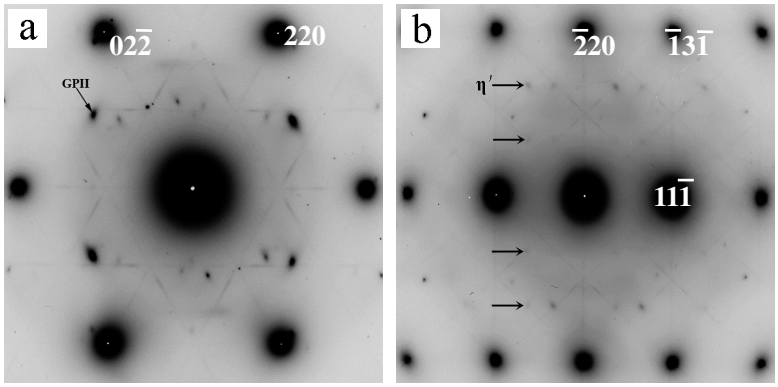

Fig.6 SAED pattern in $<111>_{Al}$ (a) and $<112>_{Al}$ (b) directions of the alloy aged at 170℃ for 10 h

Summary

(1) The average grain size of pre-aged alloy was about 20 μm. The yield strength and elongation was 137 MPa and 30% respectively. The I_E value of the alloy was 8.6 mm.

(2) After paint baking, the increment of yield strength achieved about 100 MPa. The GP(II) zones were formed during paint baking process through adding Zn. Improved paint baking response of the alloy was obtained by precipitation of GP zones, β" phases and GP(II) zones.

(3) The GP(II) zones and η´ phases were formed after the alloy ageing at 170 °C for 10 h.

KeyWords: GCrl5 bearing steel; Mn; Si; Hardness; Property

Abstract: Two bearing steels, with higher Mn and Si content than GCr15, were refined in 50kg vacuum induction furnace followed by multi-pass rolling to 12mm thick flat on two-high mill. Mechanical properties and microstructures were measured and observed. The results show that higher content of Mn and Si decreases the martensite starting temperature (Ms), which is beneficial to the forming of martensite. The microstructure changes from martensite plus troostite to martensite, leading to higher hardness of steel and improvement of wear resistance. However, the band microstructure is easily formed by increase of Mn and Si, which is harmful to transverse property.

Introduction

Bearing is one of the important basic parts of mechanical equipment. Considering the structure characteristic and working condition of bearings, the materials for bearings must have high fatigue strength, high yield strength, good toughness, better wear resistance and certain corrosion resistance[1]. Bearing steel includes high carbon chromium bearing steel, carburizing bearing steel and stainless bearing steel, etc, among which high carbon chromium bearing steel is the most commonly used. Many scholars have made a lot of research on GCrl5, a representative chromium bearing steel, which accounts for the majority use of bearing steel in many countries for its high hardness, good wear resistance and better anti-fatigue performance[2-7]. However, with the development of industries, the proprieties of GCrl5 bearing steel can hardly meet some industrial requirements. Researches have shown that the appropriate increase of Mn and Si content can improve the hardenability and elastic limit of GCrl5[8]. In this paper, the effects of Mn and Si on the microstructure and proprieties of bearing steels are studied by comparing the microstructure, hardness and mechanical property of two new steels, with higher Mn and Si content than GCr15 and being treated with multi-pass rolling process and quenching.

Experimental Scheme

The experimental steels in this research were refined in 50kg vacuum induction furnace. To study the effects of Mn and Si on high carbon chromium bearing steel, different contents of Mn and

Si were added in the test steels. The chemical compositions of the test steels are shown in Table 1. Ingots of 120 mm thickness were heated to 1250℃ at a rate of 5℃/s and held for 30min, followed by multi-pass rolling to 12mm thick flat. The rolling process is given in Fig. 1. The initial rolling temperature of steel 1 was 1074℃ and the final rolling temperature was 870℃. After rolling, steel 1 was cooled to 535℃ at a cooling rate of 15℃/s, followed by final air cooling to room temperature. While the initial and final rolling temperature of steel 2 were 1050℃ and 860℃, respectively. After rolling, it was cooled to 574℃ at a cooling rate of 15℃/s, followed by air cooling to room temperature.

TABLE 1 THE CHEMICAL COMPOSITION OF TEST STEELS(WT.%)

Steel	C	Cr	Mn	Si	Mo	P	S
1	0.965	1.495	0.428	0.341	0.050	0.008	0.009
2	1.053	1.553	1.134	0.612	0.058	0.0089	0.018

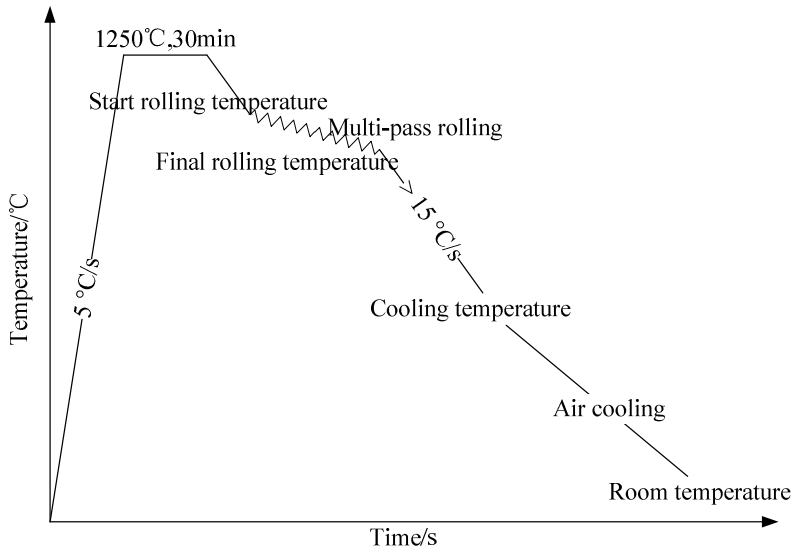

Fig. 1 Experimental Scheme

Experimental Results

Rockwell Hardness and Mechanical Property

The hardness of each experimental plate was measured for three times on a HR-150A Rockwell hardness tester. The average value of steel 2 is 57.5.5HRC, significantly higher than that of stee1 1 (45.5HRC). Then the plates were machined to standard tensile samples according to GBT228-2002. Since the high hardness of steel 2 made it difficult to be machined to standard tensile samples, the performance test both transverse and longitudinal property test were carried out only for steel 1. Table 2 gives the average value of the mechanical properties of steel 1, indicating that the longitudinal property is obviously better than transverse property.

TABLE 2 THE MECHANICAL PROPERTY OF STEEL 1

Steel 1	Yield strength /MPa	Tensile strength /MPa	Yield ratio	Uniform elongation /%	Total elongation /%
Longitudinal property	1120	1582	0.71	5.2	15
Transverse property	1009	1392	0.72	2.5	2.8

Microstructure

Metallographic samples were sampled along the rolling direction. The microstructure of the test steels were observed on Zeiss optical microscope, shown in Fig. 2 and 3, respectively. From Fig. 2 and Fig. 3, it can be seen that the microstructure of steel 1 consists of martensite and troostite, while the microstructure of steel 2 is martensite.

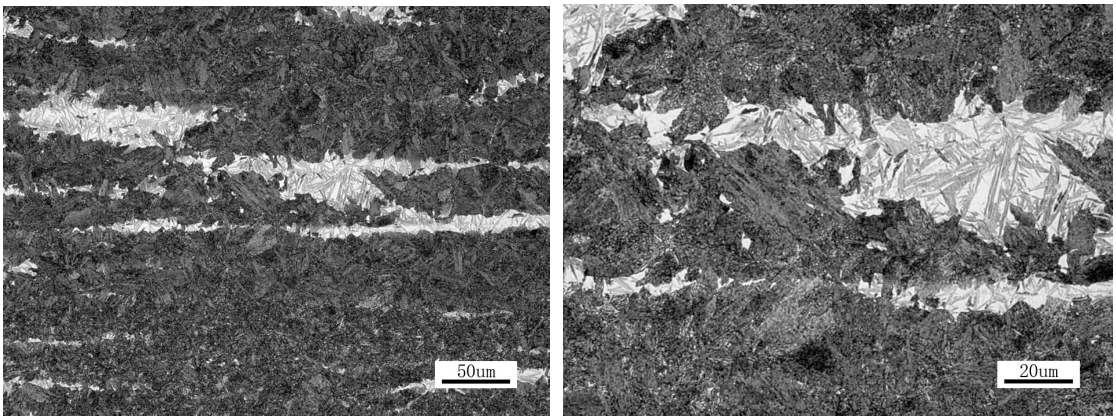

Fig. 2 Microstructure of Steel 1

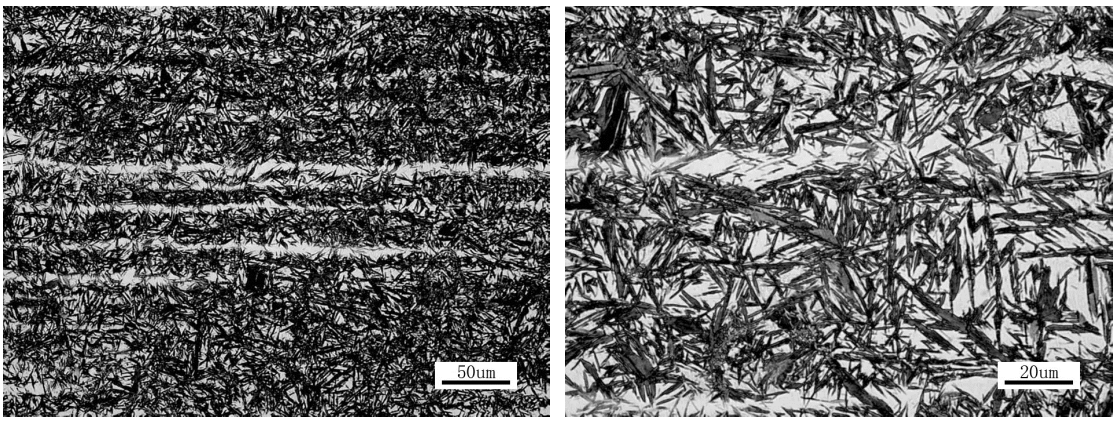

Fig. 3 Microstructure of Steel 2

Discussion

As shown in Table 1, the content of Si and Mn in steel 2 are both higher than steel 1. Silicon plays an important role in improving the stability of austenite by strongly delaying or suppressing the decomposition of cementite in overcooled austenite. Moreover, continuous carbon-riched residual austenite or martensite-austenite island can be found within the bainitic ferrite with the addition of Si. These two aspects result in crack blunting or strain-induced plasticity, thus improving the toughness effectively. However, it should be noticed that the hardness of steel is affected if the content of Si is too high. A certain amount of Mn has great strengthening effects on steel, improving the strength, hardness and wear resistance. Manganese is one of the alloy elements that can significantly enhance the stability of austenite and decrease the decomposition of austenite. Then the hardenability of steel can be increased with the appearance of bay platform on austenite transformation curve.

It can be seen from Fig. 2 that the microstructure of steel 1 is martensite and troostite with some black and white structure. The inhomogeneous distribution of Cr in alloying cementite can lead to the diversity of carbide stability. During the quenching heating process, C and Cr distributes uniformly in austenite base. After quenching, the microstructure of GCrl5 shows black and white

martensite[2,9]. The black region, low carbon martensite, appears in Cr-riched cementite, while the white region of high carbon martensite appears in low Cr cementite. Meanwhile, no martensite can be observed in the black and white martensite structure, which belongs to cover up martensite(fine martensite)[10]. As for steel 1, longitudinal property is obviously better than transverse property, that can be explained by band distribution of nonmetallic inclusions and carbide along the rolling direction. Under the function of maximum normal stress on the surface, longitudinal crack often appears in steel 1 along the distribution direction of nonmetallic inclusions and carbide. Meanwhile, band structure formed from inclusion-riched area is parallel to the rolling direction, causing the direction of mechanical properties. Transverse plasticity and toughness decrease significantly.

As shown in Fig. 3, the microstructure of steel 2 is martensite. The Si and Mn content in steel 2 is higher than steel 1, whereas other elements contents are similar. Martensite starting temperature(Ms) can be calculated according to Eq. 1. Si and Mn are beneficial for the stability of austenite and lowering the Ms, making the hardness of steel 2 (57.5HRC) obviously higher than steel 1(45.5HRC).

$$Ms=525-350(C-0.005)-45Mn-35(V+Nb+Zr+Ti)-30Cr-20Ni-16Mo-8W-5Si+6Co+15Al. \quad (1)$$

Conclusions

Two bearing steels with higher Mn and Si content than GCr15, were refined in 50kg vacuum induction furnace followed by multi-pass rolling to flat of 12mm thickness. The effect of Mn and Si on the microstructure and mechanical properties of bearing steel is investigated. The following conclusions can be obtained:

(1) Higher content of Mn and Si decreases the martensite transformation temperature (Ms), which is beneficial to the forming of martensite and changes the microstructure from martensite plus troostite to martensite, leading to higher hardness . However, the band microstructure is easily formed by increase of Mn and Si, which is harmful to transverse property;

(2) Higher content of Mn and Si can increase the hardness of steel and improve the wear resistance;

(3) The band microstructure is easily formed by increase of Mn and Si, which is harmful to transverse property.

Keywords: Alloy; Magnetic properties; Superconducting.

Abstract. $Fe_{1.125}Te$ alloys had been synthesized by solid state reaction methods. The effects of nitrogen annealing on $Fe_{1.125}Te$ lattice structure and physical properties had been studied. It was found that the lattice constants *a* and *c* increased after annealed at temperature 400~600 °C. When the temperature is above 850 °C, the size of the unit cell returns to the similar size of original samples. The step-like magnetic-thermal curves were observed after annealed at 900 °C, which is associated with two magnetic transitions. In vacuum, the transition temperatures are 122 K and 128 K, while in the nitrogen, they are 122 K and 138 K. The resistance-temperature curves indicate a semiconductor to metal transition around 69 K for N_2 atmosphere.

Introduction

Recently, Fe-based superconducting families have received wide attentions since the discovery of superconductivity in LaOFeP [1-7]. Among these materials, $Fe_{1+x}(Te,Se)$ has the simplest crystal structure. It consists of vertically stacked, tetrahedrally coordinated Fe-Te(Se) sheets which are isostructural to the Fe-As sheets in the pnictides. The same structural features may be associated with superconductivity, so compounds with the similar structure may become a new platform to explore new superconductors.

Hsu *et al* first discovered superconductivity in the tetragonal FeSe system, the transition temperature (T_C) is ~8 K [8]. The T_c could be greatly enhanced to 36.7 K under high pressure of 8.9 GPa [9]. Density functional calculations for iron chalcogenides (FeS, FeSe, FeTe) indicated a strong stability of spin density wave for FeTe [10], which could lead to a higher T_c than FeSe. $Fe_{1+x}Te$ adopts the tetragonal PbO structure with the excess Fe atoms occupying an additional Fe(2) site in the Te plane, which is equivalent to the site occupied by Li in LiFeAs [11]. The value of *x* can be determined by the stoichiometric ratio of sample, these excess Fe atoms have a significant effect in the $Fe_{1+x}Te$ lattice structure. Density-functional calculations suggest that the excess Fe is electronically active-acting as an electron donor, and has a large magnetic moment (~2.4 μ_B), which couples to the Fe in the FeTe layers [12]. W. Bao *et al.* suggested that the antiferromagnetic (AF) ordering temperature may be turned by varying the excess Fe concentration [13]. Also, it has been shown that excess Fe is correlated to the suppression of superconductivity [14]. Actually, although FeTe has the similar crystal structure with FeSe, no superconductivity is found in the bulk FeTe material [15,16]. However, epitaxial FeTe films grown on the LSAT, MgO, $SrTiO_3$ and $LaAlO_3$ substrates demonstrate superconducting transition at ~13 K [17]. It is concluded that tensile strain could lead to the superconductivity in FeTe film. However, the relationship between the vacancies at Fe(2) site of FeTe as well as the lattice strain effect on the magnetic and electronic transport properties are still unclear. In this work, we use $Fe_{1.125}Te$ as the original sample, and study the effect of electrical and magnetic properties of $Fe_{1.125}Te$ through a nitrogen atmosphere annealing.

Experimental

$Fe_{1.125}Te$ samples were prepared using a solid state reaction method, as the original samples of the subsequent experiments. Stoichiometric quantities of Fe powders (99.98%) and Te shots (99.999%) were thoroughly ground, pressed into pellets (7mm in diameter), sealed in evacuated quartz tubes under vacuum (at a residual pressure of ca. 3×10^{-4} Pa), and heated at 860 °C for 12 h followed by quenched in brine. Powder X-ray diffraction data were collected using CuK_{α} radiation. The lattice constants for original samples are a=3.8231 Å, c=6.2808 Å. The prepared $Fe_{1.125}Te$ samples were divided into several parts and inserted into quartz tubes respectively. These tubes were evacuated (about 3×10^{-4} Pa), filled with nitrogen to a pressure of 0.5×10^{5} Pa, 0.6×10^{5} Pa, 0.7×10^{5} Pa, and 0.8×10^{5} Pa, respectively. Then, all these samples were sealed and annealed at different temperatures for different times (because of the little impact, we adopt only a pressure of 0.8×10^{5} Pa). Four-probe method was employed to investigate the transport properties. Magnetic measurements were performed using Physical Property Measurement System (PPMS).

Result and Discussion

Fig. 1(a) displays the X-ray diffraction pattern of $Fe_{1.125}Te$ samples annealed at different temperatures in N_2 (550 °C, 600 °C, 850 °C, 900 °C). The pattern appears to be similar to that reported by D. Frunchart *et al*. It is fitted to the tetragonal space group *P4/nmm* of the $Fe_{1.125}Te$ phase and indexed. Fig. 1(b) shows the partial enlarged region of peak (103) in Fig. 1(a). After N_2 annealing process, the peaks of samples shift to lower degree when the temperature is below 600 °C.This might attributed to the nitrogen atoms doping, which could increase the lattice constants and broaden the inter-planar crystal spacing. As the temperature increases, the peaks shift slightly to a higher 2θ compared to the peak of 600 °C annealed sample. It indicates a decrease in the lattice parameters.

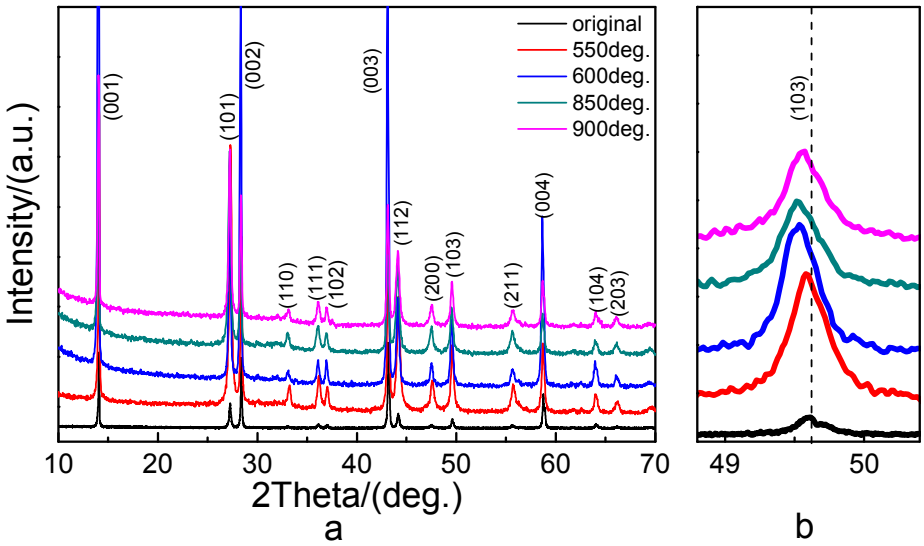

Fig. 1: (a) The XRD Patterns of $Fe_{1.125}Te$ alloys Annealed at Different Temperatures in N_2, (b) Partial Enlarged View of Lines in (103).

Table1 lists the refined lattice constants in different annealing temperatures. The a and c increases with the raising temperature when it is below 850 °C, accompanied by a unit cell volume expansion (~0.7%), which indicates the N atoms entering the lattice. When the temperature is above 850 °C, the size of the lattice contracts to the original size of unannealed samples, which indicates that N atoms can get rid of the lattice during annealing in high temperature. We also found that the value of c/a stays in a restricted range and it means that N effects lattice isotropically.

TABLE1: LATTICE CONSTANTS OF $FE_{1.125}TE$

Anneling T [℃]	*a* [Å]	*c* [Å]	*c*/*a*	*V* [Å^3]
Unannealed	3.8231	6.2808	1.6429	91.80
400	3.8269	6.2910	1.6439	92.13
550	3.8254	6.2943	1.6454	92.11
600	3.8326	6.2959	1.6427	92.48
850	3.8221	6.2859	1.6446	91.83
900	3.8259	6.2802	1.6415	91.92

Fig. 2 displays the scan electron microscope (SEM) patterns of $Fe_{1.125}Te$ samples. The left image indicates the sample is layered structure. To analyze the composition ratio of Fe and Te atoms in the $Fe_{1.125}Te$ sample, a small piece of the sample as shown in the little rectangle of the left image is picked and computed. The right image shows the EDX spectrogram and confirms the actual composition ratio of nearly 1:1.

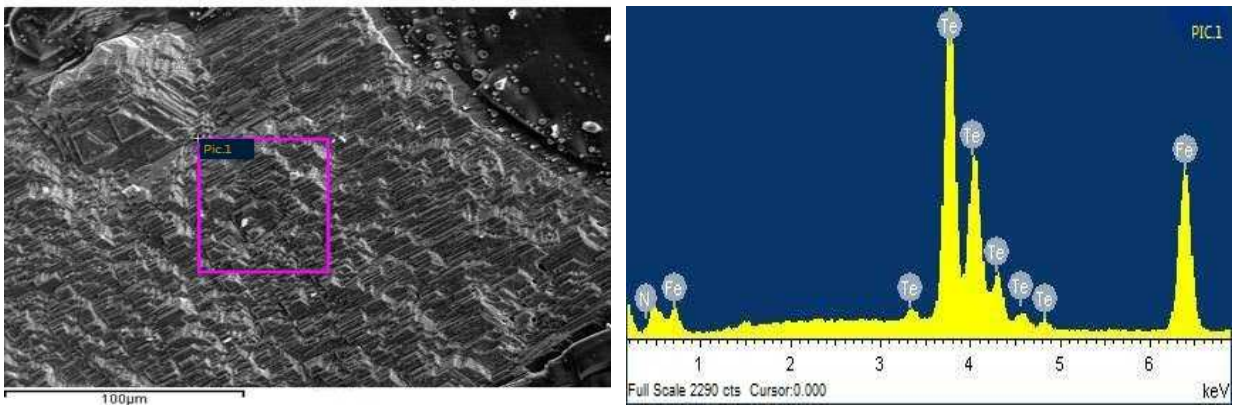

Fig. 2: SEM Images of Fe1.125Te Alloy.

Fig. 3 illustrates the initial sample's mass and heat flow curves measured in a wide temperature range (0~600 ℃). The green curve in fig. 3 shows the thermogravimetric curve of the original sample. It has a maximum increment value of 39.8 μg at 560 ℃. It corresponds with the result of XRD refining. The lattice contracts to the similar size of unannealed samples. The blue curve is the heat flow curve, which indicates that the sample is absorbing the heat during the temperature-rise period except for a slightly releasing of the heat at 527 ℃.

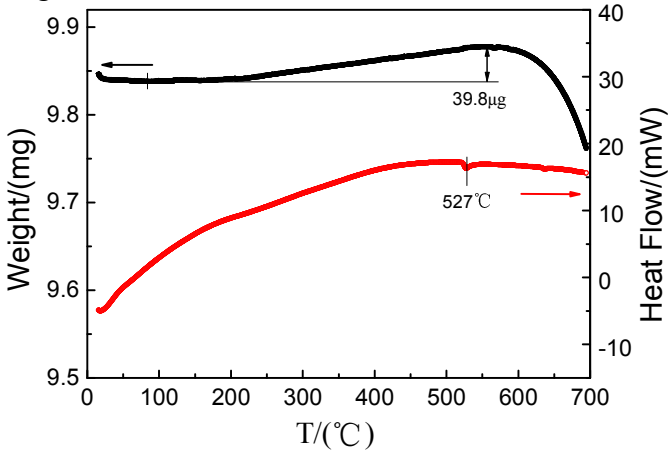

Fig. 3: Thermo#Gravimetric and Heat Flow Curves of Unannealed Fe1.125Te Alloy.

Fig. 4 shows the zero field cooled (ZFC) and field cooled (FC) magnetization (M) vs temperature (T) curves for samples annealed at different temperatures. Both samples annealed in vacuum and N_2 atmosphere have the same magnetic transition at 128 K. It indicates that N_2 takes little effect on the

sample at 600 °C annealing. The step-like curves in Fig. 4(b) are corresponding to two magnetic transitions. The critical temperatures in vacuum are 122 K and 128 K, while in nitrogen are 122 K and 138 K. Although there has no proof for the existence of two lattice structures is found in the XRD patterns, the magnetic transition points in M-T curves confirmed the magnetic phase separation caused by annealing in high temperature. As the magnetic transition temperature increases about 10 K, it indicates a remarkable effect on high-temperature magnetism with the existence of N_2. No overlap of magnetic-thermal curves in high-temperature region is observed under FC condition or ZFC condition, which indicates the impurities in the sample. For XRD shows no impurity phase, it should be caused by the low-level of the impurities, grain refinement or non-crystallizing. The magnetic material in the sample is probably α-Fe impurity.

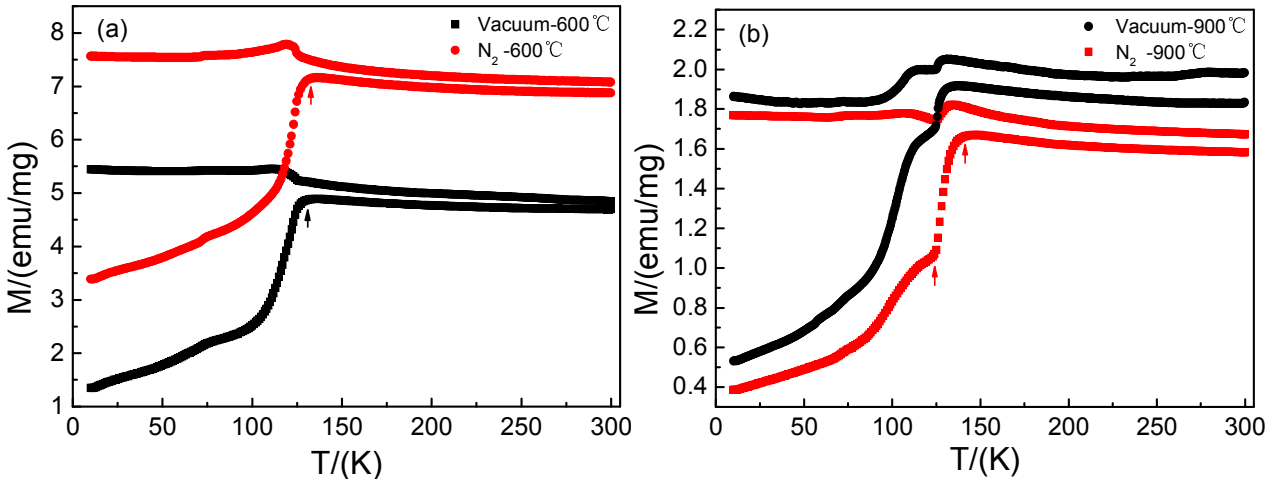

Fig. 4: (a) ZFC and FC (M) vs (T) Curves for $Fe_{1.125}Te$ in Vacuum and N_2 at the Temperature of 600 ºC. (b) ZFC and FC (M) vs (T) Curves for $Fe_{1.125}Te$ in Vacuum and N_2 at the Temperature of 900 ºC.

Conclusion

$Fe_{1.125}Te$ alloys were fabricated and annealed under N_2 atmosphere. The structural and transport properties were investigated by XRD, magnetization, resistance measurements. The lattice constants of $Fe_{1.125}Te$ were elongated after annealing in N_2. A magnetic phase separation and a shift of magnetic transition for samples annealed at 900 °C in N_2 were observed. Our results suggest that N atoms could enter the lattice of $Fe_{1.125}Te$ with a little influence on the structure of lattice and physical properties.

Keywords: Interface reaction; Thermodynamics; Alumina; AgCuTi brazing filler metal

Abstract: In this work, the interface reaction between Al_2O_3 ceramic and $Ag_{70.5}Cu_{27.5}Ti_2$ brazing filler metal at 845-860℃ was investigated. Based on the data of thermodynamics and kinetics, the Gibbs free energies of the main interface reactions in the real brazing system condition were calculated. But the values of normal equilibrium reaction condition and the real interface reaction brazing system were different; and the main influential factor was the brazing temperature, and the system vacuum of brazing condition can lead the change of equilibrium constant (Kα). The results revealed that the high temperature and vacuum active brazing is a non-equilibrium interface reaction especially to titanium alloy, the vacuum and alloy liquid solution are beneficial to the brazing process, and the by-product formation of titanium-oxygen are affected by the diffusion process.

Introduction

It was well-known that alumina ceramic played an important role in electronic industry because of its superior physical, chemical, mechanical and optical properties. Titanium as an active metal component of brazing alloys had been used on most occasions[1-11]; and Ag-Cu alloy eutectic filler metal owned the advantages of low braze temperature, low stress and simply process; So Ag-Cu-Ti alloy metal were popularly used active brazing metal.

In this research, $Ag_{70.5}Cu_{27.5}Ti_2$ eutectic alloy was used to braze hot-pressed sintered alumina ceramic. The interface reaction and thermodynamics behavior between $Ag_{70.5}Cu_{27.5}Ti_2$ alloy and alumina ceramic were investigated.

Experimental details

Materials preparation

The hot-pressed sintered 99.9% alumina used in this study was obtained from the State Key Laboratory of New Ceramics and Fine Processing, Tsinghua University, China; the alumina faying face was polished by sand paper with diamond paste. $Ag_{70.5}Cu_{27.5}Ti_2$ brazing filler metal was rolled into 500 μm strip and cut into an appropriate size for brazing. The brazing filler metal and 99% alumina ceramic were carefully cleaned with acetone in ultrasonic cleaners and baked before brazing.

Brazing tests

The test sample was fixed in an iron jig. The jig was heated in a vacuum furnace to brazing temperature and then held for a few minutes. The heating rate below 750℃ was 20℃/min, and the heating rate above 750℃ was 10℃/min to the brazing temperature (845-860℃). The cooling rate

after brazing was 5℃/min above 600℃ and then held for a while at this temperature, then about 2℃ /min to room temperature. The pressure of the furnace chamber was kept between 1×10^{-3} and 1×10^{-5} Pa during the heating and the cooling. Fig.1 showed the brazing cure of time with temperature and vacuum in process.

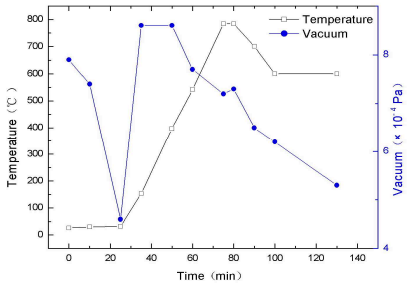

Fig. 1 Brazing cure of time with temperature and vacuum

Sample characterization

The resultant interface reaction was examined with an optical microscope and a scanning electron microscopy (SEM) equipped with energy dispersive X-ray spectroscopy (EDS), and the quantitative analysis of elemental concentration for each phase was made with the electron beam characteristic at 15 kV, life time 60.0 s and take-off angle 34.22 º.

Results and discussion

Metalloscopy and SEM analysis

Fig.2 was the elemental analysis of $Ag_{70.5}Cu_{27.5}Ti_2$ brazing filler metal with SEM EDS; it revealed that the main elements include Ag, Cu and Ti. Fig.3 showed the optical image of the brazing filler metal and alumina ceramic interface, there is an intermetallic compound (IMC) layer between $Ag_{70.5}Cu_{27.5}Ti_2$ brazing filler metal and alumina ceramic, which was sharply contrast with the original layers, confirming that some interface reactions between the filler metal and alumina ceramic happened.

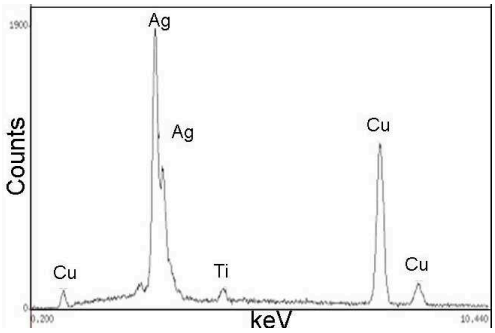

Fig. 2 EDS of elemental analysis of $Ag_{70.5}Cu_{27.5}Ti_2$

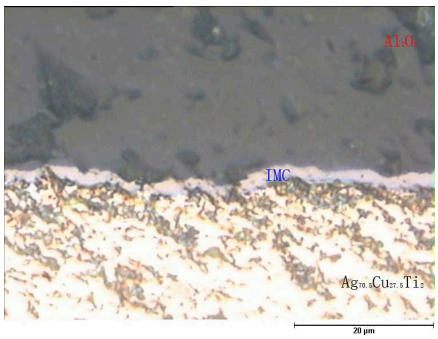

Fig. 3 Optical image of $Ag_{70.5}Cu_{27.5}Ti_2/Al_2O_3$ interface

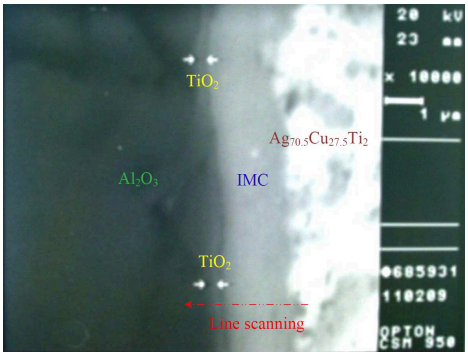
Fig. 4 illustrated the transverse cross-sectional SEM image of typical $Ag_{70.5}Cu_{27.5}Ti_2$/alumina ceramic brazing interface, there was a nanometer layer in IMC and near to the side of alumina ceramic; EDS indicated that this nanometer layer mainly composed of Ti and O, and the ratio of O to Ti is 2:1. this nanometer layer would be TiO_2 [10]. Fig.5 showed the elemental line scanning results by EDS from $Ag_{70.5}Cu_{27.5}Ti_2$ filler metal intermetallic compound layer nearby the alumina ceramic side, and it revealed that this layer is consisted of Ag, Cu, Ti, O, Al and Ca.



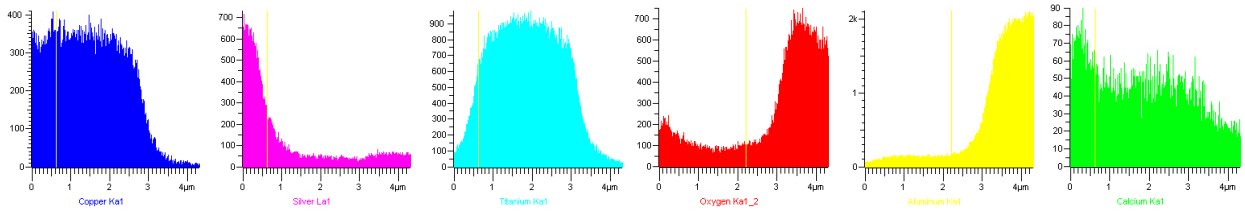


Fig. 4 Cross-sectional SEM image of typical $Ag_{70.5}Cu_{27.5}Ti_2/Al_2O_3$ brazing sample

a) Cu b) Ag c) Ti d) O e) Al f) Ca

Fig. 5 Elemental line scanning results by EDS from $Ag_{70.5}Cu_{27.5}Ti_2$ IMC nearby Al_2O_3 side

In Fig.5a, the concentration of copper kept a high level in IMC layers, indicating that Cu atoms were difficult to diffuse into Al_2O_3. In Fig.5b, the concentration of Ag decreased greatly in IMC layers, revealing that Ag atoms were less correlated to the interface reaction directly. In Fig.5c, the concentration of Ti increased greatly in IMC layers, implying that there was a Ti atom enriching zone. In Fig.5d, the concentration of oxygen kept a low level in IMC layers, but the interface between Al_2O_3 and $Ag_{70.5}Cu_{27.5}Ti_2$ kept a high level, indicating that the oxygen atoms were highly correlated to the interface reaction directly. In Fig.5e, Al atoms could diffuse from alumina into the filler metal slightly. In Fig.5f, the calcium atoms were just the background. Fig.6 was the sketch map of different elements in the line scanning from $Ag_{70.5}Cu_{27.5}Ti_2$ to Al_2O_3.

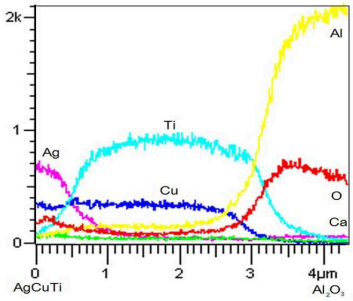

Fig. 6 Sketch map of different elements in the line scanning

Thermodynamics analysis

There were many kinds of feasibility to interface reactions between $Ag_{70.5}Cu_{27.5}Ti_2$ and Al_2O_3. If we want to get high-quality brazing between them, we need know and control the active brazing interface reactions between the main products of $Ag_{70.5}Cu_{27.5}Ti_2$ and Al_2O_3, for example, TiO_2, TiO, Cu_2Ti_4O and so on [10-11].The brazing reaction between Ti and Al_2O_3 could be described by

$$\text{Eq.1: } (Ti) + xAl_2O_3(s) \rightarrow Ti(O)_{3x}(s) + 2x(Al) \quad (1)$$

If the main product was TiO [12], Eq. 1 can be changed to Eq.2:

$$3(Ti) + Al_2O_3(s) \rightarrow 3TiO\ (s) + 2(Al) \quad (2)$$

As we know, Al_2O_3 and TiO were solid phase at 845-860℃, but Ti and Al would be dissolved in liquid alloy welding flux at that temperature; So the Gibbs free energy of this reaction could be described by Eq.3and Eq.4:

$$\Delta G_T^0 = -RT\ln K_\alpha \tag{3}$$

$$\Delta G_T^0 = \Delta H_T^0 - T\Delta S_T^0 \tag{4}$$

where R was the universal gas constant, ΔH_T^0 was the reaction enthalpy change, and ΔS_T^0 was the reaction entropy change. Maybe there were phase changes for Ti and Al from room temperature to brazing reaction temperature, so we also need consider the contribution of these changes. But there was no phase change for Al_2O_3 and TiO in this reaction temperature zone. The reaction could be calculated by Eq.5 and Eq.6:

$$\Delta H = \int_{T_1}^{T_2} C_P dT \tag{5}$$

$$C_P = A_1 + A_2 10^{-3} T + A_3 10^5 T^{-2} \tag{6}$$

where CP was the molar heat capacity at constant pressure, According to Eq.5, Eq.6 could be changed to Eq.7; and the entropy change could be described by Eq.8:

$$\Delta H = A_1 \bullet (T_2 - T_1) + \frac{1}{2} A_2 \bullet 10^{-3}(T_2^2 - T_1^2) + A_3 \bullet 10^5 (\frac{1}{T_1} - \frac{1}{T_2}) \tag{7}$$

$$\Delta S = C_1 \bullet \ln\frac{T_2}{T_1} + C_2 \bullet 10^{-3}(T_2 - T_1) + C_3 \bullet 10^5 (\frac{1}{T_2^2} - \frac{1}{T_1^2}) \tag{8}$$

For Ti and Al, it need add the enthalpy and entropy changes of phase transformation. At 1155K, Ti would change from β phase to α phase; Al would change from liquid to solid at 932 K, so Ti and Al could be described by Eq.9 and Eq.10:

$$\Delta H = \Delta H_{\text{Transformation}}(\Delta H_m) \tag{9}$$

$$\Delta S = \Delta S_{\text{Transformation}}(\Delta S_m) \tag{10}$$

The standard enthalpy and entropy changes of Al_2O_3 reduction reaction could be described by Eq. 11 and 12:

$$\Delta H_{298}^0 = (\sum n_i \Delta H_i^0)_{\text{Re}sul\tan t} - (\sum n_i \Delta H_i^0)_{\text{Re}ac\tan t} \tag{11}$$

$$\Delta \text{S}_{298}^0 = (\sum n_i \Delta \text{S}_i^0)_{\text{Re}sul\tan t} - (\sum n_i \Delta \text{S}_i^0)_{\text{Re}ac\tan t} \tag{12}$$

Table 1 listed the reference data of thermodynamic [12-14]. If we introduced these data to Eq.3 and 4, we could get the reaction equilibrium constant of TiO (Kα) [15]. After that, we could get the reaction equilibrium constant of TiO, and the detail was shown in Eq.13 and Eq.14:

$$K_1 = \exp\left(23.19 + 1.948\times10^{-3}T + 0.73\times10^5 T^{-2} - 3.03\ln T - 11260T^{-1}\right) \tag{13}$$

$$K_2 = \exp(29.61 + 0.51\times10^{-3}T + 2.45\times10^{5}T^{-2} - 2.42\ln T - 61997T^{-1}) \quad (14)$$

where K_1 was the reaction equilibrium constant of TiO, and K_2 was the reaction equilibrium constant of TiO_2. From Eq.13 and 14, the value of Kα would be enlarged with the brazing temperature

increased, and the reaction equilibrium would also lead the resultant increasing direction; if the brazing temperature decreased, the value of Kα would decrease, and the process of interface reaction would be restrained too.

In some paper, Eq.15 was used to calculate Gibbs free energy between Ti and Al_2O_3 [16]:

$$\Delta G_T^0 = \Delta H_0 + 2.303aT\log T + b\times10^{-3}T^2 + c\times10^5 T^{-1} + I\bullet T \tag{15}$$

where ΔH_0 was -407950; 2.303a was -6.19; b was -0.78; c was +3.935; and I was +102.37. At 830℃, ΔG_{830}^0 was +19899 cal/mol. Here, we need consider the thermodynamic correction term ($\Delta G_{Correction}^0$). For example, Ti was liquid phase at brazing temperature (lower than its melting point). We need add it with the solid entropy change from brazing temperature to Ti melting point ($\Delta S_{(s)} = \int_{T(Bracing)}^{2000} C_S \frac{dT}{T}$) and the liquid entropy change from Ti melting point to brazing temperature ($\Delta S_{(l)} = \int_{2000}^{T(Bracing)} C_L \frac{dT}{T}$). So $\Delta G_{Correction}^0$ could be described by Eq.16:

$$\Delta G_{Correction}^0 = \Delta H - T(\Delta S_{(L)} + \Delta S_{(S)}) \tag{16}$$

If the brazing temperature was 830℃, $\Delta G_{Correction}^0 = 20457$ cal/mol; the real Gibbs free energy change of Al_2O_3 reduction reaction ($\Delta G_{\text{Real}}^0 = \Delta G_T^0 - \Delta G_{Correction}^0$) was -558 cal/mol, indicating that this reaction could decrease the system energy, so this reaction could occur spontaneously. If Ti was in solid state ($\Delta G_{Correction}^0 > 0$), this reaction could not occur spontaneously. Otherwise, the reaction system temperature need be increased. Ti active atom dissolved in Ag-Cu alloy liquid solution; it not only lowered the required brazing reaction temperature, but also released the stress in brazing process. From Fig.4, there was a very narrow nanometer TiO_2 layer near to Al_2O_3 surface. Based on the thermodynamic theory without correction, the resultant product of TiO_2 was difficult to be formed at 845-860 ℃ because Ti could not reduce Al_2O_3 in equilibrium system. But TiO_2 layer really existed in the reaction zone; the main reason was that the brazing process was in a high vacuum (1×10^{-4} Pa) and metal alloy liquid solution system; the resultant (for example, Al) can be evaporated or dissolved in alloy liquid [17], and it could help the resultant to be removed, so the atoms of titanium and oxygen could be easily combined to TiO_2; it would lead the different resultant products other than that of equilibrium reaction. The binary phase diagram of Ti-O presented in Ref. [18] predicted that if the oxygen concentration was above 37 wt% at brazing temperature, the resultant would be TiO_2; if the oxygen concentration was about 18-37 wt% at brazing temperature, the resultant would be TiO; and this experimental phenomena in this work was a direct proofs for their predictions.

In the real reaction layer, there were Cu_2Ti_4O, Ti and $AlAg_3$, and the brazing reaction between Al and Ag could be described by Eq.17 [10]:

$$(Al) + 3(Ag) \rightarrow AlAg_3 \tag{17}$$

Near to the side of Al_2O_3, TiO_2 (high valence compound) could be easily formed because of the richness of oxygen. When the distance to reaction interface increased, TiO (low valence compound) could be popularly formed because of the difficulty of oxygen atom diffusing. Near to the side of AgCuTi filler metal, partial of TiO would dissolve into Cu-Ti to form IMC. Ref. [18] reported the phase diagram of TiO in Cu-Ti. According to Ref. [19], if the titanium concentration in reaction zone was higher than 30%, there were two kinds of $(Cu,Ti)_6O$ ternary complex oxides, Cu2Ti4O and Cu_3Ti_3O, and the resultant product of Cu_3Ti_3O could be formed through Eq.18:

$$3Ti_4Cu_2O + 5O_{(Al_2O_3)} \rightarrow 2Ti_3Cu_3O + 6TiO \quad (18)$$

In this experiment, the element concentrations of IMC layer (Cu, Ti and O) was near to the chemical composition of Cu_2Ti_4O, maybe the feasibility of reaction would be restrained by reaction kinetics or the shortage of reactant. Based on the research of G. P. Kelkar [20], $\Delta G_f^0(Ti_4Cu_2O)$ was -120 kcal/mol at 945 ℃, and $\Delta G_f^0(Ti_3Cu_3O)$ was -122 kcal/mol at 945 ℃. So these two kinds of ternary complex oxides were stable thermodynamically, and the real resultant was depended on the reaction kinetics. Ti would cluster in the reaction interface, and it was favorable to the formation of Cu_2Ti_4O.

Conclusions

The interface reaction between Al_2O_3 and $Ag_{70.5}Cu_{27.5}Ti_2$ was confirmed by SEM and EDS, and TiO_2 nanometer layer was also detected near to the Al_2O_3 side. Based on the thermo-chemical data of reactant and resultant, the resultant enthalpy was calculated, and the entropy change after the brazing condition correction items was introduced. It was found that the vacuum and alloy liquid solution were beneficial to the brazing process. The formation of TiO_2 and TiO were calculated according to the binary phase diagram of Ti-O. The result showed that the oxygen concentration played an important role in interface reaction, and Ag could not directly react with Al_2O_3, but it decreased the resultant concentration (Al). Finally, the reason for the formation of Cu_2Ti_4O was analyzed.

Keywords: Al-Cu-Mg-Si alloy, precipitation, deformation, σ phase, S' phase.

Abstract. To meet the stringent requirements of heat-resistance products for aerospace applications, an Al-4.0Cu-1.3Mg-0.6Si alloy containing a cubic σ phase ($Al_5Cu_6Mg_2$) with excellent high temperature stability was developed. Influence of deformation on aging precipitation behavior of the alloy was investigated by transmission electron microscope (TEM) and differential scanning calorimetry (DSC). The results indicated that cold deformation had great effect on aging precipitation behavior in the alloy. When the alloy was processed a pre-stretching deformation before aging, the precipitation of σ phase was restrained while the S′ phase (Al_2CuMg) was promoted. And the nucleation sites played an important role on them.

Introduction

Al-Cu-Mg (2xxx series) alloys are light materials widely used in aerospace applications because their hardness, ductility and superior creep strength at elevated temperatures [1]. The precipitation sequence of Al-Cu-Mg alloys could become very complex depending on the Cu/Mg ratio and trace alloy additions. Many studies have been carried out in order to examine and predict the influence of suitable trace alloy additions on the nucleation of desired precipitates in age-hardenable Al alloys. Several secondary phases have been found in Al-Cu-Mg alloys, including θ, S, Ω and σ phases [2~6]. Among them the cubic σ phase ($Al_5Cu_6Mg_2$) has a simple cube-on-cube orientation relationship with the aluminum matrix. It precipitates as the semi-coherent or coherent phase with a high solvus (above 700°C), which makes it quite stable at high temperatures, above 200°C. So σ phase is known as a very promising new heat-resistant strengthening phase. And some reviews show that small additions of Si to Al-Cu-Mg alloys can induce the formation of σ phase during artificial aging at commercial aging temperature [7~9]. With the rapid development of the new generation of aerospace vehicles, new Al-Cu-Mg series heat-resistance alloys that can be used at a higher service temperature are urgently required. Therefore, to make sure the precipitation behavior of σ phases becomes a concern. To meet the stringent requirements of heat-resistance products for aerospace applications, an novel Al-Cu-Mg-Si alloy containing a cubic σ phase with excellent high temperature stability was developed [10,11].

Moreover, recent demand for weight reduction in aircraft structural component calls for further enhancement in strength of commercial structural alloys. So, it may be of interest to examine the possibility of enhancing the strength of age hardenable aluminum alloys [12]. Therefore, in addition to control the suitable type of precipitation strengthening phase, cold deformation prior to aging is applied widely in the industry to increase the aging response particularly for the strength of 2xxx series alloys. The objective of this study was to investigate the effect of cold pre-deformation on aging precipitation behavior of an novel Al-4.0Cu-1.3Mg-0.6Si alloy.

Experimental Procedures

Additions of 0.6 wt% Si was made to a base alloy composition of Al-4.0Cu-1.3Mg (wt%), as shown in Table 1. Ingots of approximately Φ210 mm were produced by mold casting. After casting,

the billets were homogenized at 490°C for 24 h, and subsequently at 520°C for 12 h, followed by air cooling to room temperature. The billets were then scalped to 190 mm diameter and extruded at 420 °C into plates of 102 mm ×25 mm in cross-section (extrusion ratio 12.6:1). Specimens were solution heat treated at 500~520°C for 1~3h and then water quenched to room temperature. In order to contrast the influence of deformation on the precipitation of the A1 alloy, a 3% pre-stretch deformation was applied. And finally the A1 alloy both of with deformation and without deformation aged for appropriate time at 190°C.

The quenched as well as pre-stretched deformation samples were subjected to DSC to study the precipitation using the heating rate at 10°C/min up to a temperature of 500°C. DSC studies were carried out in a NETZSCH STA 409C/CD instrument using high purity argon gas atmosphere. The specimens for DSC studies were mechanically thinned and the thin slice weighing about 18mg was cut out of the sample strip. Specimens for TEM were thinned by electropolishing using a twin-jet polisher with a 25% nitric acid solution in methanol at -30°C and 15~20 V. The specimens were examined in selected area electron diffraction (SAED) and bright field (BF) imaging modes in a JEOL 2010FX microscope, operating at 200 kV.

Table 1 Composition of the alloys used in the present study (wt%)

Alloy Designation	Cu	Mg	Si	Al
A0	4.0	1.3	-	Bal.
A1	4.0	1.3	0.6	Bal.

Results and Discussion

DSC Curves. The Fig.1 shows the DSC thermogram of A0 alloy (Al-4.0Cu-1.3Mg) in quenching state, the A1 alloy (Al-4.0Cu-1.3Mg-0.6Si) in quenching state and A1 in 3% pre-stretch deformation state after quenching. It can be seen from Fig.1, in the process of heating up, for both of the A0 and A1 alloy in the DSC curve appeared an obvious exothermic peak in 265~300°C (mark A). The difference is that there appeared another exothermic peak between 240~260°C (mark B) in the DSC curve of the A1 alloy. Combined with the previous result, exothermic peak A is corresponding to the precipitation of S (S′) phase. Here a preliminary inference can be obtained that exothermic peak B should correspond to σ phase. For the A1 alloy with 3% pre-stretching deformation, exothermic peak A corresponding to S phase became wider, the area of the exothermic peak increases slightly, and exothermic peak B area corresponding to σ phase significantly decreased. Thus, it can be inferred that cold deformation has great effect on aging precipitation behavior in the alloy.

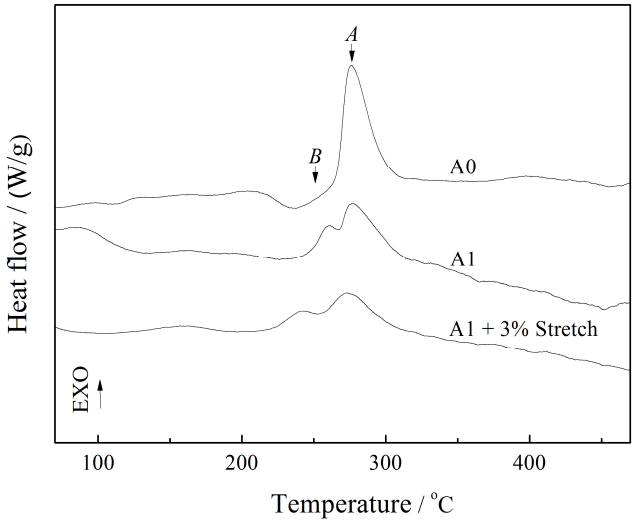

Fig.1 DSC thermogram of A0 and A1 alloy in different condition

Microstructure. Al-Cu-Mg alloys with a Cu:Mg ratio in the range 1.5:1 to 4:1 are strengthened the S′ phase. Therefore, S′ phase was the dominant precipitate in the A0 alloy (Al-4.0Cu-1.3Mg). Si addition can promote the precipitation of σ phase in the alloys. Representative TEM micrographs and corresponding $[100]_{Al}$ selected area electron diffraction (SAED) patterns of the A1 alloy (Al-4.0Cu-1.3Mg-0.6Si) without deformation in aged condition are presented in Fig.2. Fig. 2(a) and (b) shows the typical bright field (BF) image and corresponding SAED pattern, respectively, it can be seen that there are two shapes of precipitate existed in the alloy, including cubic-shaped and lath-shaped precipitate which are matching to σ phase and S′ phase ,respectively. A detailed analysis of the FFT image (shown in Fig.2(d)) indicates that the cubic-shaped precipitate is in agreement with σ phase. Diffuse spots near n/2 {100} positions associated with σ phase were clearly observed; the σ phase was showed to be a semi-coherent or coherent and coplanar phase with the Al matrix, i.e.,$\{100\}_{\sigma}//\{100\}_{Al}$ and $<100>_{\sigma}//<100>_{Al}$.

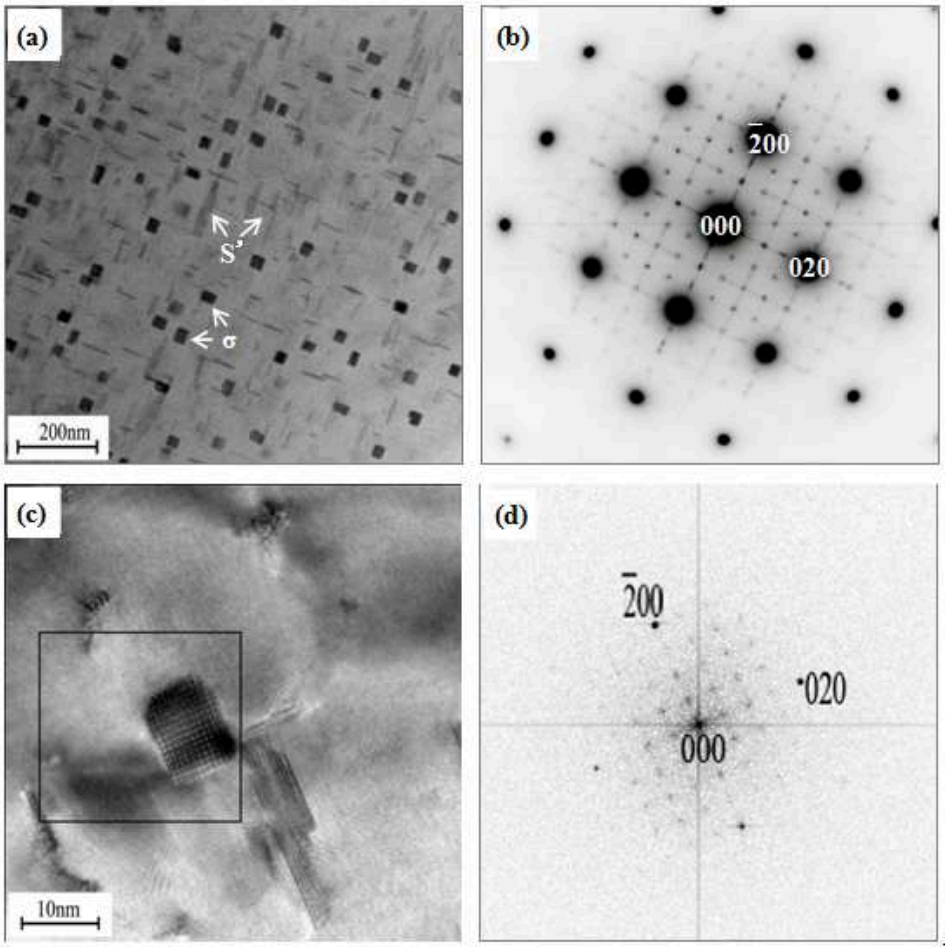

Fig.2 TEM BF images and SAED pattern near the $[001]_{Al}$ of the A1 alloy without deformation in aged condition a,c) BF images; c) SAED pattern in $[110]_{Al}$; (d) the corresponding FFT diffractogram

Fig.3. provides TEM micrographs and corresponding $[100]_{Al}$ SAED pattern of the A1 alloy (Al-4.0Cu-1.3Mg-0.6Si) with 3% pre-stretching deformation in aged condition. Fig. 3(a) shows the typical BF image, comparing to Fig.2(a), it can be found that with deformation, σ phase almost disappeared. And S′ phase is dominant, which can be validated by the corresponding SAED pattern as shown in Fig.3(b). By all appearances, there appear amounts of dislocation in the matrix after deformation. This suggests that the S′ phase precipitation occurs easily by heterogeneous nucleation at dislocations, and σ phase is prone to precipitation of homogeneous nucleation. Presence of dislocation was helpful for heterogeneous nucleation of the S′ phase, but not conducive to homogeneous nucleation of σ phase. Therefore, in the case of the alloy, to precipitate a large amount

of σ phase in order to obtain a good heat resistance property, the traditional pre-deformation technology for 2xxx series aluminum alloy is not suitable.

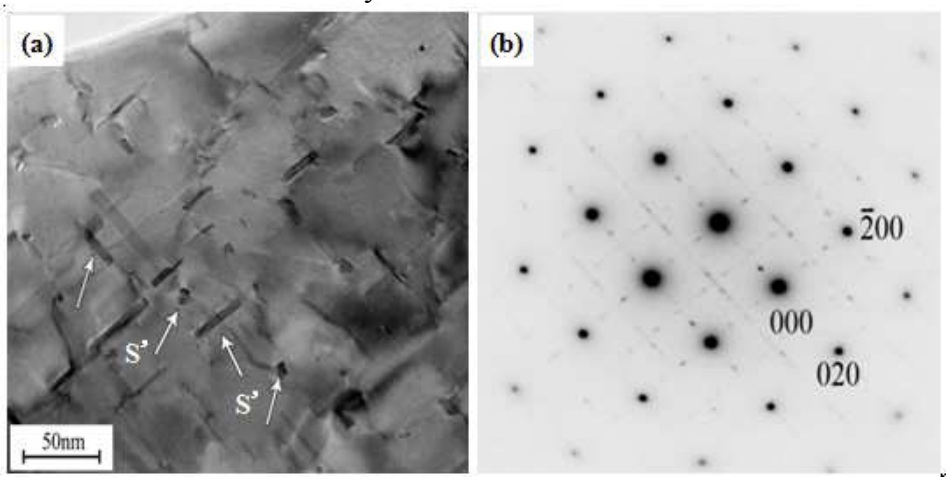

Fig.3 TEM BF images and SAED pattern near the $[001]_{Al}$ of the A1 alloy with 3% pre-stretching deformation in aged condition

a) BF images; b) SAED pattern in $[110]_{Al}$

Summary

Cold deformation had great effect on aging precipitation behavior in the Al-4.0Cu-1.3Mg-0.6Si alloy. In the alloy, in addition to the S′ phase, a cubic phase previously designated σ phase ($Al_5Cu_6Mg_2$) was appeared in large quantities. When the alloy was processed a pre-stretching deformation before aging, the precipitation of σ phase was restrained while the S′ (Al_2CuMg) phase was promoted. And the nucleation sites played an important role on them. Large numbers of dislocation were helpful for heterogeneous nucleation of the S′ phase, but not conducive to homogeneous nucleation of σ phase. In the case of the alloy, the traditional pre-deformation technology for 2xxx series aluminum alloy is not suitable.

Keywords: Nickel-based Superalloy; Belt grinding; Grinding ratio; Surface integrity; Surface roughness

Abstract: The use of GH4169 nickel-based superalloy for the manufacture of gas turbine engines components for aerospace/energy applications has become a routine exercise. However, components with complex designs specifications might pose manufacturing challenges especially when grinding processes are needed to enable their compliance with tight industrial standards for workpiece surface integrity. Information on grinding processes for such sensitive industrial applications is scarce. The paper reports on the influence of grinding methods/strategies on the quality and integrity of workpiece surfaces obtained after abrasive belt grinding methods on GH4169 nickel-based superalloy. The influences of grinding speed, contact pressure and oscillation frequency on surface roughness were discussed. The performance of the abrasive belt and surface topography were discussed. As a result, the maximum surface roughness of Ra is 0.072μm, and have a good performance of the abrasive belt, it could be concluded that abrasive belt grinding might be considered as a viable process for grinding aero-engine components.

Introduction

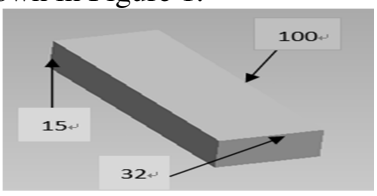
Superalloy, also called heat-resistant alloy, has high strength, excellent thermal stability and thermal fatigue resistance. Because of it can be long-term reliable working under complex stress with oxidation and gas corrosion in 600℃~1100℃, widely be used in aviation, aerospace, marine and chemical industry[1]. It also was used for the hot end components for the engine in the aviation industry, such as turbine blade, turbine, afterburner, turbine shaft and so on. Usually, the aero-engine components worked in the corrosive medium and alternating load environment, so the service life of parts were reduced by the poor surface integrity which would accelerate the fatigue destruction. Therefore, investigating and mastering the grinding performance of superalloy is very important for the safety of aero-engine components[2-3].

Due to the especially characteristics of superalloy, including multi component alloy, low thermal conductivity, high temperature and hardness, and containing a large amount of carbides, nitrides, oxides, intermetallic compounds, making its grinding performance poorly, mainly reflected in:①the grinding ratio is very low(ordinary the grinding ratio of grinding wheel is G=1~2), due to the more serious abrasion wear and adhesion blocking when grinding the superalloy;②easily produce strong plastic deformation, so the force is much larger than ordinary steel material;③the heat induced into the workpiece is relatively low, so the heat is concentrated in the thin surface layer, leading to the grinding temperature is very high;④due to the comprehensive effect of grinding force and temperature, the surface quality is difficult to be guaranteed. Therefore, the development of grinding tool which having higher performance and improving grinding efficiency and quality for the superalloy, becoming a very urgent request[4-5].

Some attempts to implement abrasive belt grinding as a grinding process for the refurbished aero-space components have been reported. Axinte et al.[6] reported on belt polishing of heat-resistant titanium alloys. The work proved that belt polishing could fulfil both economical and

part quality requirements for finishing critical aero-engine components made of heat-resistant alloys such as Ti-6-4. High surface finish was achieved after belt polishing (Ra < 0.35μm). No evidence of thermally affected layers was found on the final polished workpiece surfaces. Particularly, Zhang et al. [7]reported on the topic of simulation involving acting force, depth of cut and tool path. Additionally, Nakayamaet al.[8] published the data on the use of the cooling media when using belt grinding.

Despite the report on the surface integrity of ti-6-4 heat-resistant alloy for the critical aero-engine components, no information has been reported on the properties (e.g. surface texture, sureface raughness) of the workpiece surface obtained after belt grinding/polishing especially to the GH4169 Nickel-based Superalloy. These properties are of paramount importance for the acceptance of belt grinding as a final grinding process by the aero-engine manufacturers.



Equipment and methodology

Materials. The experiment material is nickel-based superalloy GH4169, which widely used in aero engines, and has superior performance in high wage environment, its performance parameters are shown in Table 1.

Table 1 Performance parameters of GH4169 nickel-based superalloy

Performance	Elasticity E/Gpa	Thermal λ/W.m	Elongation δ/%	Hardness HB	Impact a_K/(J.cm-2)	Shrinkage ψ/%	Melting /ºC
Parameters	205	14.65	15	346-450	573	41	1260-1320

The experiment specimen size of nickel-based superalloy GH4169 is 100mm×32mm× 15mm, as shown in Figure 1.

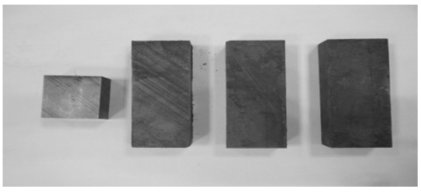


Figure 1 Experiment specimen

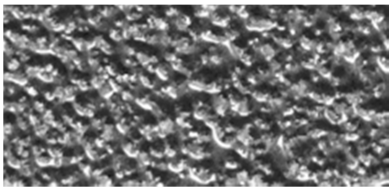

Figure 2 Abrasive belt

Abrasive belt: The abrasive belt CK918X, which is produced by German company VSM, is adopted in this experiment, belt size is 1950mm×50mm, 89#, as shown in Figure 2.

Equipment: The equipment, which is developed by the joint of the chongqing university and the chongqing three grinding Haida machine, is used in this experiment, with constant pressure in the grinding process, as shown in Figure 3. It is made of belt grinding head, driving device, tooling and fixture, the electric control system and other parts, and also equipped with frequency converter, which could achieve stepless speed regulation, is corresponding to the driving wheel of vector variable frequency speed regulation.

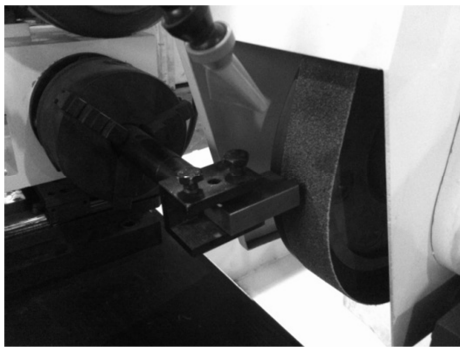

Figure 3 Constant pressure belt grinding machine

Methodology: The experiment methodology for the nickel-based superalloy specimen with abrasive belt grinding is carried out by the method of orthogonal experiment, orthogonal test table as shown in Table 2.

Table 2 Orthogonal test table

Factor	Level		
	1	2	3
Grinding speed（m/s）	18	26	34
Contact pressure（N）	30	60	90
Oscillation frequency（Hz）	0	2	1

The electronic scale is used for measuring the workpiece quality, its measurement accuracy is 0.1g; the stopwatch is used for recording the time of grinding; the roughness instrument TR200 is used for determination of surface roughness Ra by stylus method, which manufactured in Beijing times group.

Results and discussions

Performance of abrasive belt: The grinding ratio, *G*, is a measure of how much material is removed from the workpiece per unit volume of wheel wear.

$$G = \frac{V_w}{V_s} \quad (1)$$

Based on the (1) type derivation, can use the material removal rate to represent the grinding ratio, i.e.:

$$G = \frac{dV_w}{dV_s} = \frac{Q_w}{Q_s} \quad (2)$$

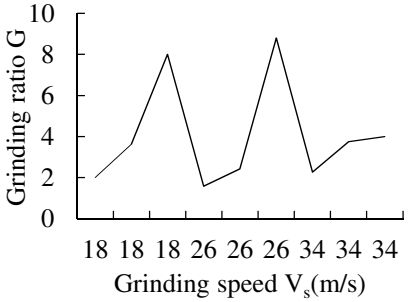

Figure 4 Grinding speed

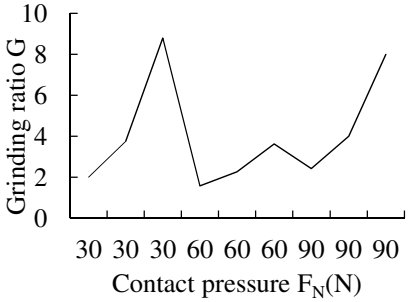

Figure 5 Contact pressure

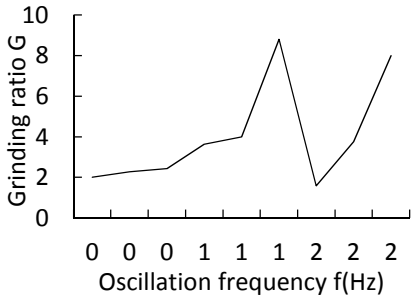

Figure 6 Oscillation frequency

A value of a grinding ratio of $G = 1$ is very low and implies that the abrasive is not hard enough for the task. A grinding ratio of $G = 1{,}000$ is high and may sometimes correspond to a wheel that is too hard for the task. For example, if the abrasive tool wears by a slow glazing of the grains, the machining forces will rise and may lead to various problems such as poor size-holding, vibrations, and poor surface texture. According to the figure 4-6, than G>2 abrasion abrasive belt grinding, its maximum value can reach 8.8, and the grinding wheel wear than G=1~2, so it can confirm the superiority of abrasive belt grinding.

Surface roughness: According to the orthogonal range analysis of surface roughness to the belt grinding of nickel-based superalloy GH4169, as shown in Figure 7, the largest effect of grinding parameter on surface roughness is oscillation frequency, followed by the contact pressure, and then is the grinding speed. At the same time, the optimal combination of process parameters were obtained on the surface roughness, including grinding speed is 26m/s, contact pressure is 30N and oscillation frequency is 2Hz.

(1) Influence of grinding speed to the surface roughness

As shown in Figure 8, with the more increase of belt speed, the better of surface roughness, combined with range analysis in the Figure 7, the best surface roughness is in the middle grinding speed. This is mainly because, on the one hand, easy to burn in condition of high grinding speed; on the other hand, the grinding zone which cutting into workpiece is increased with the lower grinding speed, so the roughness is poorly.

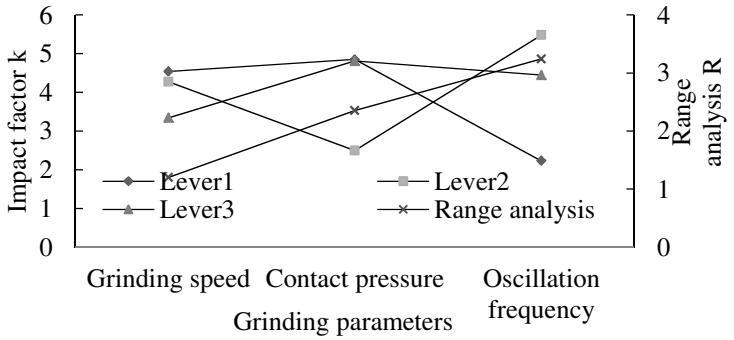

Figure 7 Orthogonal range analysis of surface roughness

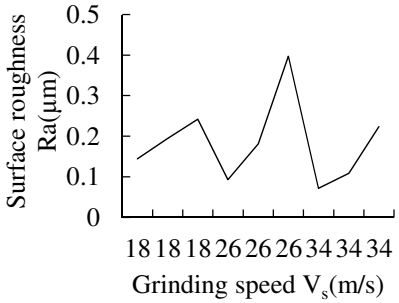

Figure 8 Grinding speed

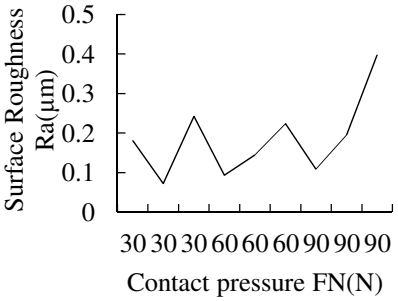

Figure 9 Contact pressure

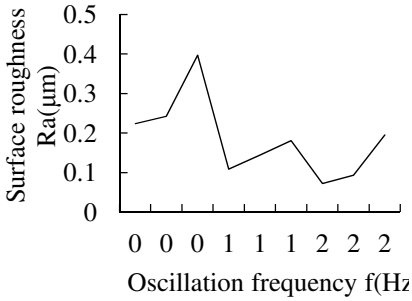

Figure 10 Oscillation frequency

(2) Influence of contact force to the surface roughness

As shown in Figure 9, the surface roughness changed poorly with the increase of contact pressure, the better of surface roughness, combined with range analysis in the Figure 7, the best surface roughness is in the middle grinding speed. This is mainly because, on the one hand, easy to burn in condition of high grinding speed; on the other hand, the grinding zone which cutting into workpiece is increased with the lower grinding speed, so the roughness is poorly. This is because that, the surface roughness is directly to the particle number Ng and the particle shape which participated in the grinding process. The particle number Ng is increased with the increase of contact pressure under lower contact pressure, so the amount of grinding surface roughness decreases uniformly. But under the higher grinding pressure, the surface roughness is increased slowly with the particle fast wear.

(3) Influence of oscillation frequency to the surface roughness

As shown in Figure 10, the surface roughness as oscillation frequency increased, of the rapid rise in. This is because thetransverse vibration of the belt grinding surface grinding trackis complex and is not repeated, i.e. the mesh lines, to reduce the surface roughness.

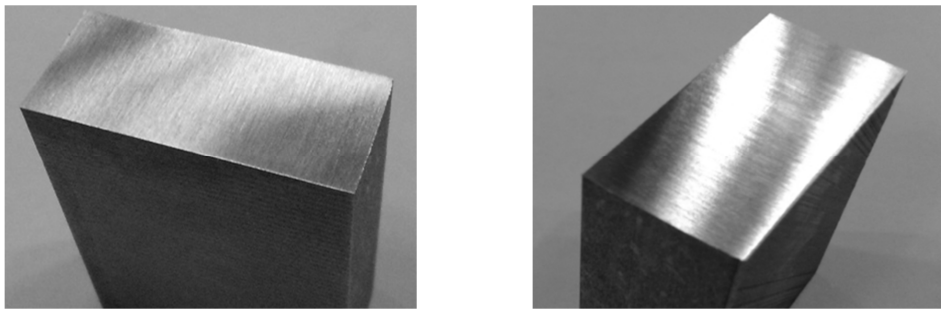

Figure 11 Surface quality of GH4169 nickel-based superalloy after belt grinding

As shown in Figure 11, the surface quality of GH4169 nickel-based superalloy after belt grinding is very good, for the surface quality, surface roughness can reach 0.072μm, more rather than 0.35μm, so it also can confirm the superiority of abrasive belt grinding.

Surface topography: The high precision and material removal processing is achieved through the analysis of the surface topography, combined with the discussion of surface roughness and grinding ratio.

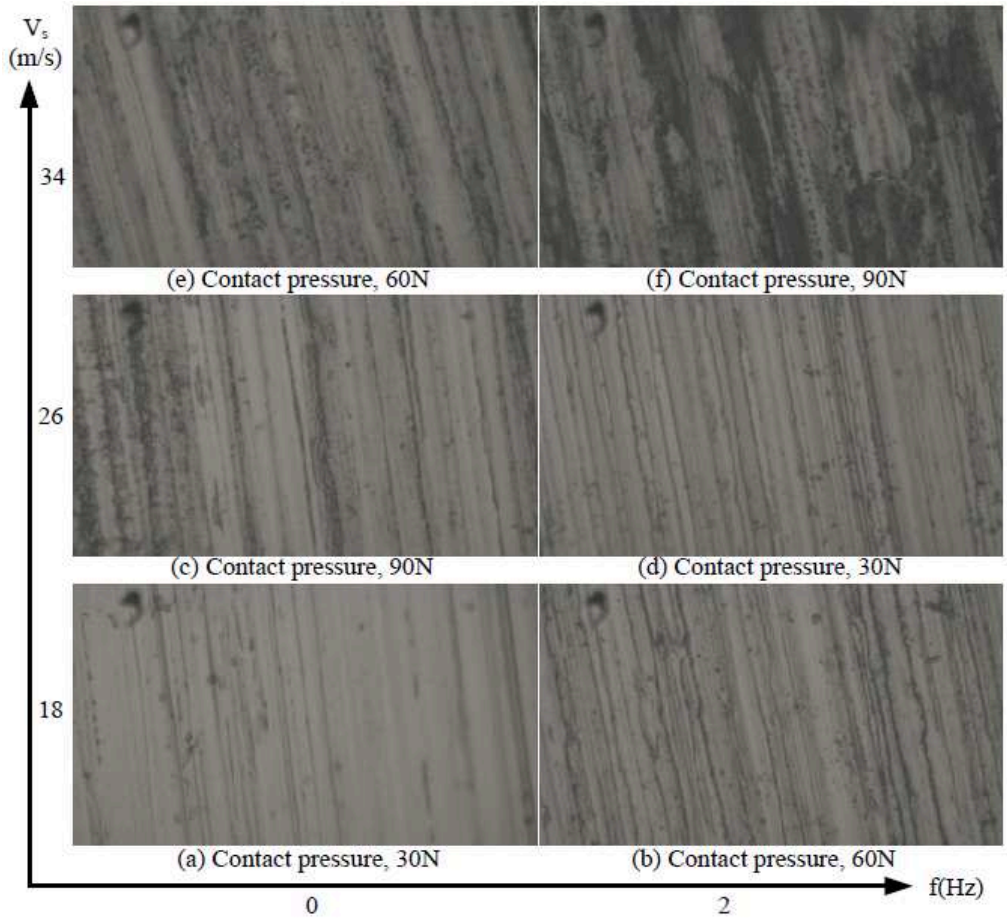

Figure 12 Analysis of surface topography

(1) Influence of grinding speed to the surface topography

As shown in Figure 12(a, d), the grinding depth is improved with the increase of grinding speed, which is useful to remove the surface texture of milling. But As shown in Figure 12(b, e) and (c, f), the grinding depth decreased as the grinding speed is too high, and also having negative effect on material removal, even easily causing workepiece surface burn. The workpiece burn is avoided by increasing the oscillation frequency as the higher grinding speed for the cutting ability to the surface texture of milling, as shown in Figure 12d. This is mainly because, with the increase of grinding speed, the cutting heat and the cutting ability is increased at the same time, and also leading to the temperature of the workpiece surface layer is difficult to dissemination timely, the temperature is distributed by increasing the oscillation frequency, and the high material removal and high precision are obtained. But if the grinding speed is too high, as shown in Figure 12(e, f), the surface is burned very serious.

(2) Influence of contact force to the surface topography

As shown in Figure 12, combining the analysis of grinding ratio, the grinding ratio is wear is relatively large as the higher or lower contact pressure, but the workpiece surface is burned as the contact pressure is too high, as shown in Figure 12(c, f). The high material removal and high precision are obtained by increasing the belt speed and oscillation frequency under low pressure. This is mainly because, the material removal is increased as the contact pressure is too large, but the plastic deformation of the workpiece surface is easy to increased, and then the abrasive belt wear serious, at the same time, the surface of workpiece is burned seriously.

(3) Influence of oscillation frequency to the surface topography

As shown in Figure 12(a, d) and (c, f), the oscillation frequency is improved not only help to improve the material removal, but also can increase the removal ability of milling mark, at the same time ensuring the surface quality.

This is mainly because, with the increase of oscillation frequency, on the one hand, the debris is removed, and the grit removal ability is increased; on the other hand, the temperature is distributed

easily, avoiding the contact pressure is too concentrated, which is resulting in the workpiece surface plastic deformation.

Therefore, in order to achieve efficient, high quality grinding the GH4169 nickel-based superalloy, the lower contact pressure, moderate grinding speed and higher oscillation frequency should be chosen.

Summary

In this paper, the grinding characteristics of the process is optimized by using the technology of abrasive belt grinding, which could reduce the impact of grinding force variation, caused by the plastic deformation. And then reduced the comprehensive effects of the grinding force and temperature, the project of high efficiency and high precision grinding are achieved.

(1) The experiment for the nickel-based superalloy specimen with abrasive belt grinding is carried out by the method of orthogonal experiment, combining with the range analysis, the optimal processes are obtained for the surface integrity: the contact pressure is 30N, the oscillation frequency is 2Hz, the grinding speed is 26m/s.

(2) The regular effect pattern of grinding process parameters to the surface roughness, surface topography and grinding ratio is obtained. The result shows that, in order to obtaining larger material removal and good surface quality, at the same time having lower abrasive belt wear, the lower contact pressure, moderate grinding speed and higher oscillation frequency should be chosen.

(3) The grinding ratio G would reach to 8.8, which much more than the grinding ratio G=1~2 of grinding wheel, by using the method of constant pressure abrasive belt grinding for the nickel-based superalloy GH4169, and the surface quality of GH4169 nickel-based superalloy after belt grinding is very good, for the surface quality, surface roughness can reach 0.072μm, more rather than 0.35μm, it could be concluded that belt grinding might be considered as a viable process for grinding aero-engine components.

Keywords: LF furnace refining process metallurgy's effect.

Abstract: The refining process was investigated, it is the refining process about 100t LF refining furnace of an iron and steel group company, the refining effect was researched and systematic analyzed, by Through systematic sampling and detection to composition, slag, gas and inclusion of different refining period on LF furnace, the measures of process improvement have been proposed, to Optimization of production process and improve the quality of products.

Forewords

A firm has set up a 100t EAF-LF-CC production line, after few years of manufacture, the technology has been stabilized and productivity has been improved. This study is based on that production line, focused on perfect process, develop new product, and bring the ladle furnace refining ability into full play. This experimental program is: using specially made samplers to take slag sample, composition sample, air sample and inclusion sample when the furnace is production same type of steel under a stable working condition; then, take these samples to test and analysis trying to table a proposal of improve production process.

General Technologies

The 100t EAF furnace is using the so called "remaining slag and remaining steel" technology, eccentric bottom tapping and controlling the amount of slag outflow furnace, steel ladles will undergoing precipitation deoxidization and alloying process when the electric furnace is tapping. The ladle furnace is using CaO-Al_2O_3-SiO_2 slag system, major slag making materials are limes and bauxite which will be added separately, approximately 60% of these materials will become bedding material and added into steel ladle,The pre-desulfurization of self-fluxing slag system. The main component of molten slag is listed in Table 1.

TABLE 1 MAJOR CONTENT OF WHIT SLAGS

Slab grade	SiO/ %	Al_2O_3/ %	CaO/ %	MgO/ %	MnO/ %	FeO/ %	R(CaO/SiO_2)
A	16～18	19～23	49～52	3.74～4.86	0.33～0.54	0.36～1.24	2.75～3.16
B	13～18	23～27	49～53	3.91～5.11	0.22～0.48	0.38～2.17	2.76～4.25
C	14～21	21～26	47～53	2.47～5.03	0.33～1.34	0.35～1.24	2.18～3.80

Study of Ladle Furnace's Desulfurization Effet

As showed in reference [1], the desulfurization capacity and rate are influenced by factors such as basicity of slag (R), (FeO) content, quantity of slag, liquidity of molten slag, molten bath temperature and rabbling method. Based on the result of testing samples of this very ladle furnace under normal working condition, major influencing factors are analyzed below.

Desulfurization Capacity of Ladle Furnace's Refined Slag

Desulfurization capacity of molten slag is usually represented by the sulfur content in molten slag divide by sulfur content in molten steel, which is partition coefficient of sulfur (Ls= (%S) / [%S]). Reference [3] indicate that the Ls value could be as high as 235 with a high desulfurization capacity ladle furnace. According to the batch sampling analysis of this study, Ls value of this furnace could be as high as 250, the test result are showed below as Fig.1.

Fig.1 illustrated that Ls value would increase as refining time extend; after it reached 40min, the uptrend would slow down.

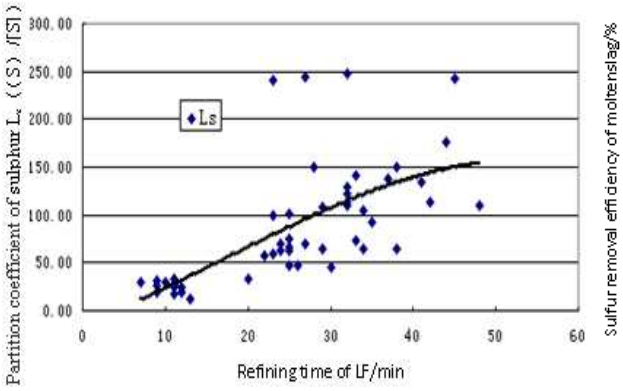

Fig.1 Relationship of refining time and Ls Value

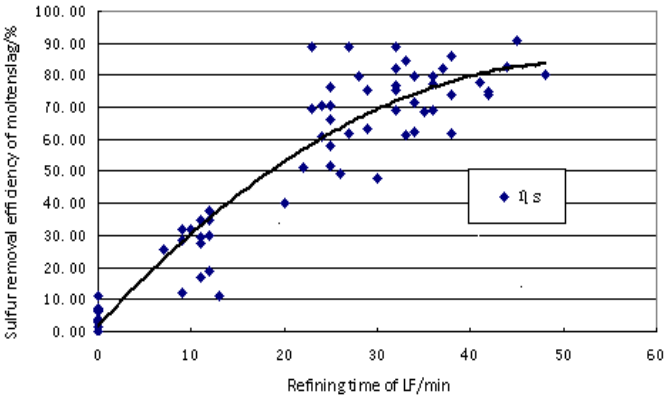

Fig.2 Relationship of refining time and Desulfurization Efficiency of slag

Desulfurization Efficiency

According to this study's batch sample analysis, the Desulfurization efficiency of molten slag during the refining process is showed as Fig.2.

Fig.2 demonstrated that desulfurization efficiency would increase as refining time extend； after it reached 40min, the uptrend would slow down.

According to the experimental result above, the refining time of normal steel types arerecommended to be controlled between 30~40min; the refining time of high grade steels are recommended to be controlled between 40~60min. This paper suggests that these recommendations shouldbe write in to operation instruction.

Influence of Basicity of Ladle Furnace's Slag on Desulfurization

Increasing of free calcium oxide's effective concentration in molten slag would increase the basicity and drive the desulfurization reaction to decrease sulfur concentration. However, basicity isnot higher the better; there is a range for that. According to batch sample analysis, the result is showed as Fig.3.

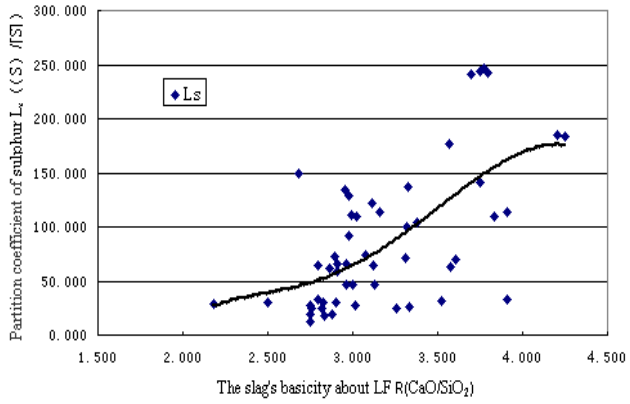

Fig.3 Relationship of slag's basicity and Ls value

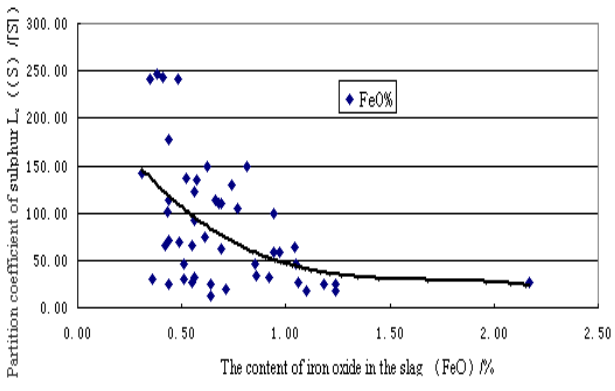

Fig.4 Relationship of (FeO) content and Ls value

What Fig.3 showed is that sulfur's partition coefficient would increase as the slag's basicity increase; it is saying that increase the effective concentration of (Cao) would benefit desulfurization. When the basicity of slag is between 3.5-4.0 desulfurization capacities is highest; after 4.0, the content of (Cao) in slag would slow down molten slag's mobility, in this way slow down the diffusion of (CaS) or (S^{2-}) and then decrease desulfurization. As indicated in Fig.3, the best basicity range of this furnace is 3.5-4.0.

Influence of (FeO) Content in Ladle Furnace's Slag on Desulfurization

According to batch sample analysis, influence of (FeO) content in ladle furnace's slag on desulfurization is showed as Fig.4.

Fig.4 illustrate that (FeO) content in slag is adverse to liquid steel's desulfurization. When the (FeO) content is less than 2.5%, desulfurization capacity of molten slag will increase as (FeO) content drops; especially when (FeO) content is less than 1%, surfer's partition coefficient will rise sharply as (FeO) content drops.

Influence of Ladle Furnace's Refining Time on Desulfurization

Refining time is defined by liquid steel's initial quality, target point and refining technics. All things equal, the rising of sulfur content and reducing of target point will lengthen refining time.

Fig.5 state that when refining time is longer than 40min, sulfur content's dropping trend will slow down in liquid steel, at that time, sulfur content in steel will be less than 0.010%. In commercial steel manufacture S≤0.020% could already meets the requirement, so this paper suggest that refining time for commercial steel could be as short as 30min.

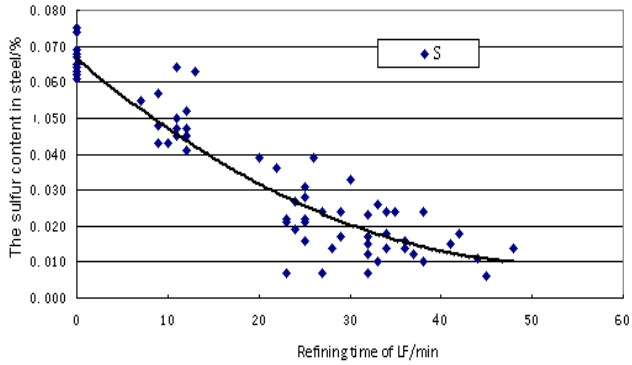

Fig.5 Relationship of refining time and sulfur content in steel

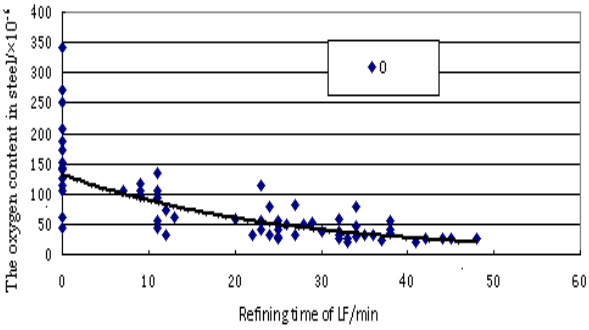

Fig.6 Relationship of refining time and total oxygen content in steel

Influence of Ladle Furnace's Finish Point Week Agitation on Desulfurization

Feed liquid steel with Ca-Si wire (3m/t) at the end point of ladle refining process and conduct argon blowing with week agitation, the argon pressure and rate of flow are controlled to keep the liquid steel sharking slightly but not boiling. Reasonably controlled wire feeding and argon blowing could not only homogenize temperature and contents, but also benefit deoxidization desulfurization and decontamination. According to batch sample analysis, when the argon blowing time is longer than 5min, desulfurization through agitation could result obviously.

Study on Deoxidization Effort of Ladle Furnace

According to batch sample analysis, total oxygen content variation during the refining process is showed as Fig.6.

As what is showed in Fig.6, oxygen content in steel drops as refining time extended; after it reached 40min, the trend of oxygen dropping in steel would
slow down.

Batch sample analysis shows that finish point week agitation would benefit to deoxidization when it last longer than 5min,

According to the result above, ladle furnace's finish point agitation of ladle refining process should be longer than 5min, and it should be listed.

Study on Control Level of Inclusion in Steel

During this study, researchers use fractional electrolytic method to exam bulk sample, steel samples before and after finish point week agitation was tested and inclusion grain was collected and elutriated. Scanning electron microscopy (SEM) and energy analysis of X ray was conducted and results are listed in Table 2.

TABLE 2 BASIC STATUE OF INCLUSL ON GRAIN OF FRACTIONAL ELECTROLYTIC

project	average of before Stirring	average of after stirring	project	average of before Stirring	average of after stirring
Sample weight/g	2352.3	2505.5	100～365μm inclusion heavy / mg	8.9	2.1
residual weight of electrolytic/g	358.8	346.3	50～100μminclusion heavy / mg	1.5	0
Weightlessness of electrolytic/g	1993.5	2159.2	inclusion of 10kg steel/ mg	65.7	12.5
Inclusion heavy of Washing/ mg	13.1	2.7	refining time / min	31.4	39.5
＞365μm inclusion heavy/mg	2.7	0.6			

According to the test result, surface wears of inclusion are majorly irregular, with some spheroid; major content is composite silicon aluminate. As showed in Table 2, inclusion content dropped by 53.2mg/10kg on average after agitation; as the finish point week agitation time of ladle furnace gets longer, the removal rate of inclusion gets higher.

Based on the ladle furnace refining technology research above, conclusions can be concluded as 1) the slag producing system is reasonable; 2) with a 30-40min refining time, sulfur content in steel could reaches 0.010%-0.020%; 3) by applying reasonable finish point week agitation, steel quality could be further improved. So effective agitation time should be longer than 5min; 4) when refining time is longer than 30min, oxygen content in steel could be less than 35×10^{-6}.

Keywords: vanadium-bearing titanomagnetite; ferro-matrix friction material; RE; TiC

Abstract. Ferro-matrix friction material was obtained by in-situ carbothermal reduction from vanadium-bearing titanomagnetite in vacuum environment. The effect of RE addition (0 ~0.3 wt.%) on the microstructure and properties of ferro-matrix friction material was investigated. As a result, compared with the specimen without RE, those with RE has better connection of substrates and smaller pores size. It results the porosity decreases and, the increase of density, micro-hardness and frictional coefficient. When the adding RE is 0.1 wt.%, the connection of substrates is best, that is to say, the pores distribution is most even and pores size is minimum. Meanwhile, the highest density, hardness and frictional coefficient are obtained with 0.1 wt.% RE addition. However, there is little influence on the properties with excessive RE addition. In addition, the morphology of vanadium-titanium carbide varies with different RE addition.

Introduction

As TiC and VC particles are high strength, inoxidizability, corrosion resistance, good wettability with Fe [1] etc., which are the optimal abrasive in ferro-matrix materials. At present, adding pure powder in metallurgy-process is the conventional method to prepare ferro-matrix friction materials, in which mechanical alloying is not taken place. As a result, it makes interface peel and effect the wear resistant. In addition, it will increase the cost of raw material.

Panzhihua vanadium-bearing titanomagnetite contains iron oxide, TiO_2, V_2O_5, SiO_2, $A1_2O_3$, Ni, S, etc. In terms of blast furnace smelting iron, some associated oxides are regarded as impurities. However, the SiO_2, $A1_2O_3$, Ni, S, etc. are the components of the ferro-matrix friction materials. In order to avoid the problem of smelting blast furnace, especially make the best use of Ti and V elements, it is very necessary to explore a new way of using natural mineral as the main primary material to obtain low cost ferro-matrix friction material. In previous studies, our group had obtained general performance ferro-matrix friction material by in-situ carbothermal reduction from vanadium-bearing titanomagnetite in vacuum environment. Recently, the relevant studies on RE in powder metallurgy are widely concerned because RE can accelerate sintering process, grain refinement, solution strength, improve hardness, decrease porosity and regulate carbonization [2-4]. To improve performances of the material, in this study, ferro-matrix friction material was obtained by in-situ carbothermal reduction, and the effect of RE addition (0 ~0.3 wt.%) on the microstructure and properties of the ferro-matrix friction material was investigated.

Experimental

Panzhihua vanadium-bearing titanomagnetite and graphite (+99.85%) powders were used to prepare the reduced powders, which are the main component of the materials investigated in this study. The constituents of vanadium-bearing titanomagnetite show in Table 1. Firstly, the vanadium-bearing titanomagnetite and graphite powders (100: 20.03 wt.%) were mixed in the planet ball mill at 400 r/min for 3 h. Subsequently, according to the thermodynamic analysis in our previous studies [5], the mixed powders were at 1290 ℃ for 3 h in vacuum furnace to reduce vanadium-bearing titanomagnetite. Table 2 lists the chemical compositions of the reduced powders. Secondly, according to the characteristic of ferro-matrix friction material, different proportional powders were prepared as given in Table 3. It is worth nothing that the RE (La and Ce) were added in the form of $FeSiMg_9RE_9$. The addition of graphite powders is not only used as lubricant of the material, but also to further

reduce surplus iron oxide, TiO_2 and V_2O_5 of reduced powders. And Ni can activate sintering in the ferro-matrix alloys [6]. Finally, the powders of materials investigated were mixed in the ball mill at 400 r/min for 0.5 h. After the mixture powders were pressed to green using uniaxial press at 400 MPa, and then sintered at 1250 ℃ for 3 h.

The microstructures and phase distribution of specimens were characterized by optical microscopy and scanning electron microscopy (SEM), which are prepared for porosity testing as the quantitative metallography image processing system [4]. The chemical compositions of phases were determined with an energy dispersive spectrometer (EDS). The density was tested according to Archimedes' method. Vickers hardness testing was conducted on a Micro-hardness Tester with a loading force of 1000 g. At least five tests were carried out on each specimen and the mean values of the results were reported. The frictional coefficient was tested in friction wear testing machine (MM-1000).

Results and Discussion

Influence of RE addition on the microstructures

Figure 1 shows the microstructures of specimens with different RE sintered at 1250 ℃ for 3 h. It can be seen from Fig.1 (a-1) that the as-sintered materials are mainly composed of light gray, gray and black regions. Table 4 lists the EDS result of the regions A, B and C of the specimen with 0.1 wt% RE. The region A (light gray area) contains Fe, Ni, C, Si and O elements, and the mass ratio of Fe to C is 99.24: 0.76. According to the Fe-C phase diagram, the region A (substrate) belongs to the ingredient of hypoeutectoid steel. Therefore, it should contain amounts of pearlites and bits of ferrites, which are necessary for the ferro-matrix friction material. The region B (black area) mainly composes of C element and a small number of Si, O and Fe elements, this region should be lubricant C and a little of abrasive SiO_2. In the region C (gray area), however, all the atomic number of C, Ti, V is about 85%. Because reinforced phase TiC and VC are stable at 1250 ℃, and Ti and V will not react with Mo, Fe and S. So it can be inferred that TiC, VC or $(Ti/V)_XC$ phases exist in the shape "Y" (C region). In the previous study [7], TiC phases generally presented granulate, featheriness, dendrite and clavate, without the shape "Y". Because of the elements of RE (La, Ce) are distributed in the gray area, whereas there are no RE elements in the light gray and black area, as presented in Table 4. This indicates that the shape "Y" may be related to RE addition.

In addition, RE also influences the connection of substrates, which is related to the density of the specimens. Form Fig. 1 (a-1), (b-1), (c-1) and (d), it is seen that the connection of substrates of specimens NO.1, NO.2 and NO.3 is greatly improved. While most of substrates without RE are surrounded by different sizes of holes and graphites. Because the oxidations RE formed under the room temperatureare are hard grains, which will grind and incise other grains during the grinding

process, resulting in rupture of the pre-existing oxidation film. Hence, decreasing the diffusion resistance between atoms in sintering process [8] and providing convenience for heterogeneous nucleation, are beneficial to the homogeneity of structure and the decrease of holes. However, the tendency doesn't increase continuously with the increase of RE. As can be seen from Fig. 1 (a-1), (b-1) and (c-1), the size of holes and graphites increase with the increase of RE addition. Meanwhile, the distribution of substrates with 0.1 wt.% RE addition are more even and the sizes of holes are less. Since MoS_2 resolves into Mo and S after adding excessive RE (0.2 wt.% and 0.3 wt.%) in sintering process, the S easily combines with Fe into FeS, which impedes the connection of substrates. Therefore, moderate RE addition can improve the connection of substrates, whereas the connection is violated with excessive RE addition.

TABLE 4 THE PERCENTAGE OF ATOM CONCENTRATION OF THE SPECIMEN WITH 0.1WT% RE ADDITION (AT.%)

	Fe	Ti	V	C	Ni	Si	Mo	S	O	Ce	La
A Region	84.12	0	0	3.09	6.09	4.24	0	0	2.46	0	0
B Region	8.84	0	0	90.44	0	0.36	0	0	0.36	0	0
C Region	4.38	20.99	4.81	59.25	0	0	8.28	1.62	0	0.10	0.57

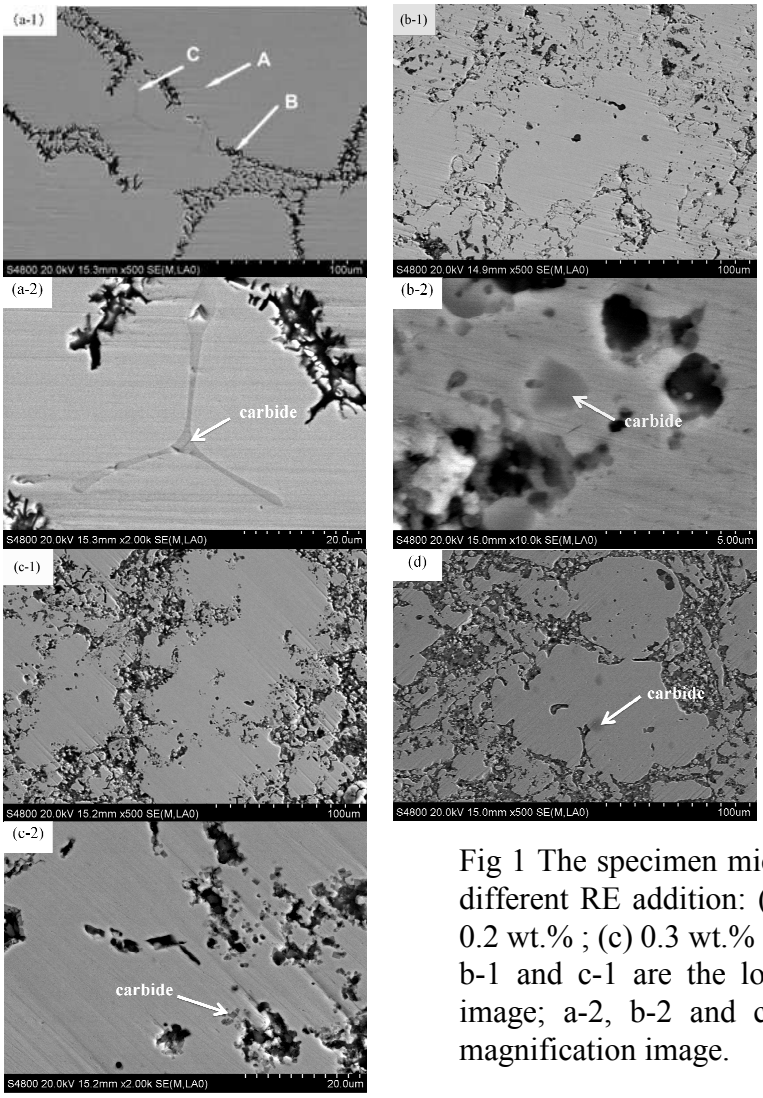

Fig 1 The specimen microstructure with different RE addition: (a) 0.1 wt.%; (b) 0.2 wt.% ; (c) 0.3 wt.% ; (d) 0 wt.%. a-1, b-1 and c-1 are the low magnification image; a-2, b-2 and c-3 are the high magnification image.

Furthermore, with increasing of RE elements (0 ~0.3 wt.%), the shape of the gray area changes from "Spherical particle" to "Y", "approximate spherical particle" and "rectangle particle", which are shown in Fig. 1 (d), (a-2), (b-2) and (c-2). As discussed above, the grey area is mainly composed of

TiC, VC or $(Ti/V)_XC$ and a small number of RE. As it well known, RE can activate and catalyze atomics[9], hence RE could prompt Ti, V and C atomics diffusion greatly during the process of sintering. Moreover, RE also has solid solubility in steel [4, 10]. With the content of RE increases to 0.1 wt%, RE can be completely absorbed in the substrate, strengthen substrates and prompt carbide to form the shape "Y". Whereas, when the adding RE is 0.2 wt.% and 0.3 wt.%, RE can't completely dissolved and the non-dissolved RE makes carbides to form "approximate spherical particle" and "rectangle particle", respectively. So, it can be concluded that the different addition of RE can affect the morphology of carbides in the ferro-matrix friction material.

Effects of RE addition on properties

The density and porosity of the specimens are shown in Fig. 2. It is clear that the densities of all the RE-containing materials are higher than that without RE addition. The density is the highest, when RE addition is 0.1 wt.%. It is known from these results that there is an optimum RE addition, at which the specimen can obtain the highest density. Since when the amount of RE was 0.1 wt.%, RE would completely dissolve in the substrates, improve the connection of substrates and therefore, increase the density of the specimens. In addition, as described in previous study [4], the porosity could affect the micro-hardness and the frictional coefficient of specimens.

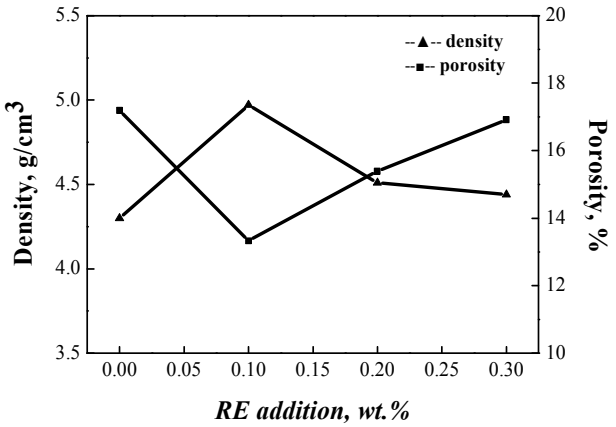

Fig 2 Density and porosity of Ferro-matrix friction material with different RE addition

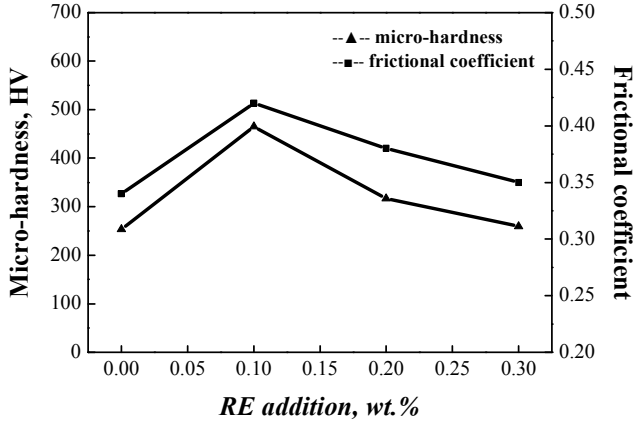

Fig 3 The micro-hardness and frictional coefficient of material with different RE addition

Fig. 3 shows the micro-hardness and average frictional coefficient of the specimens with different RE addition. The micro-hardness and average frictional coefficient of the specimens firstly increased and then decreased with the increase of RE addition. These may be caused by the following reasons: The optimum RE can improve the density and hardness. When the amount of RE was excessive, non-dissolve RE decreases the mechanical performance. Since the MoS_2 could create atomic S combining with Fe to turn into FeS that act as inclusion, which will decrease the specimens frictional coefficient. The morphology of carbides in the gray area is proposed to be a reason for this phenomenon.

Conclusion

(1) RE addition can be beneficial to the connection between the substrates, reduce the size of pores, homogenize the distribution of holes, and improve the properties (density, porosity, micro-hardness and frictional coefficient) of the ferro-matrix friction materials.

(2) The amount of RE addition can affect the morphology of carbides, which change from "Spherical particle" to "Y", "approximate spherical particle", and "rectangle particle" with the increase of RE addition.

(3) When the addition of RE is 0.1 wt.%, the density, hardness and frictional coefficient of specimens improve obviously and the percentage of pores decreases.

Keywords: 6Cr6W2MoV steel, The Mo and V contents, Ultra-fine carbide, transformation, Carbide composing, Secondary hardening, Tempering hardness, Temperature decentralization

Abstract. The influence of Mo and V contents on the microstructure and secondary hardening of 6Cr6W2MoV steel was studied in this paper, and the process factors and the transformation mechanism of the influence results were discussed by phase equilibrium thermodynamic analysis. The results show that, the microstructure of 6Cr6W2MoV steel is uniform and thin, in which the undissolved carbide size after quenching is 0.23μm. In the heating and cooling process of the annealing, the dissolution and precipitation of $M_{23}C_6 \leftrightarrow M_6C$ carbides transformation can be used to carbides distributing uniform refinement. Adding an overmany Mo content will lead to coarsening of carbide particles due to small amplitude of $M_{23}C_6 \leftrightarrow M_6C$ transformation. Adding an overmany V content will appear a small of the bulk MC carbide on the crystallization, so the heterogeneity of carbides is increasing. The tempering hardness of 6Cr6W2MoV steel is 63.5HRC, and when adding an overmany Mo content the maximal hardness arrives to 65HRC. Adding Mo changes the carbide composing, it is conducive to the variety of carbides precipitation strengthening near intermediate temperature and the tempering hardness increasing. When adding an overmany V content the more MC carbide well occupy more amount of C, the tempering temperature dispersion increases too, so the tempering hardness debases deservedly and the highest hardness only reaches HRC60.5.

Introduction

A kind of high alloy tool steel 6Cr6W2MoV was successfully developed according to alloy design calculation and experiment result, which is applicable to an edge steel of machinery knives by hot roll-jointing[1]. The microstructure of 6Cr6W2MoV steel is uniform and thin, in which the undissolved carbide size after quenching is less than 0.35μm having ultra-fine characteristic. Although the contents of C and alloy elements in the steel are opposite lowly, also that steel is capable of having high tempering hardniss HRC62-64 and has good rolling welding performance at high temperature, and is suitable for manufacturing the machinery knife by hot roll-jointing. This machinery knife has be obtained Chinese invention patent, which is applies to the slicer cutting pretty good and same as the rotary cutting better for wood working[1,2].The alloy design of the high alloy tool steel as edge steel of machinery knives is mainly using the phase equilibrium thermodynamic method to solve the relationship between carbide refinement and tempered high hardness and the steel composition[3]. And at the same time, the effect of several elements on carbide refining and secondary hardening also was studied with the experimental method. This paper was report the experimental results of the effect of Mo and V contents on the microstructure and secondary hardening, and the process factors and the phase transformation mechanism of the influence results were discussed.

Experimental Materials and Method

The chemical composition of 6Cr6W2MoV high alloy tool steel by alloy design calculation was listed in Table 1, thereinto the Mo and V contents are 1.4/1.7 and 0.4/0.5 respectively. The chemical composition of three experimental steels was listed in Table 2, in which the composition of 6S1 steel

is agreement with composition of 6Cr6W2MoV steel, but the Mo and V contents of 6S2 and 6S3 steels are evidently deviated from the contens of alloy design in order to their experimental results against that of 6S1 steel easily. The Mo content in 6S2 steel is 4.23 and the Mo and V contents in 6S3 steel are 0.87 and 1.65 respectively. The Si and Mn contents in 6S2 steel and the Si content in 6S3 steel are lower than that of alloy design composition, but the effect of their change on carbide transformation and secondary hardening of 6Cr6W2MoV steel is too tinier[3].

Table 1 The composition of 6Cr6W2MoV steel by alloy design calculation(*wt%*)

C	Si	Mn	Cr	W	Mo	V	NiCo
0.52/0.62	0.4/0.6	0.25/0.5	5.2/6.2	2.2/2.7	1.4/1.7	0.4/0.5	0.18/0.3

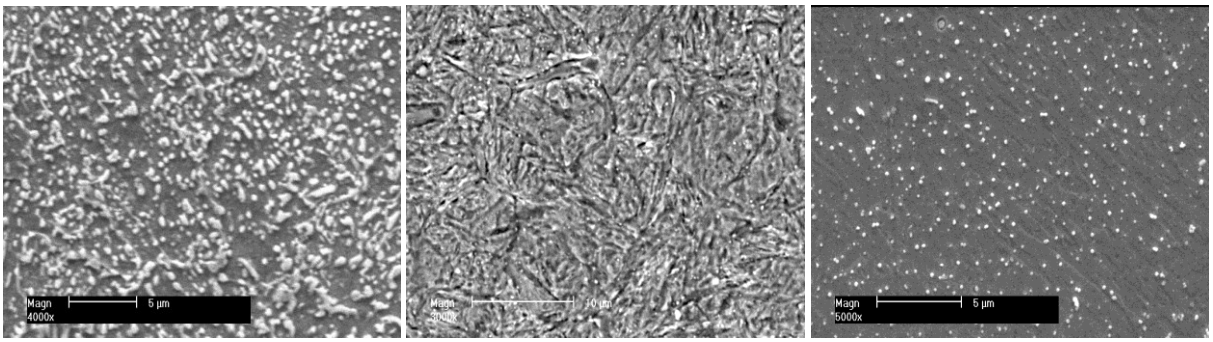

Table 2 Chemical composition of experimental steels (wt.%)

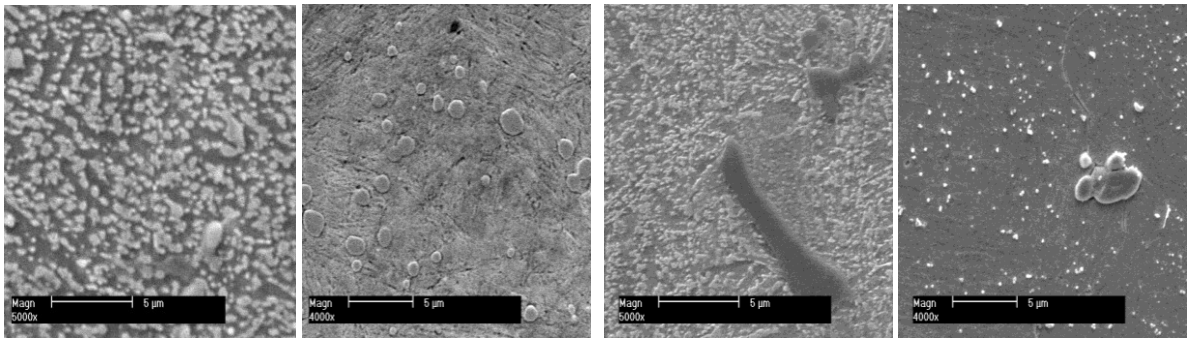
	C	Si	Mn	Cr	W	Mo	V	Ni
6S1	0.58	0.60	0.50	5.45	2.25	1.52	0.50	0.20
6S2	0.61	0.18	0.30	6.22	2.36	4.23	0.47	0.27
6S3	0.62	0.36	0.40	6.22	2.35	0.87	1.65	0.21

Experimental materials were melted in 0.5t variable frequency induction furnace adding electro-dregs remelting furnace. After forging and rolling, the steels were processed to 58mm ×11 mm×11 mm samples by incision machining. The heat treatment was investigated using KSJ-5kw electric furnace, and tempering holding time is 2.5h×2. The hardness was mensurated using 150DT-HR sclerometer, and an average value of the hardness was accounted adopting six testing points or more. The microstructure was investigated using scanning electron microscope XL30.

The Experimental Results

Microstructure The microstructure of 6S1 steel is shown in fig.1. Fig.1(a) for the microstructure of 6S1 steel annealing at 840℃the carbide particle uniformly refined, its size is mainly distributed in a range of 0.2~0.8μm almost no massive primary granular carbide. Fig.1(b) for the microstructure of 1050℃quenching of 6S1 steel the dislocation and twin martensites formed in grain each about 10μm, in which a little of very finely granular carbides distributed uniformly. Fig.1(c) for the microstructure of 6S1 steel tempered at 540℃after quenching at 1050℃the average size of uniform and fine carbide particle is 0.23μm amounting to volume fraction of～3%.



(a) (b) (c)

Fig.1 The microstructure of 6S1 steel
(a) annealed at 840℃, (b) quenched at 1050℃, (c) tempered at 540℃

Fig.2 is the microstructure of 6S2 steel, and fig.3 is the microstructure of 6S3 steel. Fig.2 shows the distribution of the annealing carbide size of 6S2 is uniform in between 0.5～2μm (Fig.2a), the quenching undissolved carbide distribution size is between 0.5～1.5μm amounting to volume fraction of ~ 4% (Fig. 2b). From Fig.3 can be seen, annealing carbide distribution of 6S3 steel is not uniform, the size of a lot of fine carbide uniform distribution is between 0.2～0.5μm, but also the size

of a small decentral of bulk primary carbide is between 2～5μm and individually or even more than 10μm(Fig.3a). The undissolved carbide distribution after quenching is not homogeneous thereinto the fine carbide size 0.2～0.5μm and inside the big size of individual ~5μm(Fig.3b).

Fig.3 The microstructure of 6S3 steel (a) annealed at 840℃, (b) quenched at 1100℃

Secondary Hardening The tempering hardness curves of secondary hardening of three experimental steels are shown in Fig.4. Fig.4a shows, the highest hardness during tempering secondary hardening of 6S1 steel is HRC62~ 63.5, and the tempering temperature is corresponding to 520～540℃ and the tempering hardness decreases sharply over 550℃. Fig.4b shows, the highest hardness during tempering secondary hardening of 6S2 steel containing high Mo content is HRC63~65, the tempering temperature is corresponding to 520～550℃ and tempering hardness decreases sharply over 560℃. Fig.4c shows, the highest hardness during tempering secondary hardening of 6S3 steel containing high V content is only HRC59.5~60.5, and with increasing of quenching temperature the tempering temperature corresponding to the highest hardness increases as well. For example, the tempering temperature of highest hardness HRC60 corresponding to quenching temperature at 1100℃ is 520℃, and the tempering hardness decreased sharply over 540℃. The tempering temperature of highest hardness HRC60.5 corresponding to quenching temperature at 1120℃ is 540℃, and the tempering hardness decreased sharply over 550℃.

Analysis and Discussion

Carbide Transformation and Morphology Fig.5 is the equilibrium phase diagram with temperature changes calculated according to the experimental steels. Fig.5a shows, $M_{23}C_6 \leftrightarrow M_6C$ transformation of the heating and cooling process during annealing of 6S1 steel happens substantially, the dissolution and precipitation process for carbides distributing newly lead to uniform refinement[5,6]. The quenching residual carbides are M_6C and MC, and the M_6C in quenching heating process is refined sequentially and the MC after hot working and heat treatment essential is more refinement, therefore, the residual carbide of 6S1 steel quenched is ultra-fine[7]. Moreover, the

initial precipitation of MC begins from lower temperature (< 1100 ℃) during melting solidification, it is difficult to occur in the early stage of MC crystallization and blocky carbide also is eliminated. Fig.5b shows, there is more M_6C in 6S2 steel containing overmany Mo content, and the amplitude of $M_{23}C_6 \leftrightarrow M_6C$ transformation during heating and cooling process of annealing is smaller, therefore, annealing carbide size is large, and in the quenching process the first solution of carbides is $M_{23}C_6$, the larger size of undissolved M_6C still is retained. Fig.5c shows, there is more MC in 6S3 steel containing an overmany V content, and the amplitude of $M_{23}C_6 \leftrightarrow M_6C$ transformation during heating and cooling process of annealing also is greater, therefore, the size of most carbides is very small but the size of a small amount of bulk MC still is very big. In the quenching process the undissolved M_6C and the original fine MC further will be refined, but the larger size of a small amount of bulk MC still is retained although after heating partial dissolution. The bulk MC carbide is occurred at the beginning crystallization of melting solidification. Although MC precipitation start temperature is in the solid region by equilibrium phase diagram but at higher temperature (1230℃), consequently, when adding V iron during melting process at lower temperature in order to reducing the loss rate of melting, the partial segregation can lead to its crystallization in early.

(a) 6S1 (b) 6S2 (c) 6S3

Fig.5 Equilibrium phase diagram with changing temperature

Precipitation Hardening and Tempering Hardness Tempering carbide appeared the metastable phase (M_2C, M_3C), and some stable phase does not appear, this is because of the phase transformation process of hysteretic transition of retained austenite to delay in sectional martensite decomposition[8]. Although the precipitation hardening process is very complicated, but the calculation of stable phase M_6C, $M_{23}C_6$ and MC in 500℃～600℃ has certain universality of review value. And the tempering temperature of highest hardness can be estimated according to phase ratio of mass fractions of the carbides equilibrium at tempering temperature[4]. The highest tempering hardness and tempering temperature are relational to the carbide type and number of the corresponding precipitation strengthening. In a nutshell, when relatively more $M_{23}C_6$ (or M_7C_3) the tempering temperature is lower of 480℃~520℃, and when relatively more M_6C it is moderate in the tempering temperature of 520℃~540℃, and when relatively more MC the tempering temperature is high at 540℃~560℃[4]. Obviously, the separating out amount of some carbide in the precipitation hardening temperature is more, the ability of precipitation hardening is stronger. If the temperatures of all sorts of carbides precipitation hardening are close to tempering temperature, the highest hardness will be higher, and when the more dispersed precipitation hardening the highest tempering hardness will be lower. In addition, research has shown that the alloy elements in steel can alter the precipitation temperature and speed of carbide precipitation[9]. Can reasoning, carbide composing also can affect on the precipitation temperature and precipitation velocity, and also will affect on the highest tempering hardness and tempering temperature.

Table 3 is the carbides composing and mole number of equilibrium carbides according to the calculation of experimental steels. Can be seen from table 3, the adding Mo modified the carbides composing, and the ratio of Mo content in $M_{23}C_6$ of three experimental steel is very high, thereinto, the Mo content in $M_{23}C_6$ carbide of 6S2 steel containing most high Mo reached 18.5%. Furthermore,

the ratio of Mo content in the MC and M_6C is higher, and the ratio is respectively 10.5% and 8.92% in 6S2 and 6S1 steel, thus it is conducive to precipitation strengthening of all kinds of carbide close to the middle temperature. On the other hand, when adding appropriate ratio of W and Mo is of result in a large number of Mo into the M_6C, the Mo content in M_6C of 6S2 steel reached 38% and the relative ratio of M_6C in the steel as well as increased, and then it is conducive to the precipitation focus at intermediate temperature, which can be see from difference values(D-value) of mole fraction at 540℃ and that at quenching temperature. Therefore, the tempering hardness of 6S2 steel is highest and as well as the tempering hardness of 6S1 steel also is higher. Nevertheless, the more MC amount as very high V content of 6S3 steel can occupy the more amount of C, and so it is reducing amount of $M_{23}C_6$ and M_6C. And more MC increases the tempering temperature and leads to disperse temperatures of the precipitation strengthening, therefore, the highest tempering hardness during secondary hardening of 6S3 is lower as well.

Table 3 Carbide composing(wt%)and mole number (%)by equilibrium phase of experimental steels

	Type	Carbide composing at 540℃						Mole 540℃	Quenching (℃)	Quenching mole	D-value of mole
		C	Fe	Cr	W	Mo	V				
6S1	MC	15.2	0.01	0.77	9.81	8.92	65.2	1.02	1040	0.42	0.60
	M_6C	1.92	27.4	2.63	60.9	6.05	0.83	1.78		1.05	0.73
	$M_{23}C_6$	5.04	25.5	49.2	3.69	14.8	0.03	9.37		0	9.37
6S2	MC	15.5	0.01	0.43	3.05	10.5	70.5	0.78	1120	0	0.78
	M_6C	2.16	23.3	3.82	31.7	38.0	0.82	4.78		2.48	2.30
	$M_{23}C_6$	5.08	19.4	55.1	0.95	18.5	0.05	8.93		0	8.93
6S3	MC	15.8	0.01	0.54	5.01	2.28	76.4	2.92	1100	2.11	0.81
	M_6C	1.93	27.6	3.13	62.3	2.62	2.34	1.74		0	1.74
	$M_{23}C_6$	5.09	16.0	59.8	4.58	13.1	0.11	6.11		0	6.11

According to the quenching austenite matrix composition of the steel, can be used to calculate the highest hardness of secondary hardening[4]. Actually, the stable carbides at tempering temperature are $M_{23}C_6$, M_6C and MC carbides basically, thus the balanced carbon formula of matrix can be writed as

$$C_p = 0.011W + 0.02Mo + 0.057Cr + 0.19V \quad (1)$$

here the coefficients are carbon contents of W_6C, Mo_6C, $Cr_{23}C_6$ and VC carbides respectively, and alloy elements are from the matrix composition. The saturation level of carbon Cs in the matrix is C_s/C_p, the tempering hardness value can be obtained from

$$H_S = a(1+b)/(0.0127a + 0.00297k) \quad (2)$$

in which a is the square root of the saturation level of carbon in the matrix, and k is temperature decentralization coefficient and takes 1～1.2, and carbide precipitation correction factor b is as

$$b = 0.00374(Cr-6.6877) + 0.00907(W-2.7554) + 0.01521(Mo-1.3777) + 0.04194(V-0.5961) \quad (3)$$

Table 4 shows the calculational value and the testing result of the hardness of experimental steels, and the calculational results are agreement with testing values.

Table 4 Calculation value and testing result of tempering hardness of experimental steels

	Quench T/℃	Matrix composition(*wt%*)					Calcul-parameter			Calculat /HRC	Testing /HRC
		C	Cr	W	Mo	V	a	$1+b$	k		
6S1	1050	0.515	5.47	1.63	1.25	0.32	1.1121	0.972	1	63.24	63.5
6S2	1140	0.552	6.28	1.58	3.38	0.42	1.0262	1.011	1	64.84	64.9
6S3	1120	0.420	6.20	2.17	0.79	0.82	0.8740	0.993	1.1	60.43	60.5

Conclusion

(1) The microstructure of 6Cr6W2MoV steel is uniform and thin, in which the undissolved carbide size after quenching is 0.23μm. An overmany Mo content will lead to coarsening of carbide particles, and An overmany V content will lead to appear a small of the bulk MC carbide during the crystallizing process, so the heterogeneity of carbides is increasing.

(2) The tempering hardness of 6Cr6W2MoV steel is 63.5HRC and the maximal hardness arrives to 65HRC when an added high Mo content. Whereas, the tempering hardness is decreasing when adding an overmany V content and the maximal hardness arrives barely to 60.5HRC.

(3) When adding an overmany Mo content the M_6C carbide amount is biggish and the range of $M_{23}C_6 \leftrightarrow M_6C$ transformation is less, so the carbide size becomes bigger. When adding a overmany V content, there is being very big MC carbide during crystallizing process after steel melting, so the asymmetric distribution well became badly as inequality of size of carbide particles.

(4) The reason of high tempering hardness is due to the temperature convergence of precipitation strengthening and the amount increasing of carbide precipitation as a result of the change of various carbides composing of the steels containing Mo. When adding an overmany V content the more MC carbide well occupy more amount of C, the tempering temperature dispersion increases too, so the tempering hardness debases deservedly.

Abstract:A cladding layer of Ni_3Al matrix composite reinforced with 18 vol. % Cr-carbides was applied by using tungsten inert gas (TIG) welding process on high strength steel substrate. The filler metal as welding wire prepared by horizontal continuous casting process with a composition of Ni-2.5C-30Cr-9Al-0.02B (in wt. %) is used. A bulk material of NAC-alloy composite with 18 vol. % Cr_3C_2-particles produced by Hot Isostatic Pressing (HIP) was also investigated as a reference material. The composition of NAC-alloy is Ni-9.87Al-11.63Fe-0.50Mn-0.50Ti-0.2B in weight percentage. The pin-on-disk (POD) tribometer tests were carried out at room temperature in dry sliding condition at a pressure of 2.83 MPa (20N). The results revealed that Ni_3Al/ Cr-carbides cladded layer by TIG process improved wear properties significantly with very low values of the friction coefficient (0.13 ± 0.02) and the specific wear rate (0.162 x 10^{-5} $mm^3/N{\cdot}m$) as compared to the reference HIP processed composite with the friction coefficient (0.68 ± 0.02) and the specific wear rate (0.908 x10^{-5} $mm^3/N{\cdot}m$) under the same testing conditions.

Introduction

High-temperature wear-resistant intermetallic materials have attracted recently material researchers' attention, especially the Ni_3Al-based materials. Ni_3Al-based alloys exhibit increased yield strength with increase of temperature to about 650-750 ºC, which made them an attractive engineering materials with good wear resistance. Due to these properties, Ni_3Al-based alloys have significant potential in wear critical applications at temperature range between 400 ºC and 650 ºC [1-6]. Intermetallic matrix composites (IMC) with hard particles reinforcements are considered for wear applications in severe, i.e. chemically aggressive environments. For instance, chromium carbide reinforced Ni_3Al matrix composite was developed as candidate wear resistant material under elevated temperatures [7]. Chromium carbides have very high hardness and good wetting ability with the Ni_3Al matrix, and also excellent oxidation resistance [8]. Karin et al. [9] illustrated that the addition of 6 vol. % Cr_3C_2 particles reduced wear rates of the pin and the disk up to 50 %. Clearly, the characteristics of worn surfaces were recognized that the hard Cr_3C_2-asperities supported a couple of sliding surfaces apart during the sliding wear process, then reduced the specific wear rates of the pin and the disk. A surface modification by forming wear resistant layer on steel substrate is a useful technical method to produce components to resist against wear damages under severe wear condition. Therefore, chromium carbides reinforced Ni_3Al composite cladded layer produced by tungsten inert gas (TIG) welding process was investigated in this study. A HIP processed bulk material of NAC-alloy composite with 18 vol. % Cr_3C_2-particles was also investigated as a reference material.

Experimental Methods and Results

Testing Materials and Preparation

The chemical composition of the steel substrate is Fe-0.35C-24Cr-8.5Ni-1.6Si-1.2Mn-0.24N-0.25Re in weight percentage. The welding wire with composition of Ni-2.5C-30Cr-9Al-0.02B in weight percentage was used for TIG welding process, which was prepared by means of horizontal continuous casting process. A vermicular graphite cast iron, a monolithic NAC-alloy and its composites prepared by HIP process were selected as reference materials. The vermicular graphite cast iron is usually used as piston ring material in engines. A grey cast iron was applied as counterpart disk material for tribo-test in this study. The designation of the tested samples is summarized in Table 1.

TABLE 1 DESIGNATIONS OF THE TESTED SAMPLES

Designation	Composition (wt. %)	Process
Pin 1	Ni-2.5 C-30 Cr-9Al-0.02 B	TIG
Pin 2	Ni-9.87Al-11.63Fe-0.50Mn-0.50Ti-0.2B +18 vol.% Cr3C2	HIP
Pin 3	Ni-9.87Al-11.63Fe-0.50Mn-0.50Ti-0.2B	HIP
Pin 4	Fe-3.05C-1.20Si-0.85Mn-0.10±0.05P-0.05S-0.65±0.05Mo-0.9±0.05Cu-0.02V-0.03Ti	as-cast
Disk	Fe-3.20C-1.1Si-0.8Mn-0.2P-0.1S-0.02B-1.0Cu-0.22V	as-cast

During the TIG welding process, it was assumed that all of the C-content in the welding wire reacted with Cr and formed chromium carbides. Afterwards residual Cr-content ~11 wt. % will be dissolved in the Ni_3Al alloy matrix and formed Cr-rich Ni_3Al phase. By taking the densities of the Ni_3Al-matrix and chromium carbides as 7.25 g/cm^3 and 6.68 g/cm^3 from the previous study into consideration, the volume percentage of Cr-carbides formed in the welding wire alloy was calculated ~ 18 vol.%. Therefore, 18 vol. % Cr_3C_2-particles were added to obtain HIP processed bulk Ni_3Al-matrix composite and selected as reference material for studying the influence of the microstructure on tribological behavior. Table 2 showed three different welding parameters were applied in TIG process.

TABLE 2 WELDING PARAMETERS IN TIG PROCESS

	Voltage [V]	Current [A]	Argon flow rates [L/min]	Welding speed [mm/s]	Cooling
1#	10～12	50	8	0.4	air
2#	10～12	70	10	0.8	air
3#	10～12	90	10	0.8	air

Fig. 1 Top Views of the Cladded Layer Prepared by Three Different TIG Process Parameters

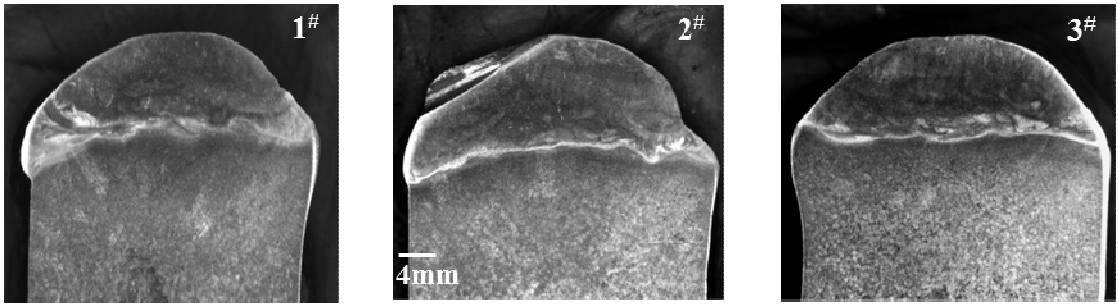

Fig. 2 Cross-section Photographs of the Cladded Layers for Three Different TIG Process Parameters

Figure 1 and Figure 2 show that each cladding area formed is about 80 mm x 40 mm and the thickness of each cladded layer is around 8 mm. The cladded layer of the number 2# shows a uniform thickness (Fig 1b) which was produced with stable TIG process parameters. So the welding parameter of the number 2# was selected to prepare a qualified cladding layer for tribo-test investigation. Two intermetallic reference materials of NAC-alloy and its composite were produced by HIP process. The powders of NAC-alloy for HIP process were prepared by using Plasma Rotating Electrode Process (PREP). The PREP system was evacuated to 0.1 bars to minimize oxidation of the powders formed. The chamber was then filled with argon to attain a clean atmosphere. The electrode rod of the master NAC-alloy is accelerated up to the desired speed of rotation, 14500±500 rpm. An argon plasma arc is then ignited and the plasma jet melts tip of the rotating rod. A fusion film is formed on the front end of rod, which disintegrates into small liquid metal droplets as a consequence of action of centrifugal force. Due to surface tension effects and enough time for spheroidisation, the droplets are spherical. On their trajectories towards the chamber wall, the droplets solidify rapidly in the inert atmosphere and form spherical solid particles. The powder sizes of NAC-alloy and Cr_3C_2 particles applied for HIP processed are in a range of 45µm-120µm, respectively. The density of NAC-alloy and Cr_3C_2 particles used for calculating volume composition of the composites are 7.25 g/cm^3 and 6.68 g/cm^3, respectively. The HIP process data are 1130 -1160 °C as heating temperature under 140 MPa for 3 hours. Dimension of the HIP processed material is Φ70 mm x 150 mm.

Characterization of the Cladded Layer

Chemical analysis of the cladded layer shows Ni-2.33C-29.50Cr-7.46Al -7.99Fe (in wt. %) composition. Comparing to the initial composition of the welding wire Ni-2.5C-30Cr-9Al-0.02B (wt. %), the cladded layer clearly shows less contents of Ni, Al, Cr and C elements, but higher Fe content. Cladding process may result in loss of C and Al by oxidation [7]. It is obvious that the content deviations of Cr and Fe were initiated due to dilution during welding process.

The cladded layer was analyzed by means of Holland Panalytical X'per Pro MPD X-ray diffraction spectrometer to identify phase constitution of the material. The Cu-Kα X-ray radiation with wavelength of 1.5406Å was used to get the diffraction patterns. The XRD pattern (Figure 3) reveals that there are four phases existed in the cladded layer which is Ni_3Al- NiAl-, M_3C_2-, and M_7C_3-types.

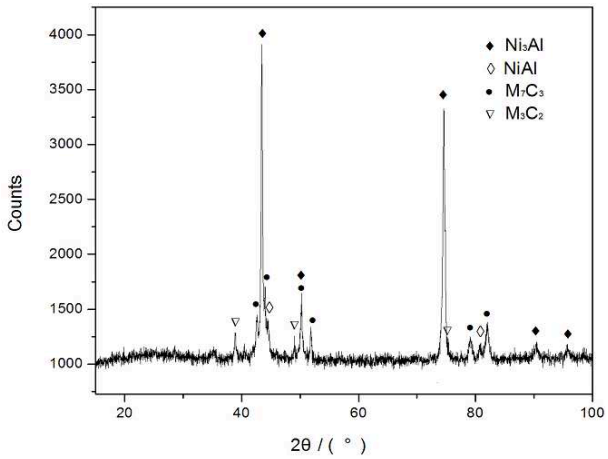

Fig. 3 XRD-spectrum of the Cladded Layer Prepared by Parameter of the Number 2#

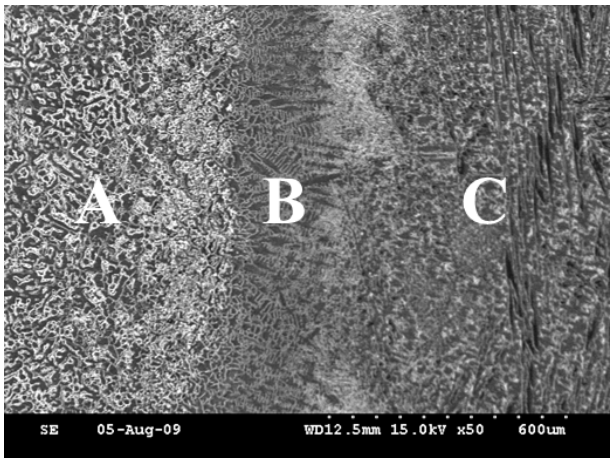

Fig.4 BEI from a Cross-section of the Cladded Layer on (A) Based Material, (B) Fusion Layer and (C) Welding Material

A scanning electron microscope (SEM) equipped with energy dispersive spectrometer (EDS) was utilized to evaluate quality of the testing sample and perform the microstructure analysis. Figure 4 is a backscattering electron image (BEI) from a cross-section of the cladded layer. Three different morphology zones were observed which are based material (A), fusion layer (B) and welding material (C). Furthermore, a good metallurgical bonding can also be observed in the microstructure.

Figure 5 (a) and (b) show backscattering electron images of the HIP processed Ni_3Al/Cr_3C_2 composite and the cladding layer, respectively. It is clearly observed that the morphology of the carbides in these two microstructures is diverse.

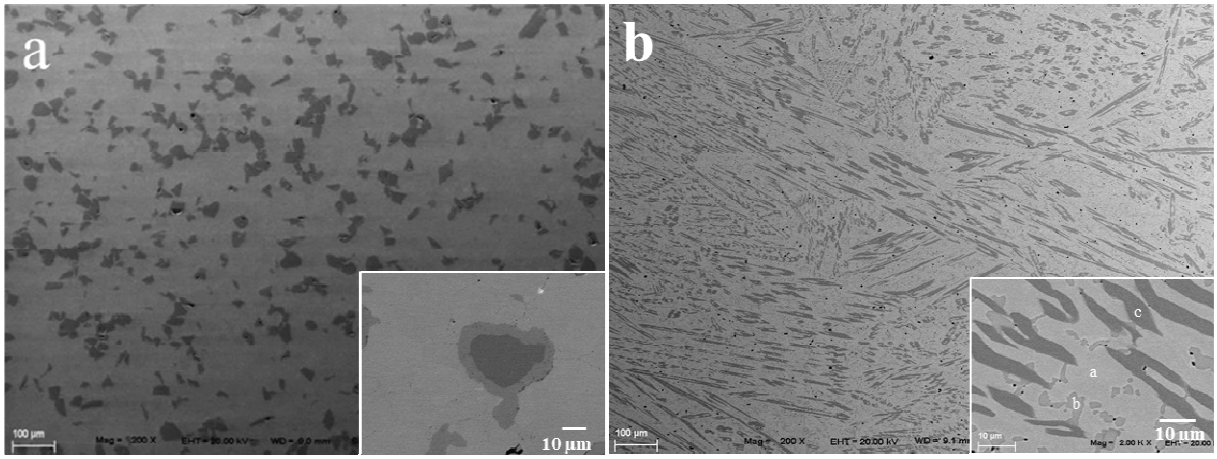

Fig. 5 BEI of (a) HIP Ni_3Al/Cr_3C_2 Composite from Pin 2 and (b) the Cladded Layer from Pin1.

The Cr_3C_2-particles in the HIP bulk composite reacted with Ni_3Al-matrix and formed a good metallurgical bonding with a light grayish boundary area as shown in the inset Figure 5a. From our previous study [10], EDS analysis revealed that the grey reaction zones have higher content of Cr as compared to the matrix, but lower Ni- and Fe-contents. This reaction zone is formed due to the diffusion process during HIP process. The composition of the matrix was same as the Ni_3Al-based alloy. Figure 5b is a backscattering electron image of the cladded layer and the inset figure shows three different phases which were identified by EDS analysis as Ni_3Al-, NiAl-phases and carbides represented by a, b and c respectively. The in-situ formed carbides (Figure 5b) are distributed in the Ni_3Al-matrix with as lamella-like carbides. A secondary phase was also formed in the specimen and the Al content (25.09 at. %) in this secondary phase was much higher than the Al content (12.44 at. %) of the matrix. Fe-content was detected as 14.55 at. % in the matrix and 8.80 at. % in the secondary phase. The Cr content in Ni_3Al-matrix and NiAl-phase were also recorded as 16.52 at. % and 7.01 at. % , respectively. Considering Fe- and Cr-elements with equivalent opportunity to replace Ni- and Al- position in crystals of Ni_3Al and NiAl, the matrix should be specified as Ni_3Al-phase, and the secondary phase as NiAl-type. The reason to form NiAl phase in the cladded layer is due to fast cooling rate during the TIG process, resulting in the non-equilibrium microstructure. The results from the analytical study can be coupled to the experimental data of tribological tests for understanding and evaluating wear behavior of the studied materials.

Hardness Measurement

Vickers hardness on the cross section of cladded layer was measured by using FM-300; the results were referred to a Chinese standard of GB/T 4340.1-1999. The applied load was 200 g and loading time was 10 seconds. The measurement was applied on three different areas along the cross section of the cladded sample; they are the regions of Welding materials (WM), Fusion layer (FL) and Based materials (BM), see Figure.6 and also referred to Figure.4. In the middle of fusion layer, a central line was selected as an initial position for performing indentation. Therefore, the measured indentations were perpendicular from the central fusion layer (FL) towards the WM and BM. The collected data from two tested specimens $2^{\#}$ and $3^{\#}$ were summarized in Fig.6.

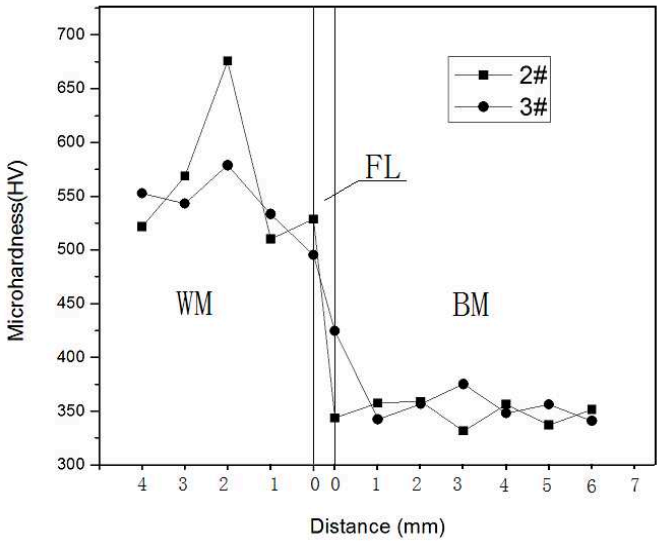

Fig.6 Vickers Hardness Profile on the Cross-section of Two Tested Cladding Layers.

Vickers hardness measurement was also applied on the reference bulk materials and the disk which were used in this investigation. In order to obtain the hardness measurements statistically, 10 indentations on each tested sample were performed. And then, the average Vickers hardness of the tested samples were obtained and listed in table 3.

TABLE 3 MICROHARDNESS OF THE TESTED SAMPLES

Tested samples	Pin 1	Pin 2	Pin 3	Pin 4	disk
HV200	558	560	420	240	237

Hardness results reveal that carbide addition obviously increased hardness of Pin1 and Pin2, as compared to the monolithic Ni_3Al-based alloy Pin3. But, the composites of Pin1 and Pin2 which were reinforced by the same volume percentage of carbide addition exhibited the same average hardness, even though Pin1 contains the in-situ formed carbides in its microstructure.

Pin-on-Disk (POD) Test

To evaluate friction coefficient and wear resistance of the cladded layer and the reference bulk materials, a conventional pin-on-disk tribometer was used. The measurements were performed at room temperature in laboratory with relative humidity of about 45 %. The disks with dimension of Ø30 mm x 4 mm and the pins with dimension of Ø3 mm x16 mm were machined to the surface roughness (Ra) less than 0.2 μm. The tests were performed under the normal load of 20 N, corresponding to contact pressure of 2.83 MPa. For each specified test, three pin-samples of the tested material were investigated in POD test in order to obtain statistical results. The sliding speed of $8cms^{-1}$ was applied as constant value by adjusting the rotation speed (200 rpm) of the disk and the diameter (Ø8 mm) of the wear tracks. The duration of sliding time was 6 hours. Wear volumes of the pin-samples were calculated from weight loss during the test by assuming density of 7.25 g/cm^3 of the cladded layer and HIP processed bulk composite. Wear volumes of the disks were measured accurately by using computerized three-axis profilometer (Taylor-Hobson). Wear tracks of the disks in 3D profiles were also mapped. The results on sliding wear in this study are demonstrated in terms of Archard`s specific wear rate (mm3/N·m) by the following formula.

$$\text{Specific wear rate} = V/ F\times S. \quad (1)$$

where V is the worn volume in mm^3, F is the applied normal load in Newton and S is the total sliding distance in meter.

Friction Coefficient

The friction coefficients of the testing cladded layer and the reference composite were investigated under the load of 20 N. The measured friction coefficients of the cladded layer and the HIP processed Ni_3Al/Cr_3C_2 composite were 0.13±0.02 and 0.68±0.02, respectively, see Figure 7. The friction coefficient of the HIP processed monolithic NAC-alloy (0.45±0.02) and the commercial vermicular graphite cast iron (0.48±0.02) from our previous investigation [9] were also given in the figure, as evaluation references.

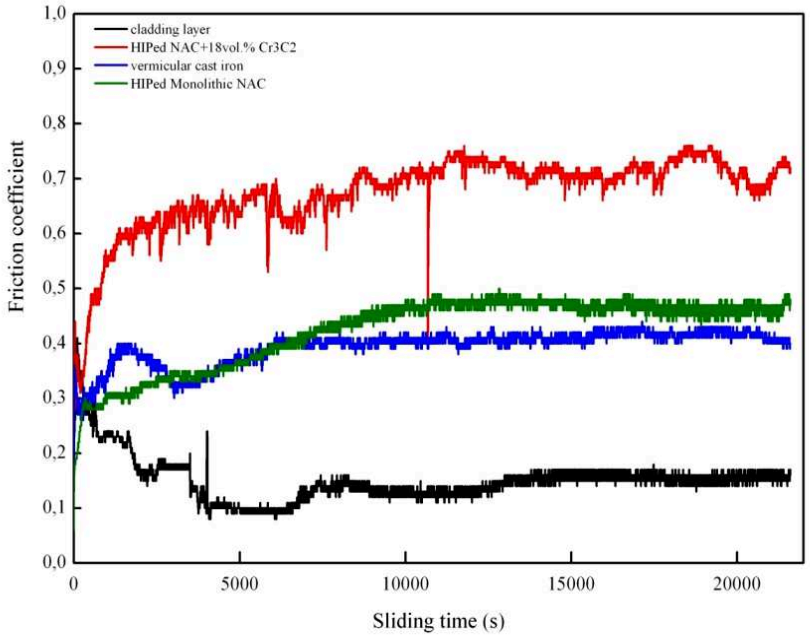

Fig. 7 Friction Coefficients of the Cladded Layer from Pin1, the References Ni_3Al/Cr_3C_2 Composite from Pin2, Monolithic NAC-alloy from Pin3 and the Commercial Vermicular Graphite Cast Iron from Pin4.

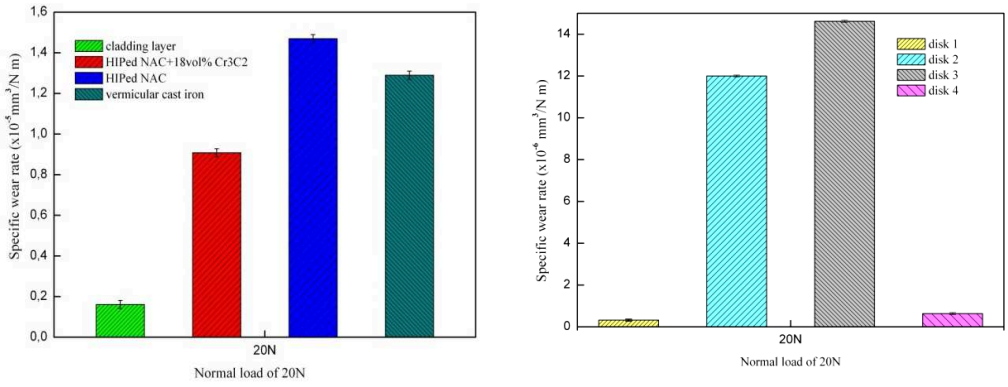
Specific Wear Rate

The specific wear rates of the pins and disks were also measured under the normal load of 20 N. The calculated values were illustrated in Figure 8. The specific wear rates of HIP monolithic NAC-alloy and the vermicular cast iron from our previous study [9] were also collected in the Figure 8.



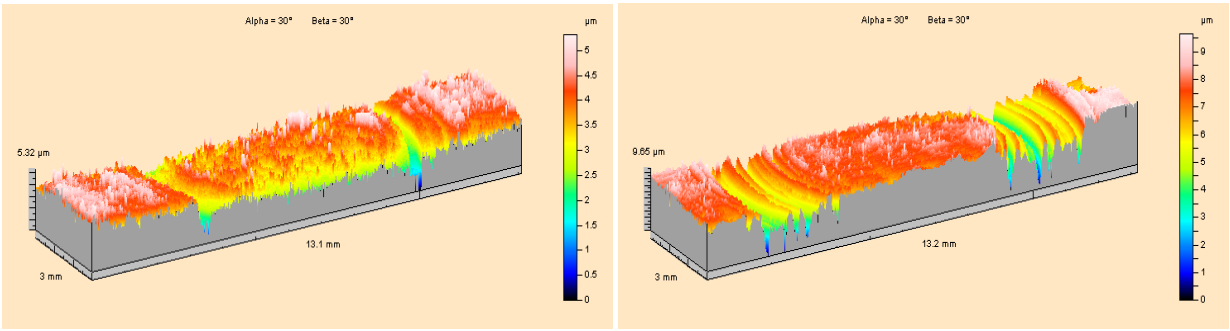


Fig. 8 Shows Specific Wear Rates of the Cladded layer, HIP Ni3Al/Cr3C2 Composite, Monolithic HIP NAC-alloy and Vermicular Cast Iron from (a), and Specific Wear Rates of the Corresponding Disks from (b).

The cladded layer clearly exhibited lower specific wear rate 0.162 x 10^{-5} $mm^3/N \cdot m$ as compared to the commercial cast iron 1.29 x 10^{-5} $mm^3/N \cdot m$ in the same working condition. The specific wear rate (0.91 x 10^{-5} $mm^3/N \cdot m$) of the HIP processed Ni_3Al+18 vol. % Cr_3C_2 composite was reduced as compared to the specific wear rate (1.47 x 10^{-5} mm^3/N) of the monolithic NAC-alloy. Meanwhile, the counterpart disk against to cladded layer showed lower specific wear rate (0.319 x 10^{-6} $mm^3/N \cdot m$) as compared to the specific wear rate (0.633 x 10^{-6} $mm^3/N \cdot m$) of the disk against to vermicular cast iron. The disk worn off by the HIP processed Ni_3Al-18 vol.%Cr_3C_2 composite showed the high specific wear rate of 12 x 10^{-6} $mm^3/N \cdot m$. Clearly, the HIP processed Ni_3Al+18 vol. % Cr_3C_2 composite were working inadequately with its disk. Figure 9 (a and b) illustrated the 3-D images of the disks worn off by the cladded layer and the HIP processed Ni_3Al+18 vol. % Cr_3C_2 composite, which revealed that the disk worn off by the HIP processed Ni_3Al+Cr_3C_2 composite had severe and deeper wear tracks on the surface as compared to the disk worn off by the cladded layer. It indicates that the artificially added coarse hard particles Cr_3C_2 induced mostly the asperities on the worn surface which caused the severe wear tracks on the counterpart disk. In contrast, in-situ formed Cr-carbides from the cladded layer were coupled to smooth worn surface of the disk.

Discussion

It is well known that the mechanical properties of a MMC (Metal-matrix composites) are important in determining their tribological behavior. During tibological interaction between two surfaces, temperature rises significantly at and near the surface, and the mechanical properties of the composites at elevated temperatures may be of direct relevance. The dispersed hard particles such as chromium carbides are helpful in retaining the high temperature strength of the matrix. During TIG process, chromium and carbon are partially dissolved in the Ni_3Al matrix and resulted in solid-solution strengthening. Then, the dispersed Cr-carbides were formed which increased hardness of the cladded layer. In our previous study, it indicated that the wear rate of metal-matrix composites decreased with an increase in volume fraction, if the bonding between the matrix and the particles is adequate.

Karin et al. [9] investigated previously the sliding wear behavior of the Ni_3Al-based NAC-alloy and its composites reinforced by 6 vol. % Cr_3C_2-particles under unlubricated condition. The experimental results revealed that the bulk monolithic NAC-alloy has similar friction coefficient and specific wear rate to commercial vermicular cast iron used in ship engines under same testing condition. Definitely, the addition of Cr_3C_2 hard particles reduced wear on both sides of pin and disk. The phenomenon was more obvious under the high applied load of 40 N testing conditions. Furthermore, considering other excellent physical, chemical and mechanical properties of the Ni_3Al-based intermetallic materials, the investigation has indicated that it could be meaningful and possible to develop Ni_3Al-matrix composites, reinforced by the hard Cr_3C_2-particles for tribological applications. Therefore, the high contents of Cr-carbides (18 vol. %) composites were prepared by both HIP and cladding process in this study. Clearly, the Ni_3Al/Cr_3C_2 intermetallic cladded layer on

the steel substrate performed superior wear behavior as compared to the wear-resistant vermicular cast iron and the other Ni_3Al-based materials. The Ni_3Al/Cr_3C_2 intermetallic cladded layer exhibited the lowest friction coefficient (0.13±0.02) in this group. It was considered that the superior wear behaviors of the Ni_3Al/Cr_3C_2 intermetallic cladded layer were connected to its unique microstructure. Two types of carbides with different sizes were in-situ formed in the Ni_3Al-matrix during solidification of the TIG process. They are distributed homogeneously with less spacing in the layer material compared to the interval distance of the artificially added carbide in the HIP processed Ni_3Al/Cr_3C_2 composite. Furthermore, the in-situ formed hard NiAl-particles will also be beneficial to the wear properties of the layer material. It should be noticed that the secondary NiAl-phase increased the total volume percentage of the hard phase in the microstructure, although the amounts of the chromium carbides in both of the Ni_3Al/Cr_3C_2 intermetallic cladded layer and the HIP processed composite are in the same range of 18 vol. %. Therefore, it is reasonable to consider that the material with hard particles with less spacing will protect the matrix more effectively and resulting in low friction coefficient with low specific wear rate at same wear conditions.

The present study suggests that such cladded intermetallic layer worked adequately with its grey cast iron disk during sliding wear and obtained the specific wear rate as 0.319×10^{-6} $mm^3/N \cdot m$. This value is only about 50 % the wear rate (0.633×10^{-6} $mm^3/N \cdot m$) induced by the reference vermicular cast iron under the same wear testing conditions. The HIP processed Ni_3Al+18 vol. % Cr_3C_2 composite worked with its counterpart disk shows low wear resistance and induced high specific wear rate of 12×10^{-6} $mm^3/N \cdot m$. This reveals that the microstructure of the composite played a key role and influenced the wear properties. Hence, the fine microstructure is preferable in all aspects. Furthermore, the composition of the matrix in the HIP processed Ni_3Al/Cr_3C_2 composite was maintained invariant during the heating process. In contrast, the added Cr-element in the welding wire was partially dissolved in the solid Ni_3Al-matrix which strengthened and hardened the material resulted in improved the wear-resistance.

Conclusions

From the study, several points can be concluded as follows:

The Ni_3Al-18 vol. % Cr-carbides intermetallic cladded layer on the high strength steel substrate worn off against the grey cast iron disk exhibited less friction coefficient 0.13±0.02 which is one quarter in magnitude of the friction coefficient (0.48±0.02) from the vermicular cast iron under the same testing condition.

The specific wear rate of the Ni_3Al/Cr_3C_2 composite cladded layer is 0.162×10^{-5} $mm^3/N \cdot m$, which is almost equal to one tenth in magnitude of wear rate (1.29×10^{-5}) of the vermicular cast iron under the load of 20 N.

The intermetallic Ni_3Al/Cr_3C_2 cladded layer worked more adequately with its grey cast iron disk, comparing to the reference vermicular cast iron and other tested intermetallic matrix composites. A specific wear rate 0.319×10^{-6} $mm^3/N \cdot m$ of the disk was obtained under the testing condition.

The outstanding properties of the Ni_3Al/Cr_3C_2 intermetallic cladded layer on wear were related to its unique microstructure. The in-situ formed hard Cr-carbides of various sizes with the small spacing may play a key role on the tribological properties of the cladded layer.

The wear behavior of the Ni_3Al/Cr_3C_2 intermetallic cladded layer may also respond to the in-situ formed un-equilibrium hard NiAl-particles and Cr-alloyed Ni_3Al-matrix. Therefore, the cladding process is promising selection to produce wear-resistant layer of Ni_3A-matrix composites in further investigation.

Keywords: volume fraction; retained austenite; tensile test; mechanicl stability; TRIP effect

Abstract: The mechanical stability of the retained austenite in the cold-rolled medium-Mn steel was studied. Tensile tests were carried out to measure the mechanical properties of the annealed steel. Scanning electron microscopy was applied to characterize the microstructure evolution during the tensile process; X-ray diffraction analysis was used to determine the residual austenite content in the deformed steel. It was found that the volume fraction of retained austenite gradually decreases with strain .The value of the stability coefficient of retained austenite *k* was small in the test steel, which indicated high mechanical stability of retained austenite. Due to TRIP effect, the high mechanical stability of the retained austenite strongly delays the onset of necking, which resulted in good comprehensive mechanical properties with ultrahigh strength and plasticity.

Introduction

The TRIP (transformation induced plasticity)-effect was observed in high alloyed austenitic steels already 30 years ago [1]. The excellent combination of strength and ductility of these steels was attributable to the irreversible strain-induced austenite-to-martensite phase transformation during plastic straining. Since the TRIP effect contributes to the high work-hardening rate of the microstructure and delays the onset of necking [2], they have been received increasing attention as new high-formability cold-rolled steel sheets for automobile bodies [3-6]. Nowadays the studies on the development of a new generation of steel with high strength and high ductility at reasonable cost have been promoted worldwide. In light of the high ductility contributed from metastable austenite in TRIP steel and stable austenite in TWIP steel [7-9], together with the high strength from grain refinement by severe plastic-deformed materials [10], increasing the volume fraction of retained austenite and refining the grain size into the submicron region in high-strength low-alloyed steel is a promising approach to design a new type of steel with both ultrahigh strength and high ductility [11].

Previous studies [12-14] confirmed that the volume fraction, the distribution of various phases, especially the stability of retained austenite is of great importance to the mechanical properties of transformation induced plasticity (TRIP) steels. In this study, the medium-Mn steel was produced by intercritical annealing after cold rolling to obtain a certain amount stable retained austenite. The main purpose is to determine the mechanical stability of the retained austenite in the steel and study the relationship between the mechanical stability and mechanical properties, which will provide a theoretical basis for the production of cold-rolled sheet with high strength and high ductility.

Experimental procedure

The chemical composition of the test steel investigated in the present work was shown in Table 1. The vacuum melted material was first made as a hot rolled strip with a thickness of 4 mm through the conventional hot rolling process. Then, the strip was cold rolled to a thickness of 1.2 mm. In order to obtain the TRIP behavior, the cold rolled strip was further processed by austenite reverted annealing, which is bell-type annealing at 650℃for 18h.

TABLE 1 CHEMICAL COMPOSITION OF THE TESTED ALLOY [WT %]

C	Mn	P	S	N
0.1	5	0.008	0.002	30ppm

After annealing, the sheet steel was machined into a tensile specimen shown in Fig.1. And the uniaxial tensile test was carried out on the WE300B tensile testing machine. The microstructure observation of each different tensile strain was conducted in the cross section of the specimen. The sample was treated by means of cold mounting, grinding and polishing, corrosion for 30s with 2% nitric acid alcohol solution, and observation of the microstructure with S-4300 cold field emission scanning electron microscopy (SEM).The X-ray diffraction was used to determine the residual austenite content (volume fraction) on the rolling surface after grinding and polishing. After mechanical polishing the rolling surface was electrolyzed for about 50s with 10% chromic acid electrolysis (voltage 5V) to remove the surface stress, then the residual austenite content was determined by PHILIPS APD-10 X-ray diffraction measurements. The Co target was used in the X-ray diffraction, and tube current and voltage were 30mA and 30kV. The graphite crystal monochromatic was used get to the diffraction patterns with the step scan mode in which scanning 2θ ranged 45-115°, step was 0.02° and integration time was 0.4s.Then X-ray diffraction analysis software was used to search the peaks and compute the angle of diffraction peaks, the FWHM and integral intensity. The amount of retained austenite was derived by comparing the integral intensities of Ferrite (200) and (211) and Austenitic (200) (220) and (311) crystal surface and the retained austenite content is calculated by equation [15] (1):

$$V_i=1/[1+G(I_\alpha/ I_\gamma)]. \quad (1)$$

In the equation, V_i is the amount of retained austenite (volume fraction), G is the parameters of some crystal surface in the austenite and martensite,I_α， I_γ was the integral intensity of the peak in the martensite and austenite. The carbon content of the austenite was calculated by equation (2) using of the austenite lattice constant [16]:

$$a_0=3.555+0.044x. \quad (2)$$

Where a_0 was the austenite lattice constant by actual measurement, x was the mass percentage of carbon in the retained austenite.

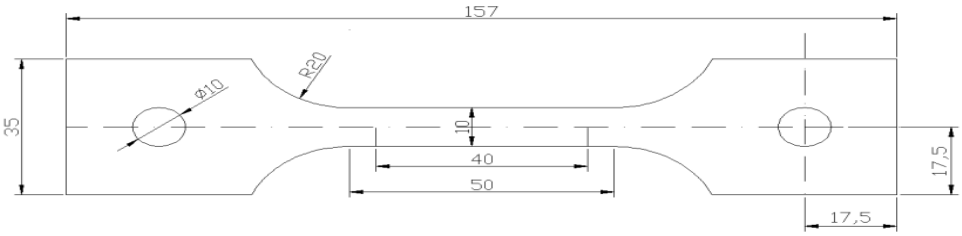

Fig.1 Tensile specimen size chart

Results and discussion

The microstructures before and after tensile test of the steel

The microstructure of the start and deformed steel was characterized by the SEM as shown in Fig.2 (a-d).The microstructures in the four states were quite similar and they all consisted of the convex and concave grains. After annealing the austenite reverted transformation took place [17], so the microstructure was composed by slightly recovered ferrite grains, some precipitated carbides and a few of austenite grains. As the austenite grain was easy to be etched and the ferrite grain was difficult to be etched, the concave grains were identified as the austenite grains. The grain size of the recovered ferrite phase was about 1.5μm.It can be seen that the volume fraction of retained austenite decreased and the grain size of the ferrite was refined with strain increasing.

As the driving force of the applied stress, the transformation from the metstable austenite to martensite occurred during the tensile process which is called “stress-induced martensitic transformation”, which resulted in reduction of the retained austenite. There was another interesting phenomena that the change of the austenite and the grain size of ferrite vary in their pace which implied that the deformation behaviors of different phase were different due to the different interaction behaviors among phases and thus results in the heterogeneous deformation structure.

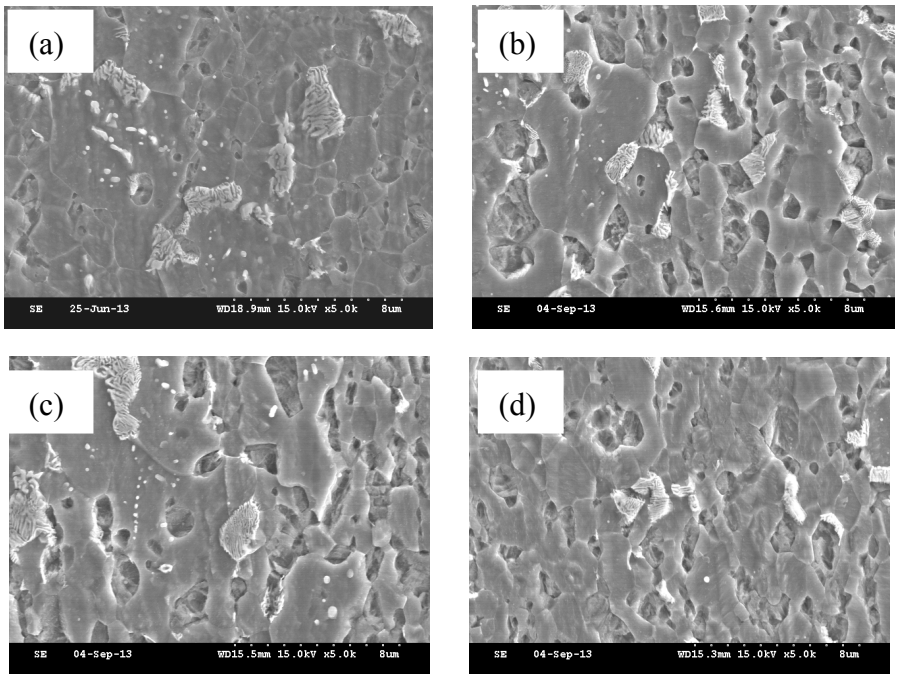

Fig.2 The starting and deformation microstructure of test steel deformed at room temperature characterized by SEM, (a) As-received, (b) 7% elongation, (c) 20% elongation and (d) 30% elongation.

The tensile curve of the steel

The mechanical properties of the steel were measured by the tensile test and the results were shown in Table 2. It can be seen that there is little difference in the mechanical properties between the specimens in the RD (rolling direction) and TD (transverse direction).The ultra tensile strength was about 700MPa and the total elongation was 40% in both of these two direction. The product of the ultra tensile strength (UTS) and total elongation (A) was applied to evaluate the combined mechanical properties of the medium-Mn steels, which intuitively express the forming ability and the deformation energy absorbed in the collision. The product was about 28GPa%, which was higher than that of the traditional TRIP steel and DP steel (normally about 20-24GPa% for TRIP and DP steel).

TABLE 2 MECHANICAL PROPERTIES OF THE TEST STEELS IN DIFFERENT DIRECTION

Direction	UTS[MPa]	YS[MPa]	A[%]	Agt[%]	UTS*A[GPa%]
RD	685	400	40.3	26.0	27.6
TD	704	453	40.0	23.0	28.2

The true stress-strain curves of the tensile test at room temperature with different direction are shown in Fig.3 (a and b). It can be seen the stress increase with strain increasing but the work hardening rate decrease with strain increasing. As we know, the formation of matensite under stress produces more effective “strain hardening” than the ordinary slip mechanism in fcc austenite. From the above analysis, it is suggested that martensitic transformation in TRIP steel has “strain hardening” effect and “uniform elongation” effect due to martensitic transformation causing the redistribution of stress, as a consequence, TRIP steels exhibit greater tensile strength and ductility than many commercial steels currently used in the manufacture of automobiles.

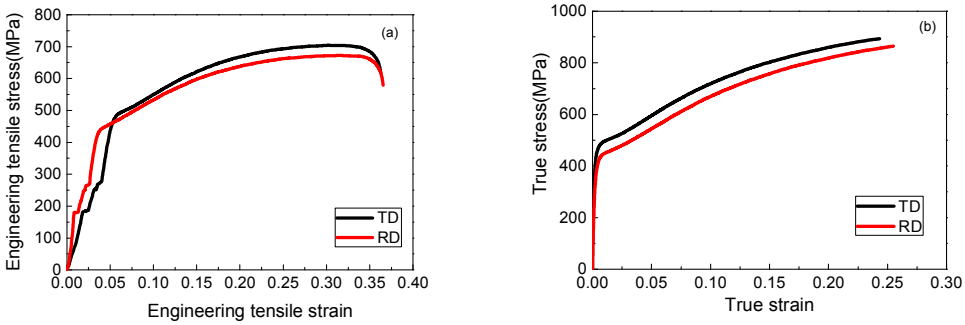

Fig.3 The stress-strain curves during tensile test at room temperature (a) the engineering stress-strain curve (b) the true stress-strain curve

The stability of retained austenite

It can be seen qualitatively from Fig.2 (a-d), the retained austenite fraction decreases with strain increasing during deformation process. In order to describe the changing rate quantitatively, the volume fractions at different strain are given in Fig.4. It can be seen clearly in Fig.4 (a) that the volume fraction of retained austenite gradually decreased with strain increasing. The exponent decreasing trends of retained austenite fraction with strain were clearly indicated in Fig.4 (b), which results were similar to the formula suggested by Chung and Chang et al. as described in equation(3) are already used by researchers [18]. However, in our study, the value of $f_{\gamma,\,u}$ is 0, which means there are no “dead retained austenite” as proposed by these authors. Thus the changing formula of retained austenite can be rewritten as in equation (4).

$$\log\{\ln[(f_{\gamma,0}-f_{\gamma,u})/(f_{\gamma,0}-f_{\gamma,\varepsilon})]\}=\log k+\log \varepsilon. \quad (3)$$

where, $f_{\gamma,0}$, $f_{\gamma,u}$ and $f_{\gamma,\varepsilon}$ refer to the austenite volume fraction in the starting materials, the volume fraction of retained austenite after broken during tensile and the volume fraction of retained austenite at given strain (ε), respectively. k is defined as the stability coefficient of retained austenite, and the larger k value indicates the lower stability of retained austenite and the faster martensitic transformation.

$$f_{\gamma,\varepsilon}=f_{\gamma,0}\exp(-k\varepsilon). \quad (4)$$

Where the parameters assume same meaning as described in equation (3).

In the range where the true strain is lower than 0.11, the retained austenite fraction drops dramatically with increasing strain, indicating very fast strain-induced transformation. Even the true strain rises over 0.17; the austenite fraction of the steel still decreases very slowly, indicating that the strain-induced transformation still continues.

The slope of straight line in Fig. 4 corresponded to the k in equation (4). In general, lower k value indicates higher stability of retained austenite [18]. This stability of retained austenite is closely related with the mechanical properties of cold-rolled steel sheets, with uniform elongation in particular. This is because necking is delayed as the strain-induced transformation lasts up to the higher strain region when the stability of retained austenite is high. The mechanical stability value of k under tensile test at room temperature is 12.9, which is a little lower than the k (from 16.20 to 20.99) in the TRIP steel [12].

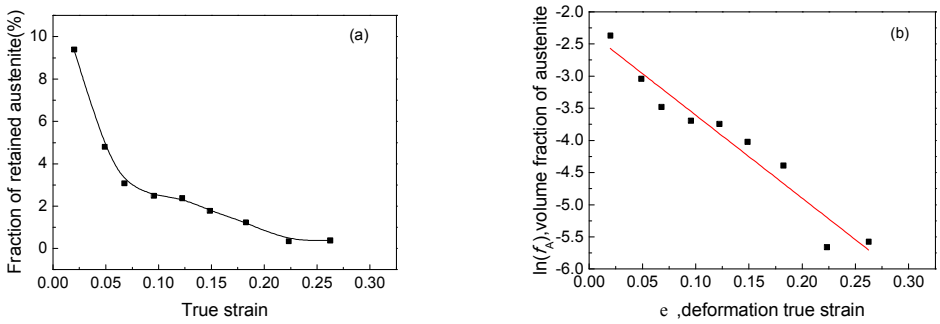

Fig.4 The volume fraction of retained austenite at different tensile strain of the steel deformed at room temperature (a) in the normal scale and (b) in the natural logarithm scale.

Conclusions

The microstructure of the cold-rolled medium-Mn steel was investigated by means of SEM. In addition, the mechanical stability of retained austenite was evaluated by tensile tests through the evolution of the volume fraction of the retained austenite. Main conclusions can be drawn as follows:

(a) It was demonstrated that the recovery and austenite reverted transformation took place during the annealing process in the cold-rolled medium-Mn steel. The duplex ferrite and austenite microstructure was obtained in the steel.

(b) It revealed a very good comprehensive mechanical property with the tensile strength 700MPa and the total elongation 40% in the test steel. Moreover the product of the tensile strength to the total elongation was 28GPa*%, which is higher than that of the conventional TRIP steel.

(c) The TRIP effect of the austenite phase plays an important role in the high strength and high plasticity of the cold-rolled medium-Mn steel. At the same time the stability coefficient of retained austenite *k* was 12.9, which implied the retained austenite was rather stable during the tensile test, so that the high strength and high plasticity was obtained in the test steel.

Keywords: TI -35Nb-7Zr-5Ta, four point bending fatigue, Powder metallurgy

Abstract: Mean stress on fatigue strength of Ti-35Nb-7Zr-5Ta, used in the manufacture of orthopedic prosthesis, was evaluated. Samples of Ti-35Nb-7Zr-5Ta were pressureless sintered and tested using microhardness (Vickers) and four point bending fatigue apparatus. Characterization was carried out using optical microscopy, scanning electron microscopy, EDS analysis, oxygen analysis and density. The density analysis shows almost 98% of density and microscopy reveals some precipitates of α phase and presumably ω phase at the grain and grain boundaries. The bending fatigue resistance limit reached ($Se(10^6) \approx 88$ MPa), due to, presumably, the influence of coarse α phase precipitates at grain boundaries as well as the high oxygen content in the material after sintering (0.96 %). In this study, Kwofie model best explains the influence of mean stress on fatigue strength of this alloy.

Introduction

The use of Powder Metallurgy (P/M) aims to obtain orthopedic implants with almost net-shaping and adequate mechanical properties and surface porosity. The surface porosity is necessary to improve an efficient interaction between the implant and the bone [1].

The control and quantification of porosity is very important because its size and morphology are essential to the cellular adhesion. It is necessary to obtain a high porosity to improve bone-formation inside the pores [2].

Sintering is irreversible, so a perfect control during the process is necessary. After the sintering, alternative technologies are used to modify some properties, to improve the shape or dimensional accuracy so as to extend the range of application [3].

The lower modulus of β Ti alloys have been developed recently because they exhibit a elasticity modulus near of bone modulus and those alloys have other desired properties like ideal bio-alloy. Biomedical alloys needs a good relation between low modulus and enough strength and alloying additions that are biocompatible [4]. The P/M Ti 35Nb 7Zr 5Ta alloy (TNZT) with 55 GPa modulus is considered one of the best to be used as a orthopedic implant. This TNZT has excellent non-toxic components with good mechanical properties and workability [5 - 7].

The recent trend in research and development of titanium alloys for biomedical applications is to develop low rigidity β type titanium alloys composed of non-toxic and non-allergic elements with excellent mechanical properties and workability [8]. According to this concept, different new β type have been developed like Ti–29Nb–13Ta–4.6Zr [9 - 12] and Ti 35Nb 7Zr 5Ta obtained just by P/M [13] alloy composed of elements like Nb, Ta, and Zr [14, 15] for biomedical applications. It is still necessary to evaluate various performances of Ti–35Nb–7Zr-5Ta for practical use.

Fatigue performance is one of the most important mechanical properties for biomaterials because, in general, these materials are used under cyclic loading. Fatigue performance of titanium alloy varies according to mean stress applied. The influence of mean stress on fatigue strength of the new β type titanium alloy M/P obtained, Ti 35Nb 7Zr 5Ta, were investigated in relation with microstructures in this study.

Basic Relations of Load Characterization

The fatigue life is described by the Wöhler curve or *S-N* curve, Stress-Life, where the number of cycles to failure, *N*, is correlated with the alternating stress, S_a. This method is a relation that can be well used to adjust appropriately experimental data in the sense to correlate the alternate stress and the number of cycles to failure between 10^3 and 10^6 cycles.

Some practical applications and also fatigue tests in materials involve maximum and minimum level stresses that characterize the amplitude loads. The stress range, ΔS, is the difference between the maximum value and minimum value. The mean stress, S_m, is the average between maximum value and minimum value. The half of the range stress is called amplitude stress, S_a. These are basic relations that characterize one load cycle.

And to describe the mean stress, a factor used to characterize the degree of symmetry of the load, is load ratio, *R*. The relation between S_a, S_m and *R* is expressed in the Eq. 1.

$$S_a = (1+R / 1-R) \times S_m \quad (1)$$

Mean Stress Effect Prediction Models

Initially, empiric models were proposed by Gerber (1874), Goodman (1899), Haigh (1917) and Soderberg (1930) to compensate the effect of mean stress in the high cycle fatigue strength. Gerber proposed a parabolic representation of the Wöhler's limit fatigue data on the graphic S_{max}/S_u *versus* S_{min}/S_u , Eq. 5. Goodman introduced a theoretical line to represent the evaluated fatigue data, Eq. 4. Haigh was the first to plot the fatigue data in the graphic S_a *versus* S_m. Starting around 1960, some models to determine the effect of mean stress have been proposed as improvements of the previous models. Fatigue tests indicate that the tensile normal mean stress should reduce the fatigue strength coefficient and that the compressive normal mean stress should increase it [16].

In order to overcome the failure prediction's problem under load conditions with relatively low amplitude and relatively high mean stresses, Smith, Watson and Topper - SWT [17] proposed a model in which the equivalent stress to the endurance limit for the load ratio, $R = -1$, S_{ar}. On this same year, Walker [18] presented a criteria similar to SWT, however using a factor γ that makes possible an adjustment of the curve in relation to the experimental data, Eq. 6. According to empiric data, Berkovits and Fang [19] and more recently Kwofie [20] proposed widespread mathematical relations to describe the effect of mean stress on the fatigue behavior of endurance limit. Such model consists in the substitution of the Basquin's equation's constant, for a function that will depend on the mean stress, S_m, on the limit of fatigue strength for the reverse load condition, S_{rt}, and on the ultimate strength, or yield strength, S_y. According to this model, the stress-life relation can be presented by Eq. 2.

$$\sigma_a = S_{ar} \times e(-\alpha(\sigma_m/Srt)) \quad (2)$$

Expressed in form of power series, the Eq. 2 can be expressed by Eq. 3:

$$\sigma_a = S_{ar} \, X \, e^{(-\alpha(\sigma_m/S_{rt}))} \approx \Sigma^{N}_{i=0} \, X \, 1/i! \, X \, (-\alpha \, \sigma_m/S_{rt})^i \quad (3)$$

Admitting that the argument of the exponential function tends to zero, $\alpha(\sigma_m/S_{rt}) \rightarrow 0$, the consequence is that the terms of superior order converge quickly to zero.

Materials and Methods

For the preparation of the alloy, the blended elemental method followed by a sequence of uniaxial and cold isostatic pressing with subsequent densification by sintering was chosen. All the powders were obtained by hydriding method and sintered in hydride state. The starting powders were weighed and dried for one hour in stove and blended for 30 minutes in a planetary mill. After blending, the powders were cold uniaxially pressed under pressure of 60 MPa. Afterwards, samples were encapsulated under vacuum in flexible rubber molds and cold isostatically pressed (CIP) at 350 MPa during 30 seconds in an isostatic press. Sintering was carried out in niobium crucible in high vacuum condition (10^{-7} Torr), at 1500 °C. Metallographic preparation was carried out using conventional techniques. Specimens were etched with a Kroll solution: 1.5 ml HF: 2.5 ml HNO_3: 100 ml H_2O, for 50 seconds, to reveal its microstructure. Microhardness measurements were carried out with a load of 200g for 20 seconds (15 indentations). The micrographs were obtained using a SEM Philips Quanta model 200 3D and optic microscope "OLYMPUS BX51. The porosity was

determined by the Arquimedes method. The analysis of oxygen and nitrogen was made in the Material's Lab at University of Trento. Bending fatigue at four points was developed in a universal testing machine MTS 810.

The material used in the development of this research was the Ti 35Nb 7Zr 5Ta alloy, a β titanium alloy. This is a new biocompatible alloy used in the production of orthopedic implants. The mechanical properties (Young modulus, E, tensile strength, S_{rt}, and yield strength, S_y), oxygen and nitrogen content, density and densification of the alloy are summarized in Table 1.

TABLE 1 MECHANICAL PROPERTIES OF TI 35NB 7ZR 5TA.

Ti35Nb7Zr5Ta	β	596.5	547.1	55	0.96	0.0111	5.60±0.05	97.9

* Theoretical values. **Experimentally Determined Values

Results and Discussion

In the microstructure presented in Fig. 1 one can see a β-homogeneous microstructure with relative high porosity. Due to the complete dissolution of the alloys elements in the titanium matrix, a good combination of microstructure, mechanical properties and desired densification could be reached.

The samples sintered at 1500°C presented a β-homogeneous microstructure with medium porosity. The alloy presented microhardness values around 340 HV, next to the observed in samples produced by the melting conventional method [22]. The microstructure of the TNZT alloy in the sintered condition, observed in optical and scanning electron microscope, are shown in the Figure 1 and Figure 2. The microstructure consists of relatively large grains of phase β with grain boundary α precipitates. In addition, some amount of intra-granular α precipitation is also visible within β grains. These intra-granular primaries α precipitates often exhibit rather different morphologies (plates and needles).

The Figure 2 allows to see α and β areas (sintered at 1500^{o}C) where the analyses for EDS were carried out. Areas 1 and 2 are, preferably, β and α region respectively.

The medium porosity presence, area 3 (observed in Figure 2a) is an important feature for osseointegration, when aiming for surgical implants application, where a medium-high porosity is necessary. An efficient route to control the pore content in TNZT samples is selecting an adequate space holder. This sintering method in order to manufacture highly porous metallic materials was investigated in other research [13]. In Figure 2b are signalized (region 4) the probably ω phase. These precipitates will be certainly identified through the Transmission Electron Microscopy and will be published in future papers. It is possible that the same precipitate would be formed into the grain boundary.

Figure 3 shows the S-N log-log linearization obtained through the Grapher 7 software, based on the experimental data of fatigue test in alternated stress. Figure 4 shows the adjustment of the experimental data considering a Mono-log linearization. Based on test result the fatigue strength of this alloy for the sintered and aged condition is approximately S'_e = 78MPa and approximately S'_e = 88MPa for solubilized samples.

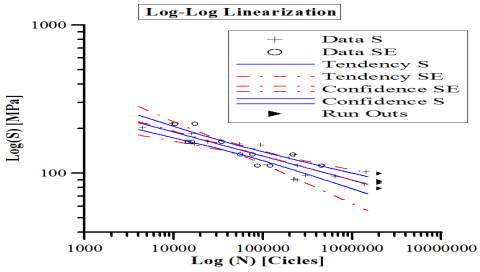

Figure 3. S-N Log-log Linearization

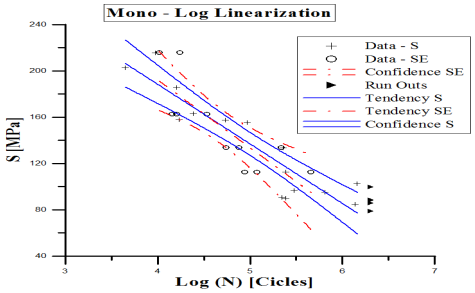

Figure 4. S-N Mono-log Linearization

Considering the goal of this work, it is necessary check the adherence of the Goodman, Gerber, Kwofie and Walker´s models making a comparison between the results and obtained graphics with the results of the S-N linearization results. Since the S-N graphics do not include the mean stress effect it is necessary standardization of the equivalent alternated stress, for Goodman:

$$\sigma a = \sigma alt / 1 - (\sigma med / Srt) \quad (4)$$

Once found, the equivalent alternated stress using Eq. 4 takes in consideration the experimental mean stress. For each point, the S_{ar}-N relation was obtained for Goodman model, considering the adherence of log-log. The Eq.5 was used to calculate equivalent alternated stress at the Gerber Model and the associated graphics were constructed.

$$S_{ar} = \sigma_{alt} / 1 - (\sigma_{med} / S_{rt})^2 \quad (5)$$

The Eq. 6 was used to calculate equivalent alternated stress for the Walker Model and the associated graphics were plotted.

$$S_{ar} = \sigma_a * (2/1-R)^{1-\gamma} \quad (6)$$

Using the Eq. 7 the equivalent alternated stress was calculated for Kwofie Model and the associated graphics were plotted.

$$S_{ar} = \sigma_a / 1 - \alpha(\sigma_m / S_{rt}) \quad (7)$$

From Figure 5 to Figure 8 is showed both the just sintered (S) and sintered and aged (SE) conditions tendency and its confidence curves. Figure 5 shows the log-log linearization obtained for Goodman model. Figure 6 shows the log-log linearization obtained for the Gerber model. Figure 7 shows the log-log linearization obtained for the Walker model. Figure 8 shows the log-log linearization obtained for the Kwofie model. All log-log linearization were obtained using the experimental data.

Models Comparison

It is possible, with the aid of Table 2, visualize the adhesion for both treatments: sintered (S) and sintered and aged (SE).

TABLE 2 DETERMINATION COEFFICIENTS AND FATIGUE RESISTANCE OF STUDIED MODELS FOR LOG-LOG LINEARIZATION.

Treatment		S-N	Goodman	Gerber	Walker	Kwofie
S	R^2	0.844	0.638	0.741	0.753	0.834
	S_e	88	129	98	121	88
SE	R^2	0.672	0.448	0.545	0.616	0.668
	S_e	78	107	87	109	77

The line S-N shows the analysis done without mean stress influence and, apparently, represents a better grip to the material behavior. Considering also that, according to Kwofie, the closer to zero (0) the parameter α is, the lower the sensitivity of the material to the mean stress. The material (depending on tested samples) is not much sensitive to the mean stress. The coefficient of determination for both the log-log and mono-log curves, show little fit of the experimental data. In all cases, the curves have a better adjustment when analyzed in Log-log linearization.

The diagrams obtained by applying the procedures of ASTM E 739 [23] to the experimental data also reveal that the material has narrow confidence bands; for both the S-N curves (without main stress) and for the Kwofie model, even when some points appear with some scattering. This behavior of the confidence bands reinforces the above statement about the influence of mean stresses in the material. It was also observed that most dynamic models, such as Kwofie tend to have the better fit to the data.

Soderberg model may be considered to be the most conservative of the analyzed criteria, knowing that a safety factor is included in the mathematical model used by him. However, this method is not widely used by engineers in projects. Goodman would be the following more conservative criteria, depending on tested material and levels of loads used in the study. Goodman

has a more conservative behavior when used for analysis of the influence of mean stresses values higher than those studied in this thesis, which are considered low.

The analysis of the influence of thermal treatment applied on the fatigue strength of the alloy showed not improvement or worsening. The trend curves for both analyzed conditions are virtually superimposed, indicating that the material behavior was similar for each heat treatment. Nevertheless, is important to note that the analysis of 10^5 cycles life in solubilized and aged material has a better behavior, keeping trend curve always approximately 10 - 15% above the sintered material.

High values of fatigue strength in titanium alloys obtained by melting electric arc, associated with mechanical forming reported in literature [24], are linked to the formation of cracks beneath surface of material in a more stable phase β, favored by the refinement of precipitates. In the alloy studied in this work, metastable β phase is associated with the presence of coarse precipitates of alpha phase, favoring the formation of internal cracks in the material. These cracks facilitate the advancement of the fracture and consequently causes lower values of fatigue resistance [25].

The value of Se (fatigue resistance) obtained for the Ti-35Nb-5Ta-7zr in this work was 89 MPa. Taylor [26] reported values in the region of 23-30 MPa for human long bones and 32-43MPa for bovine compact bone. Niinomi et al. [27] reported values of fatigue resistance in cattle bones compact 40-50 MPa. Taylor et al. [28] have reported fatigue resistance values of 70-80Mpa to bovine bone. After performing analysis of all these results, it was considered that the material under consideration provides consistent resistance values for use which has been designed.

It is considered that microstructure obtained combined with the level of porosity of the alloy is mainly responsible for mechanical behavior of studied alloy. If necessary, to achieve higher strength values for any other design requirements, one may add to the manufacturing process a rolling step as well as a high cooling rate (quenching water) after the aging treatment as described in other studies that have been achieved fatigue resistance values of 700 MPa [5]. Those high ´Se´ values were also described in other studies [29, 30].

In Table 2, S-N column represents the analysis without the influence of the mean stress effect; apparently it is who better explain the material behavior. Based in Kwofie criteria, when $\alpha \rightarrow 0$, the material mean stress sensibility tend to be lower. Considering the experimental results Ti 35Nb 7Zr 5Ta alloy showed big mean stress insensibility. Mono-log linearizations show us a better adherence to the experimental data and hence, are the models who offer us a better analysis of the statistical test results. Results analysis using ASTM E739 [23] show that S-N curve without incidence of mean stress and Kwofie model presents better confidence rate even in more dispersed points.

Conclusions

The aim of this research was to evaluate the effect of solubilization and aging treatment and mean stress on the fatigue behavior of Ti 35Nb 7Zr 5Ta alloy. In that sense, *S-N* curves were experimentally determined for different stress values. Results obtained allow only for a qualitative study, being this an exploratory research. The results were used to determine the endurance limit of the material and to evaluate the predictions of such models. The Goodman, Gerber, Walker and Kwofie's models were used to predict the mean stress effects. Through the analysis of the test results it is possible to conclude that:
a) Through the micrograph analysis, porosity was determined. These surface porosities are necessary for a good osseointegration [31]. Nevertheless, those pores could affect the mechanical properties, hence, should be controlled. At β matrix, and even at grain boundary, precipitates were found, presumably α and/or ω phase.

b) The fatigue strength limit for this sintered TNZT alloy is approximately $S_e(10E6) = 88$ MPa for solubilized material and $S_e(10E6) = 78$ MPa for solubilized and aged, analytically obtained. Probably the coarse precipitation of α phase as well as the possibility of ω phase precipitation had influenced S_e value; the fatigue strength identified in this research is compatible with some results shown in the literature for different kind of bones [26 - 28]

c) The fatigue strength was not strongly influenced by the presence of mean stresses. ;

d) Goodman model was shown inadequate to describe the statistical test results of mean stress effect on the fatigue strength;

e) Gerber and Walker's model presents a reasonable prediction for the presence of mean stress;

f) Kwofie's model was the model that best describe the effect of the mean stress on the fatigue strength of Ti 35Nb 7Zr 5Ta alloy.

Keywords: Hydrogen, Micro strain, Macro strain, Phase transformation, Austenitic stainless steel

Abstract. The objective of this study is to evaluate the effect of hydrogen on the micro- and macro-strain of austenitic stainless steel using X-ray diffraction. When hydrogen is trapped in lattice sites, it can affect both the micro- and macro-strain. The micro-strain was evaluated through fitting profiles to measured X-ray diffraction profile using a fundamental parameter method. The macro-strain, i.e., the residual stress, was evaluated by a 2D method using a two-dimensional PSPC. The experimental samples were charged with hydrogen by a cathodic charging method. The results revealed that the induced residual stress was equi-biaxial and compressive, and that the micro-strain increased. Both of these varied rapidly with increasing hydrogen charging time. Saturation occurred at a compressive stress of around 130 MPa. On reaching saturation, the hydrogen charging was terminated and desorption of hydrogen began at room temperature. Then, the strains decreased and the compressive stress reverted, ultimately, to a tensile stress of 180 MPa. Martensitic transformation occurred due to hydrogen charging and this had a significant effect on the X-ray diffraction profile.

Introduction

It is well known that hydrogen has an effect on several of the properties of metals, e.g., it can cause embrittlement. Due to its complexity, the mechanism for this is not yet clearly understood. Hydrogen invades the surface of metals, and becomes trapped in the lattice. When hydrogen is trapped at lattice sites, it can lead to changes in both the micro- and macro-strains. The micro-strain refers to the strain between adjacent grains and the random strain within grains. Hydrogen trapped at lattice sites can increase the strain in the lattice. The macro-strain is a more homogeneous quantity and is on a larger scale involving many grains, i.e., the residual stress. In this case, the hydrostatic stress may be affected by hydrogen. In this study, the variations in these strains with the time for which the metal had been charged with hydrogen were evaluated using an X-ray diffraction method.

Hydrogen trapped in the lattice can diffuse freely in the metal and concentrates around inclusions, grain boundaries, dislocations and at the tips of cracks [1]. It can become a trigger for the initiation of micro-cracks around an inclusion and/or accelerate the propagation of cracks due to hydrogen-dislocation interactions. In order to safely use metals in hydrogen environments, the effect of hydrogen on the mechanical properties, i.e., the micro- and macro-strain, yield stress, Young's modulus and the hardness etc., should be examined. It is interesting to note that hydrogen significantly hardens the surface of austenitic stainless steel, as has been demonstrated by indentation tests [2]. In the case of austenitic stainless steel, the effect of hydrogen is more remarkable near the surface because of its low rate of diffusion. Because of the low diffusion rate, austenitic stainless steel, especially type 316L stainless steel, appears to have a high resistance to the effects due to hydrogen. However, in a recent study it was found that hydrogen caused the unstable propagation of fatigue cracks in type 316L stainless steel [3]. In this case, it was found that

cavitation peening, a technique used to modify the surface, could suppress it. For type 304 stainless steel, austenite can be transformed into martensite with relative ease, not only by work hardening, i.e., strain-induced martensitic transformation, but also by the incorporation of hydrogen at lattice sites, i.e., hydrogen-induced martensitic transformation. This transformation enhances the diffusion and concentration of hydrogen. Although type 316L stainless steel has a higher resistance to martensitic transformation than type 304 stainless steel due to its phase stability, there is a possibility that martensitic transformation can occur in type 316L stainless steel when a large amount of hydrogen is absorbed in the austenite lattice. Since the martensitic transformation might be caused by large increases in the micro- and macro-strains, these should be examined in order to understand the effects hydrogen has on the mechanical properties of metals.

Since hydrogen desorbs rapidly from metals, observations have to be made quickly in order to examine the effects it has on the micro- and macro-strains and the martensitic transformation. Therefore X-ray diffraction methods were utilized in this study. The micro-strain was evaluated through fitting profiles to the measured X-ray diffraction profiles using a fundamental parameter method. The macro-strain was evaluated by a 2D method using a two-dimensional position sensitive proportional counter (2D-PSPC).

Experimental Apparatus and Procedures

The material under test was Japanese Industrial Standards JIS SUS316L which has a higher resistance to hydrogen embrittlement than both ferritic and martensitic steel. The specimens used were square, 25 mm on each side, and 4 mm thick. They were thermally refined to remove any pre-strain. The yield stress defined as a 0.2 % offset stress and the tensile strength were 304 MPa and 576 MPa, respectively.

Hydrogen absorption was carried out by employing a cathodic charging method. The solution used for this was 0.5 mol/l sulfuric acid at a temperature of 50oC, and charging was done by controlling the current at a current density of 0.8 mA/mm2. The cathodic and anodic electrodes were the specimen and a platinum wire, respectively. Hydrogen was generated at the cathode, i.e., on the specimen. Thus, the specimen surface was exposed to hydrogen during the cathodic hydrogen charging. For each specimen, the area exposed to hydrogen was 20 mm in diameter. X-ray diffraction measurements were done on specimens that had been charged with hydrogen for various times ranging from 0 to 48 hours. After being charged for 48 hours, the charging was stopped and X-ray diffraction measurements were done continuously for 144 hours during the hydrogen desorption process.

Measurements of the micro-strain were made using an X-ray tube with a Cu target, producing Kα X-rays. Bragg-Brentano geometry was used. The operating voltage and current were 40 kV and 40 mA, respectively. The measurements were focused on the γ-Fe (1 1 1) plane, for which the maximum intensity of diffracted X-rays is at an angle (2θ) of 43.6 deg. The measurements were made from 42 to 45 degrees in steps of 0.001 deg, with the diffracted X-rays being counted for 0.5 sec in each step. The micro-strain was calculated through fitting a profile based on a fundamental parameter method [4]. Furthermore, in order to investigate whether or not the martensitic transformation had been induced, the X-ray diffraction profile was also obtained after hydrogen charging for 48 hours. For this, 2θ was varied from 40 to 95 degrees in steps of 0.005 degree, and the diffracted X-rays were counted for 0.2 sec in each step.

The macro-strain, i.e., the residual stress, was measured by a 2D method using a 2D detector [5]. The method focuses on the direct relationship between the stress tensor and the distortion of the diffracted Debye ring and can measure the biaxial stress, including the shear stress, in one

measurement. The analysis was done using Cr Kα X-rays from a tube operated at 35 kV and 40 mA with a 0.8 mm diameter collimator. The measurements focused on the γ-Fe (2 2 0) plane which has a diffractive angle (2θ) of 128 deg.

Results and Discussion

Figure 1 shows the X-ray diffraction profiles from the γ-Fe (1 1 1) plane for hydrogen charging times of t = 0 (Uncharged), 12, 24 and 48 hours, and 96 hours after termination of the hydrogen charging (t = 144 h). Figures 2, 3 and 4 plot the full width at half maximum of the profile, FWHM, the micro-strain, ε, and the biaxial residual stress, σR, respectively, as functions of the time, t. As shown in Fig. 1, the intensity of the diffracted X-rays decreases significantly and broadens due to hydrogen charging. As shown in Fig. 2, FWHM increases steadily until t = 16 h, and then changes rapidly. The intensity is almost 17,000 before hydrogen charging and decreases to less than 10,000 for a hydrogen charging time of 12 h. At t = 24 and 48 h, the X-ray diffraction profiles have anomalous shapes and it seems that other peaks appear at around 2θ = 43.2 deg due to phase transformation. It is questionable whether the phase transformation, i.e., hydrogen-induced martensitic transformation has occurred, since the peak is close to the γ-Fe (1 1 1) peak. The phase transformation is discussed in more depth later. Interestingly, long after termination of the hydrogen charging (t = 144 h), the sharp profile is restored as a result of hydrogen desorption from the surface.

As shown in Fig. 3, the micro-strain is ε = 0.0003 before hydrogen charging and increases with time until t = 12 h. At t = 12 h, the micro-strain is ε = 0.1853. After that, it was not possible to evaluate it due to the X-ray diffraction anomalies. After terminating the hydrogen charging, it decreases as a result of hydrogen desorption, similar to FWHM. At t = 144 h (96 h after terminating the hydrogen charging), it is ε = 0.1442. Fig. 4 shows that an equi-biaxial compressive stress was introduced by the hydrogen charging. Before charging, the residual stresses in the orthogonal x and y-directions were σRx = -65 MPa and σRy = -110 MPa and these increased to σRx = -147 MPa and σRy = -183 MPa after 8 h of charging. Beyond this, X-ray diffraction anomalies were generated. After termination of the hydrogen charging, the residual stress was rapidly restored, but reverted ultimately to tensile stress, with σRx = 140 MPa and σRy = 127 MPa at t = 144 h (96 h after terminating the hydrogen charging). It is likely that constriction due to a rapid decrease in the concentration of hydrogen as a result of the hydrogen desorption process had occurred. It has been reported that constriction due to hydrogen desorption sometimes causes tensile stress and micro-cracks at the metal surface [6].

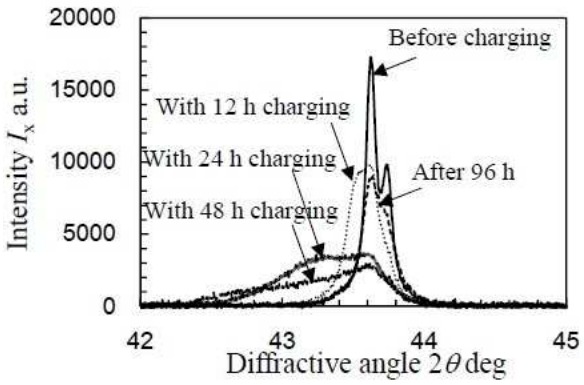

Fig.1 X-ray diffraction profiles from the γ-Fe (1 1 1) plane with and without hydrogen charging

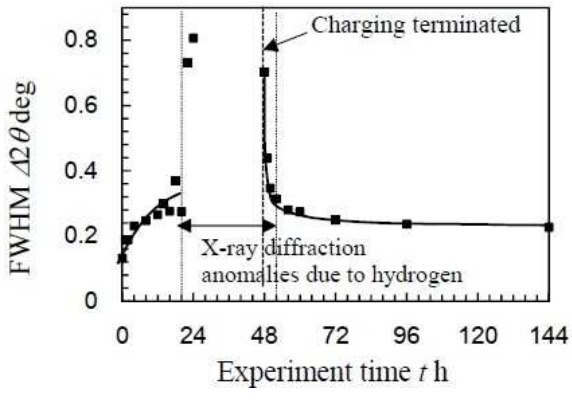

Fig.2 Increase and decrease in the FWHM of the XRD pattern from the γ-Fe (1 1 1) plane due to hydrogen absorption and desorption

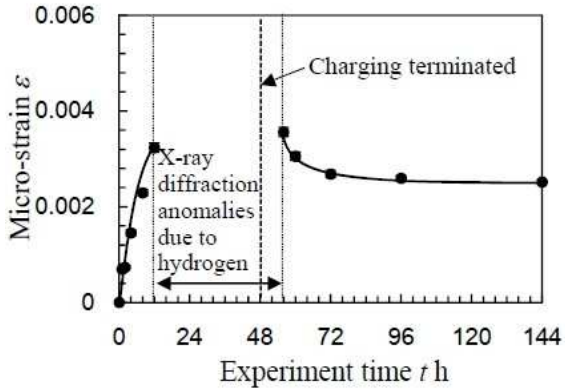

Fig.3 Increase and decrease in the micro-strain due to hydrogen absorption and desorption estimated using a fundamental parameter method

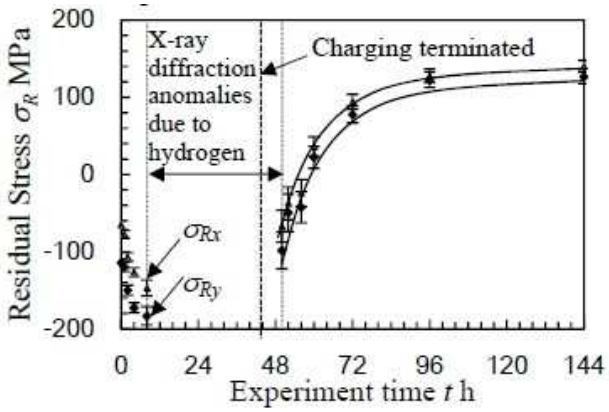

Fig.4 Introduction of compressive and tensile stress due to hydrogen absorption and desorption

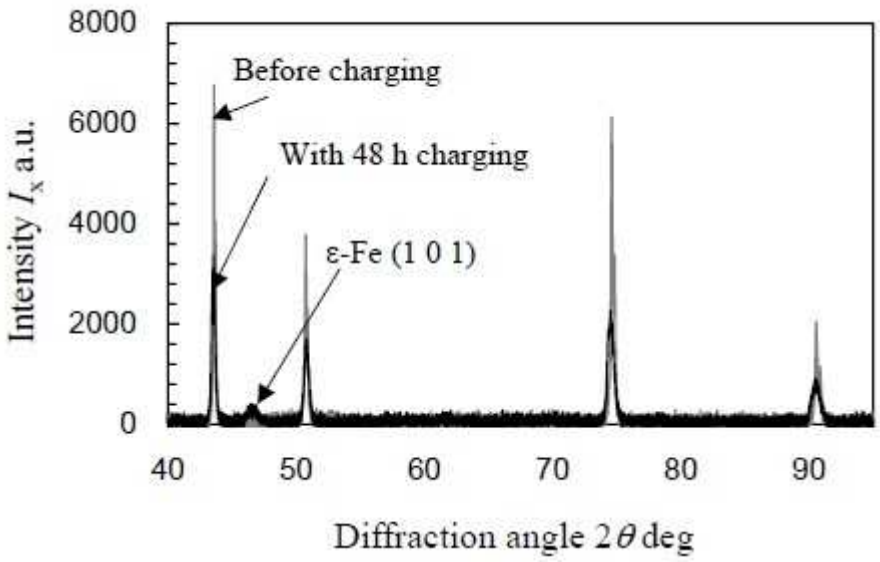

Fig.5 X-ray diffraction profiles before and after hydrogen charging

Figure 5 shows X-ray diffraction profiles (2θ = 40 ~ 95 deg) before and after hydrogen charging (t = 48 h). As shown in the figure, a diffraction peak for the ε-Fe (1 0 1) plane at around 2θ = 46 deg has appeared after 48 hours hydrogen charging. This shows that hydrogen-induced martensitic transformation occurs, not only in type 304 stainless steel, but also in type 316L stainless steel. Moreover, the X-ray diffraction anomalies may be due to the hydrogen-induced martensitic transformation. It is quite likely that the hydrogen-induced martensitic transformation occurs when the micro-strain has increased beyond a certain threshold level.

Summary

In order to investigate the effect of hydrogen on the micro- and macro-strain near the surface of austenitic stainless steel, the micro-strain was evaluated through fitting profiles to measured X-ray diffraction profiles using a fundamental parameter method and the macro-strain was evaluated by a 2D method using a 2D-PSPC. The conclusions obtained from this study are summarized below.

1. The micro-strain, ε, increases significantly from ε = 0.0003 to 0.1853 and an equi-biaxial compressive macro-strain of 80 MPa is introduced by hydrogen charging. After termination of the hydrogen charging, the compressive macro-strain reverts to a tensile strain due to hydrogen desorption.

2. Hydrogen-induced martensitic transformation occurs in type 316L stainless steel. It is quite likely that it occurs when the micro- and/or macro-strain increases beyond a certain threshold level.

This work was partly supported by JSPS KAKENHI Grant Number 24360040, 25820001 and JFE21st Century Foundation.

Keywords: ASTM A743 CA6NM, AWS 410 NiMo, GMA welding multiple steps, thermographic analysis, microstructural changes.

Abstract. The martensitic stainless steel ASTM A743 CA6NM is typically used in the production of hydroelectric turbines due to its known high resistance to cavitation induced surface damages. Despite the fact the material presents a high resistance to cavitation, depending on the loading condition to which the turbine runner is subjected and on its geometry, fatigue cracks can develop, thus requiring repair by means of removing material around the crack, up to its complete elimination, and by depositing weld metal in the cavity followed by a grinding process, in order to recover the original runner geometry. Such a repair process is normally done on site, which means that it is not possible to carry out the post weld heat treatment necessary to bring the newly deposited weld metal and the base metal to the same microstructure encountered in the runner when it comes out of manufacture. In order to study the effect that a layered welding has on the base material and on the weld metal, this work aims at studying the microstructural changes that occur in the CA6NM stainless steel welded in multiple layers with a AWS 410 NiMo welding wire. In order to attain such an objective, several 410 NiMo weld beads were deposited in successive layers on the border of a 5mm thick sheet while the resulting temperature fields were monitored by a thermographic camera. After the welding process, the samples cut from the welded sheet were examined in the perpendicular direction of deposition and their resulting microstructures where analyzed and correlated with the temperature history recorded during the welding process. Hardness tests were also carried out.

Introduction

Martensitic Stainless Steels belong to a category of high alloy stainless steels which exhibit lower carbon content and higher concentrations of alloying elements such as nickel. They were developed in the 1960s in order to increase the limited weldability of martensitic stainless steels for the construction and repair of hydraulic turbines and their components. Among the alloys belonging to this class of steels, the CA6NM grade presents attractive mechanical properties and solidification characteristics that enable casting of large sections, maintaining an almost uniform martensitic microstructure, even at very slow cooling rates. It facilitates the processes of construction and, also, the repair by welding[1] Due to these characteristics, the CA6NM has been typically used in the production of hydroelectric turbines due to its known high resistance to cavitation induced surface damages. Such turbines are normally manufactured in separate casting processes followed by heat treatment and surface finishing with subsequent coupling via a welding process, in which a similar filler material is used, normally the AWS 410 NiMo grade. Since the turbine runners parts have large thicknesses, typically the welding takes place in several layers in order to fill the joint cavity. After the welding process, normally the whole runner is taken to a final heat treatment, which takes place in big furnaces that provide a means to attain a uniform temperature over the entire part. Despite having

a higher cost compared to carbon steels, the CA6NM facilitated the repair operations during maintenance and reduced their frequency, thus decreasing the downtime of the machine.

The chemical composition of the alloy is shown in Table 1 and the typical mechanical properties of ASTM A743 CA6NM in the most usual condition of hardened and tempered is illustrated in Table 2.

Table 1: Chemical composition of the ASTM A743 CA6NM alloy [2].

Element	%wp
C	$0{,}06_{máx.}$
Mn	$1{,}00_{máx.}$
Si	$1{,}00_{máx.}$
P	$0{,}04_{máx.}$
S	$0{,}03_{máx.}$
Cr	11,50 – 14,00
Ni	3,50 – 4,50
Mo	0,40 – 1,00

Table 2: Mechanical properties of the CA6NM alloy in molten condition, hardened above 955 °C, cooled in air, and tempered [2].

Tensile strength (MPa)	Yield Strength (MPa)	Stretching on 50 mm (%)	Area Reduction (%)	Hardness (HV)	Charpy "V" (J)
827	689	24	60	284	94,9

Despite its higher resistance to cavitation surface damages, the CA6NM is still prone to fatigue cracks, which may result from the cyclic loading conditions at which the runner is subjected during operation. The cavitation erosion and the fatigue crack damages normally require the removal of material from the damaged area and the recovering of the original runner geometry by means of metal deposition using arc welding processes. Fig. 1 shows a crack caused in a turbine blade at ITAIPU hydroelectric power plant[3].

Figure 1: Damaged turbine from ITAIPU hydroelectric powerplant [3].

As outlined before, since the hydraulic turbine components involve large sections, the welds carried out for filling the joints, whether for repair or construction, are made in several layers. Note, therefore, the importance of investigating the behavior of these alloys and the deposited weld metals when they are subjected to multiple temperature cycles.

Therefore, this paper aims at investigating, through an experimental methodology, the effects of sequencial thermal cycles on the microstructure of the CA6NM stainless steel welded in multiple

layers with an 410 NiMo welding wire, in order to study the effect that a layered welding has on the base material and on the weld metal it self.

Methodology

The experiments involving the welding of the base metal CA6NM and 410 NiMo deposition were carried out in an experimental apparatus illustrated in Fig. 2, together with an ABB IRB 2000 welding robot, for controlling the welding torch movement. The experimental apparatus was developed for the study of the transient heat and mass flow involved in the welding of flat plates with small thicknesses, applied to the problem of fast prototyping by metal deposition in successive layers [4]

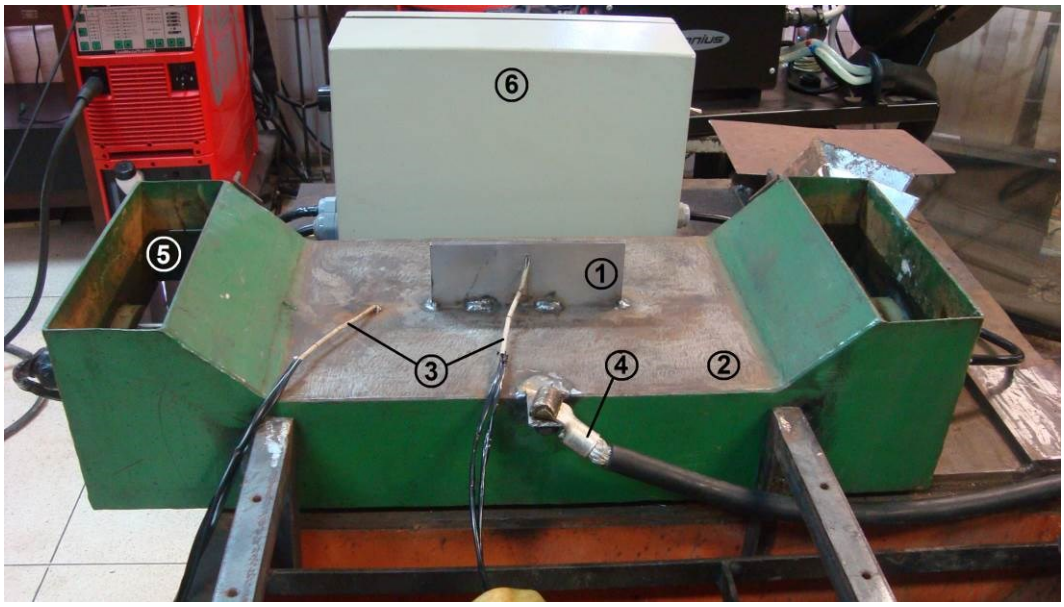

Figure 2: Experimental apparatus for the experiments of metal deposition welding in multiple layers.

In Fig. 2, it is possible to observe the experimental apparatus parts, indicated by numbers and described below:

1. Sample to be tested;
2. Warmed base;
3. K-type thermocouples, being the left one welded at the base and the right in the sample;
4. Ground connection of the welding equipment;
5. Water tank containing two electric resistances for heating;
6. Heating System Control panel.

The experimental apparatus consists horizontal flat surface (2) that is kept at an approximately constant temperature, provided by its permanent heat exchange with a temperature controlled water bath (5). A low thickness sample plate (1) is then spot welded vertically on the top of heated surface and the robot is programmed to move the torch forward along the upper border of the spot welded sample plate, such that it deposits one weld bead. After finishing it, the torch position is increased vertically (direction “y” in Fig. 3) by the amount corresponding to the height of the bead just deposited. The robot then waits for an input signal from the operator to proceed with a new weld deposition, moving the torch in the backwards direction. Such an input signal was issued every time the just deposited material reached 150 ºC (the interpass temperature indicated for layered welding with CA6NM and 410NiMo grades). This cicles is repeated until the desired number of weld runs is attained. Care was taken in the spot welding of the sample plate to provide good electrical and thermal contact with the heated base, were the power source negative connection was located (4). The procedure is showed in Fig. 3:

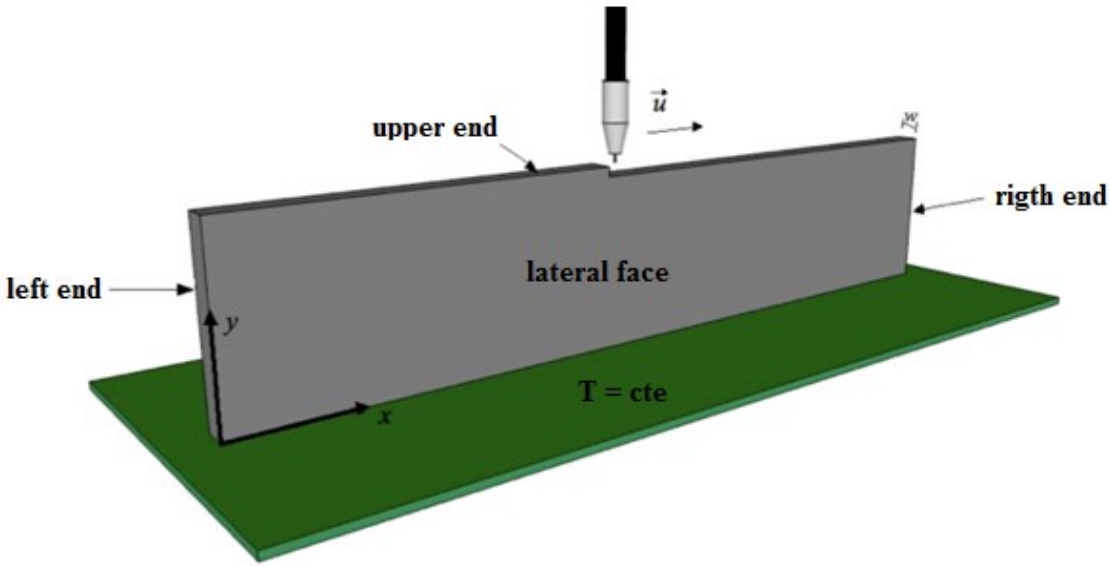

Figure 3: Illustration of the procedure used for the welding experiments [4]

To monitoring the temperature of the whole process, it was accepted that the weld interpass temperature dropped to 150°C, in order to avoid the stress concentration in the welding, facilitate the diffusion of hydrogen out of the weld process and promote tempering of the last weld layer. Twenty-two (22) weld layers were performed; being the location of the end of a step is the same as the beginning of the next step. Fig. 4 shows the equipment used to promote the thermographic monitoring.

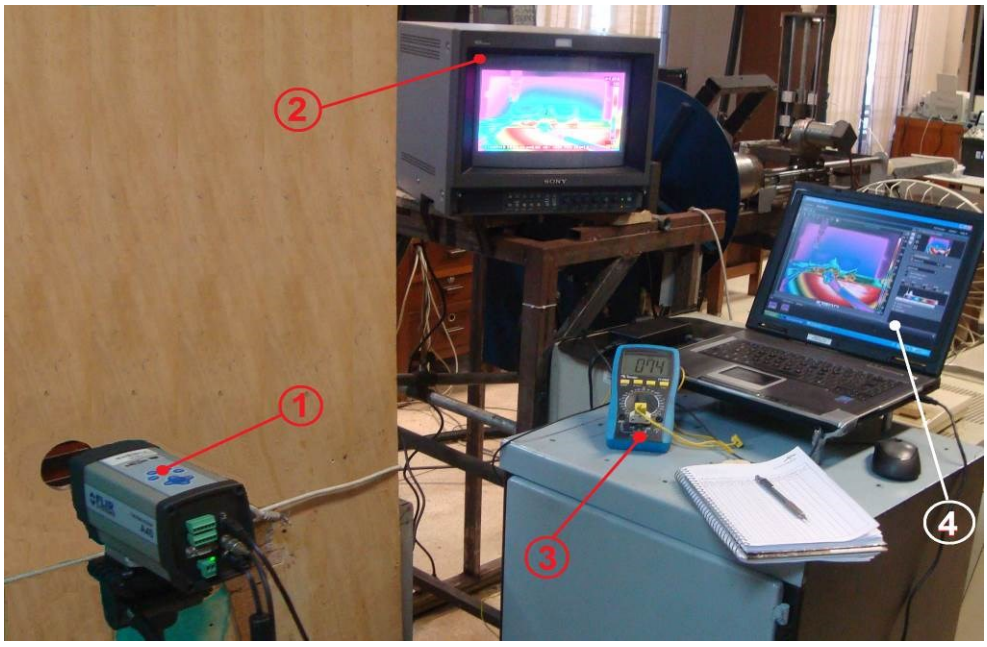

Figure 4: Used equipment for the thermographic monitoring of the welding.

Figure 4 shows the following equipments: (1) InfraRed Camera model ThermoVision A40 M, brand FLIR SYSTEMS™, firewire connection; (2) Sony™ 14" Monitor connected to the camera to control the camera parameters; (3) Digital Multimeter Model 187, brand FLUKE™, 180 series, for controlling the base and sample temperature; (4) Notebook brand ASUS with 3,07 GHz and 1,87 GB RAM memory.

Parameters required for the use of thermography as focal length, emissivity surfaces analyzed, relative humidity, temperature and temperature range to be analyzed, were allocated through measurements and parameters provided in the previous works. In order to investigate the microstructure of the base material (CA6NM) and the joint base material/addition material (410

NiMo) was chosen a sample for the study approximately with 64 mm in height, in the Y-Z plane. Choose the section to be analyzed, were realized consequent steps, such as cutting the sample in the required dimensions; Embed the sample in an appropriate acrylic resin for easy sanding; Realization of sanding the surface with sandpaper grain size from 180 to 1200; Polishing surface finishing, using Alumina 1μm; chemical etching using a Kalling n˚1 reagent, for identifying the phases presents; and microstructural analysis with an optical microscope. Fig. 5 presents the Y-Z section, chosen to be analyzed in the optical microscope.

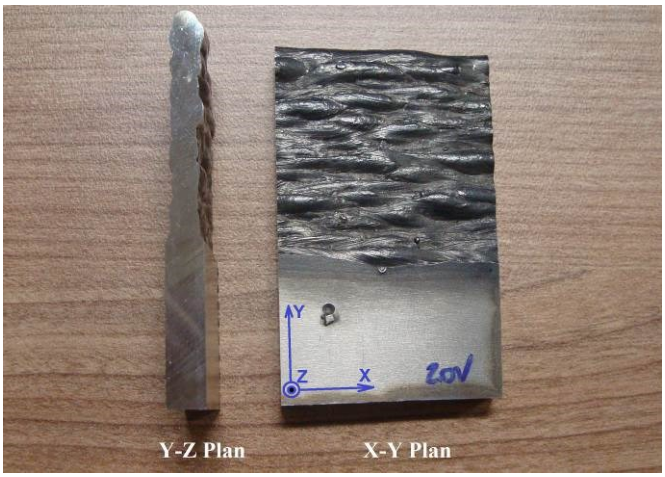

Figure 5: Y-Z Sections to be analyzed

Results and Discussion

The quality of the weld obtained by GMAW process is influenced by some parameters such as current intensity, voltage and arc length, welding speed, shielding gas, electrode type and position of the torch, their types and flow. The welding parameters found that provided better homogeneity, lower sparks, a suitable thickness for the base plate, increment close to the value determined as standard and less welding energy, are shown in Table 3.

Table 3: Defined parameters for the welding trials.

Welding Process: GMAW Short Circuit - Multiple Steps						
Interpass Temperature: 150˚C						
Base Material: ASTM A743 CA6NM						
Added Material: AWS 410 NiMo						
Sample Positioning	Number of Weld Beads	Speed of Wire Feed (m/min)	Speed of Torch Translatory (mm/s)	Tension (V)	Stand Off (mm)	Gas Flow (l/min)
Vertical	22	5,6	12,0	18,0	12,0	15,0

In the process of GMA welding, type short-circuit performed in this work it, was observed that the electrical contact is extremely important to the effectiveness of the welding process, i.e., if there is a contact resistance, the quality result of the weld bead and the process stability are compromised. Due to this fact it was adequate to use the ground connection in the experimental apparatus, in a manner that facilitates the passage of electrical current.

Throughout the time of the experiment happened the thermographic filming of the welding process (Fig. 6), being attentive to the temperature of the base (this always kept around 90°C) and the interpass temperature (that around 150°C as a condition for the beginning of the next step).

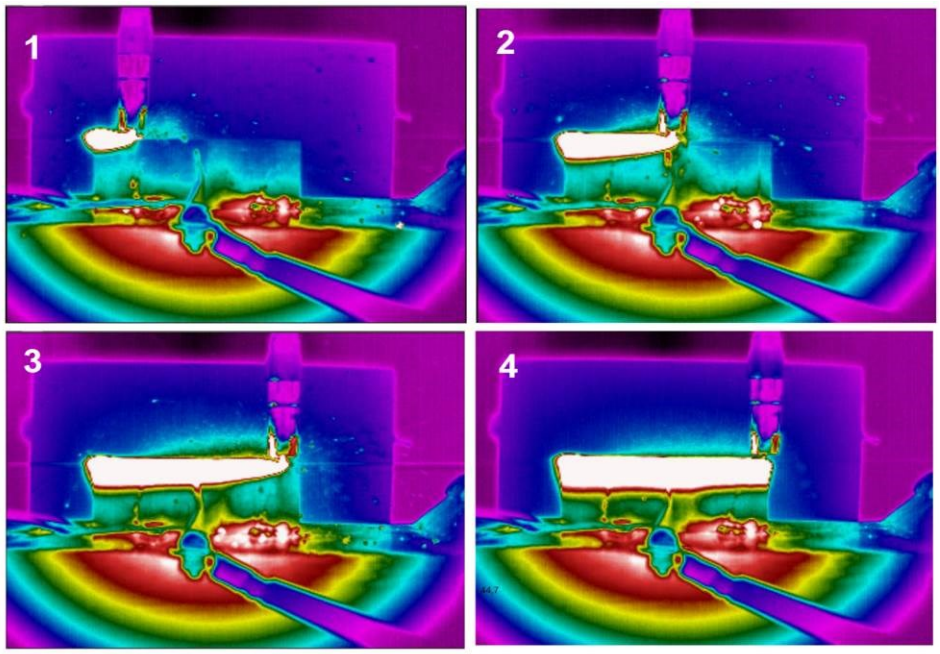

Figure 6: Thermographic monitoring of the GMA welding process.

The interpass temperatures expected, in course of time, can be evaluated in the graph of Fig. 7, together with an indication of each one of the 22 steps made in the weld tested sample.

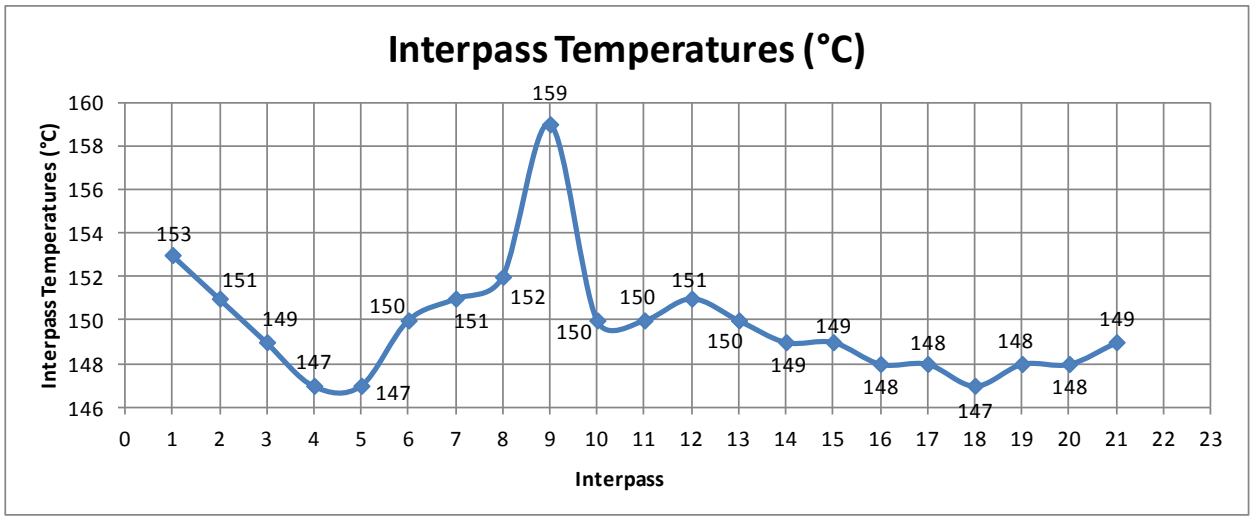

Figure 7: Interpass vs Interpass Temperature during the welding test.

Interpass temperatures varied a little around the 150°C, but remained in the expected value, with an average of 149,6°C. The average real increment was slightly higher than expected, and needed to be adjusted in the next tests. With the use of water as the fluid of the experimental apparatus, it can be seen that the maximum temperature obtained at base was 91,0°C.

It can be noted that in vertical welding condition requires the first 15 mm to equalize and stabilize their dimensions. This fact does not cause problems, since the repairs on the turbine blades require larger fillers and the sample taken for this study is located in the central region.

The metalography of the Y-Z plane, with chemically attacked and polished conditions of the sample, indicating areas of sampling, their microstructures with increased 500X, time attack by chemical reagent Kalling n°1, and their respective Vickers hardness HV10, can be enjoyed in Fig. 8.

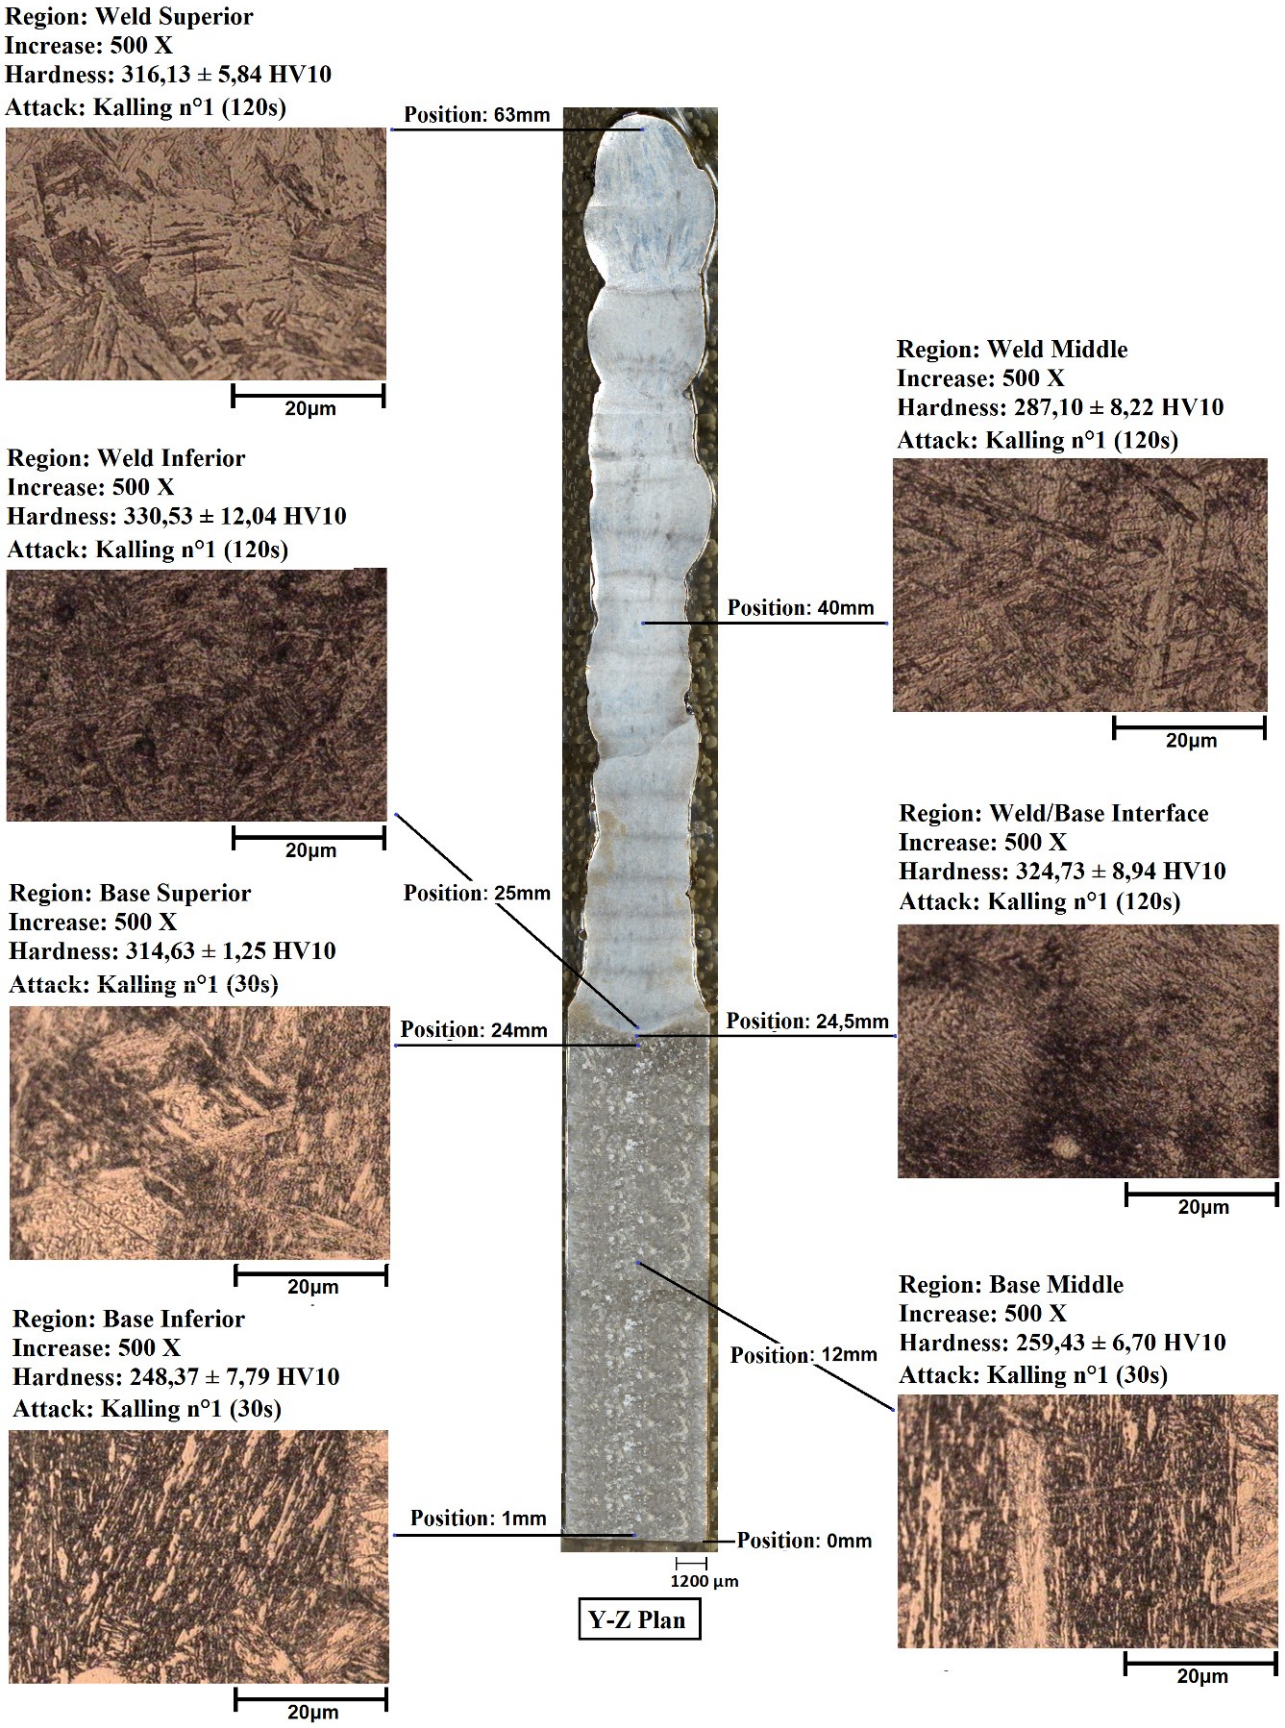

Figure 8: Metallography of the Y-Z plane of the tested sample with their respective hardnesses.

By analysis of the macrostructure above, it can be observed that each weld bead have the appearance of a heat affected zone as evidenced by a dark boundary of steps and provided from the different thermal cycles in which the sample has been subjected. There was found no defect welding

as lack of fusion, inclusions, cracks for retaining hydrogen, pores or cracks during phases of welding and metallographic analysis. The cooling rate low, outdoor, contributed to this fact.

The use of the of GMA welding process, short-circuit type, resulted in a weld bead with height ratio (amount of material added) and heat input proportional to the tests performed by Gouveia, 2008 [5]

The microstructure of the median and lower region of the base material, as evidenced by chemical attack is characteristic of a hardened and tempered material, consisting of a martensitic matrix and is consistent with the microstructure expected for the martensitic stainless steel ASTM A743 CA6NM according to literature [6]

The presence of inclusions - black spots - probably from gas welding [7]or from even their own alloy may be noted in the median region of the addition material in Fig. 8.

Conclusions

Through the micrographic analysis it was observed that the microstructure of the tested sample is predominantly martensitic. In the superior region of the base material, located on the heat affected zone, it can be found refined martensite from a tempering heat treatment. By the conducted analyzes, it wasn't possible to find in any of the regions the presence of ferrite, which would be evidenced by colored pieces. The microstructure of the interface, inferior and middle regions of the filler metal have a characteristic appearance of a weld bead heat-treated [8], as shown in Fig. 8. Based on the same micrographs, it can be concluded that after the 17th step of welding, the microstructure no longer has the appearance of heat-treated. After this welding pass, it is possible to determine a microstructure more dendritic and coarser, unlike the microstructures observed in the literature [8]

The resistance values of Vickers hardness found in the superior region of the base material, at the interface of the base material with the addition material, in the inferior region of the additional material, in the median region of the additional material and the superior region of the material addition are slightly higher compared to the values from the literature [1] [2] [9] (11:11%, 14.73%, 16.78%, 1.45% and 11.66% higher, respectively).

The results of hardness tests on the substrate is 18.78% lower than in deposition metal and in the interface region material has a hardness significantly increased (24.62%) compared to the substrate. This hardness increase in the interface region and in the bottom of the weld metal can be due to precipitation of carbides, requiring further investigation to confirm this fact. A reduction of impact toughness in additional material may also have occurred. Subsequent tests of resistance to fatigue and impact will be required to verify the occurrence of embrittlement of the heat affected zone.

The shield gases containing fractions of CO and CO_2 can lead to incorporation of increasing amounts of carbon in the weld metal, increasing its hardness. This fact can also be responsible for the increased hardness at the interface and in the lower portion of the additional material.

Keywords: Offshore Steel, Martensite, Bainite, Microstructure, CCT

Abstract. The purpose of this investigation is focused on two high strength low alloy steels for offshore application. TTT, CCT curves, Vickers depth profiles and microstructures of direct water quenched steels are evaluated in the experiment. Microhardness of the direct quenched surface is as high as 400 Hv, and the central region hardness of water quenched specimen is above 250 Hv. Martensite dominates the microstructure of quenched surface. In contrast, the mixture of martensite, bainite and ferrite is widely observed from the center of quenched specimen.

Introduction

Offshore steels belong to the category of high strength low alloy steel (HSLA) [1-3]. They are featured with high strength, better toughness and good weldability as compared with traditional low carbon steels. They have been widely applied in construction of bridge, pressure vessel, oil piping and the offshore wind power foundation [4]. The demand from clean energy such as wind power has been rapidly increased in recent years. For example, the floating turbine foundation is made of high strength low alloy steel, and the weight of each foundation is as high as 200 tons. Therefore, it is important to develop high-performance offshore steel applied in next generation.

Based on the NORSOK standard, S690Q steel is featured with high yield strength (> 690 MPa) and excellent low-temperature toughness (> 100 J at – 40 ºC) for the offshore application [5]. The chemical composition in weight percent of S690Q specification is 0.16 C (max.), (0.2-0.4) Si, (0.9-1.0) Mn, 0.015P (max), 0.005 S (max), (0.8-1.0) Ni, 0.65 Cr (max.), 0.5 Mo (max.), 0.4 Cu (max.), 0.08 Al (max.), 0.009 N (max.), 0.06 V (max.), 0.02 Nb (max.), 0.02 Ti (max.), 0.003 B (max.) and Fe balance [5]. Because the weldability of such a steel is crucial for offshore application, the carbon equilibrium content, C_{eq}, defined by International Institute of Welding (IIW) provides a standard for its chemical composition in weight percent as displayed in equation (1). Additionally, the critical metal parameter for weld cracking, P_{cm}, has been defined by Japanese Welding Engineering Society included in equation (2).

$$C_{eq}\,(IIW) = \%C + \%Mn/6 + (\%Cu + \%Ni)/15 + (\%Cr + \%Mo + \%V)/5 \quad (1)$$

$$P_{cm} = \%C + \%Si/30 + (\%Mn + \%Cu + \%Cr)/20 + \%Ni/60 + \%Mo/15 + \%V/10 + 5B \quad (2)$$

The chemical composition of designed S690Q grade steel should meet the requirements of C_{eq} (IIW) < 0.66 % and P_{cm} < 0.32 % [5].

Experimental Procedures

Chemical compositions in weight percent of two offshore steels designed as OS-A and OS-B are illustrated in Table 1. Chemical compositions of both OS-A and OS-B steels meet the NORSOK S690Q standard. There is a minor difference between these two alloys due to V addition. According

to equations (1) and (2), C_{eq} (IIW) and P_{cm} of the above steels are 0.45 (< 0.66) and 0.22 (< 0.32), respectively. Two steel plates were experienced direct water quench from 900 ºC after hot rolling. Dimension of two steel plates was 200 mm in width, 1000 mm in length and 50 mm in thickness. Specimens were machined perpendicular to rolling direction in order to perform metallographic examination and microhardness test. The specimens were cut, mounted and etched by 2% nital prior to metallographic inspection. Metallographic specimens were examined by using a Nova 450 field emission scanning electron microscope (FESEM). Its operation voltage was 15 kV, and the minimum spot size was set at 1 μm. Vickers microhardness tests of cross sections of OS-A and OS-B steels after direct water quench were performed using Mitutoyo HM microhardness tester with the load of 500 g and duration time of 15 s. CCT and TTT curves are simulated by JMatPro software for comparison's purpose.

TABLE 1 CHEMICAL COMPOSITIONS IN WT% OF TWO DESIGNED OFFSHORE STEELS

Alloy	C	Si	Mn	P	S	V	Fe	others	Ceq (IIW)/Pcm
OS-A	0.1	0.3	0.9	0.01	0.001	0.0	balance	< 1.75	0.45 / 0.22
OS-B	0.1	0.3	0.9	0.01	0.001	0.03	balance	< 1.75	0.45 / 0.22

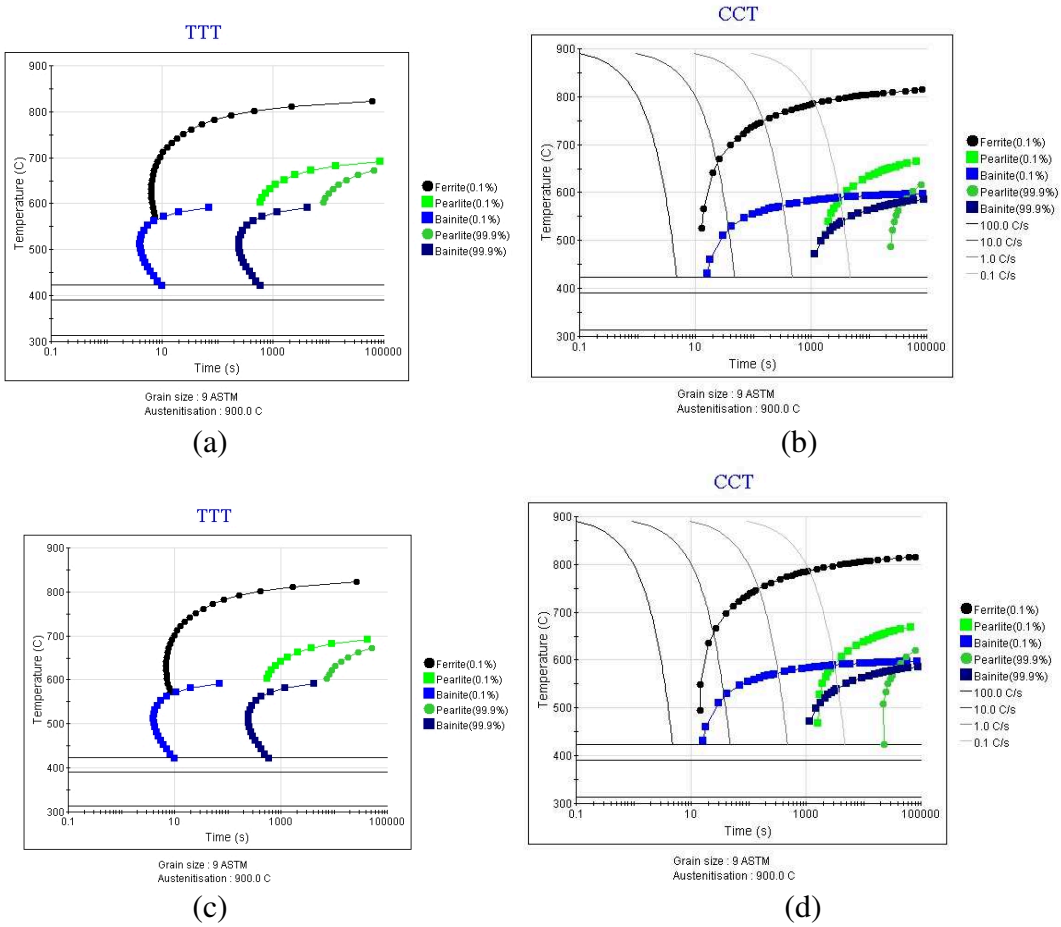

Fig. 1 (a) TTT, (b) CCT Curves of OS-A and (c) TTT, (d) CCT Curves of OS-B Steels Based on JMatPro Software Simulations.

Results and Discussion

Fig, 1 shows TTT and CCT diagrams of two steels based on JMatPro simulation results. Similar TTT and CCT diagrams of two steels are observed from the figure. According to the figure, pearlite will not formed in the specimen direct water quenched from 900 °C. Martensite will be formed on the quenched surface, and proeutectoid ferrite and bainite are formed in the center of specimen due to slower cooling rate.

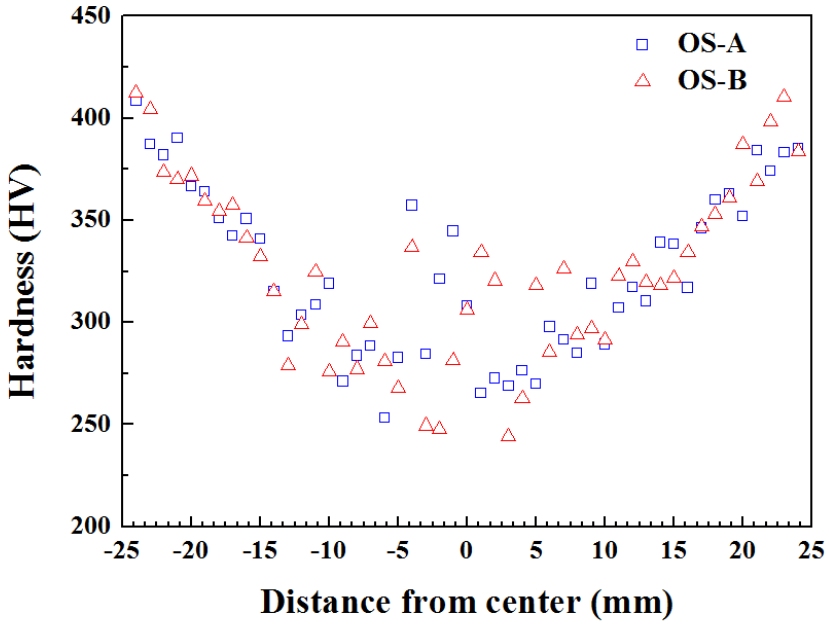

Fig. 2 Microhardness Depth Profiles of OS-A and OS-B Steels after Direct Water Quench.

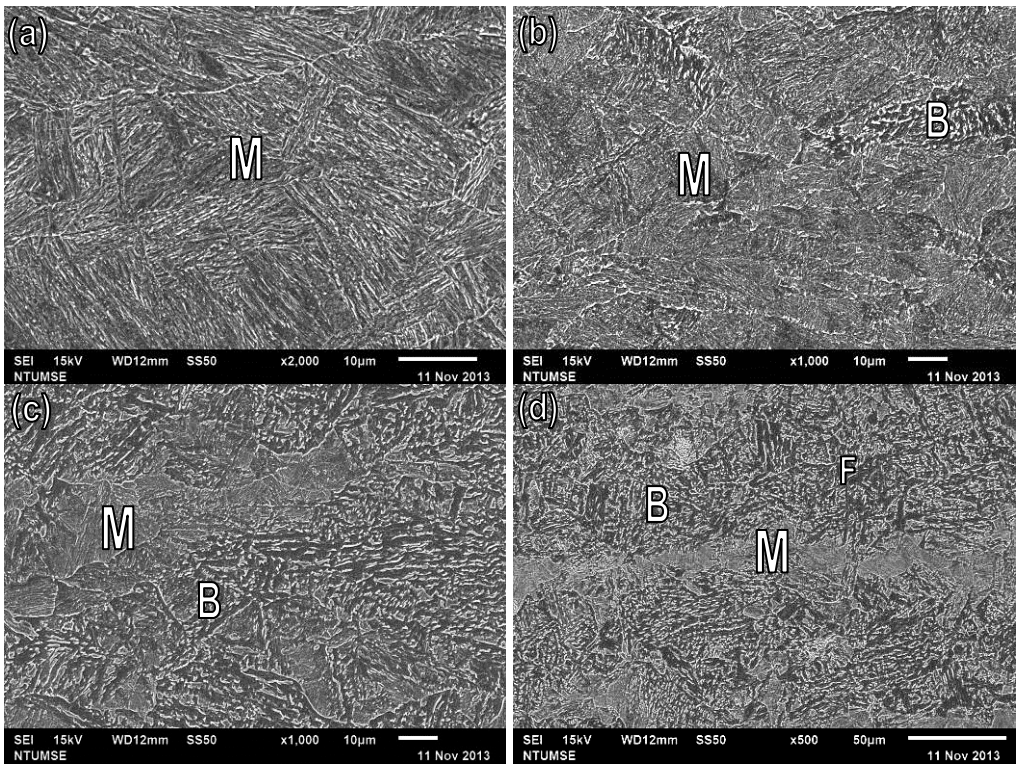

Fig. 3 Metallographic Examination of OS-A Steel at Depths of (a) 5 mm, (b) 10 mm, (c) 20 mm, (d) 25 mm (center) from the Direct Water Quenched Surface. (M: Martensite, B: Bainite, F: Ferrite)

Fig. 2 shows microhardness depth profiles of OS-A and OS-B steels after direct water quench. The microhardness of OS-B specimen at surface is slightly higher than that of OS-A specimen. Minor V addition, 0.03 wt%, slightly increases the hardenability of OS-B steel. The hardness of specimen's surface is approximately 400 Hv. In contrast, the lowest hardness in the central region of steels is 250 Hv. It is worth mentioned that measured microhardness data are scattered in the central region of the specimen as illustrated in Fig. 2. The scattered hardness data are resulted from multiple phases in the center of specimen.

Fig. 3 displays FESEM SEIs (secondary electron images) of OS-A steel after direct water quench from 900 ºC at various depths below the quenched surface. The microstructure of 5 mm below the quenched surface is primarily dominated by martensite as shown in Fig. 3(a). Increasing the depth below the quenched surface results in increasing the amount of bainite and ferrite as illustrated in Figs. 3(b) - 3(d). The amount of martensite at center of specimen is below 50 %, and its microstructure is dominated by bainite and ferrite (Fig. 3(d). Because the hardness of martensite, bainite and ferrite is quite different, microhardness of these multiple phases is scattered in the center of specimen. It is consistent with the aforementioned results (Fig. 1 and Fig. 2). Fig. 4 displays FESEM SEIs (secondary electron images) of OS-B steel after direct water quench from 900 ºC at various depths. Microstructures of OS-B at different depths below the water quenched surface are very similar to those of OS-A specimen.

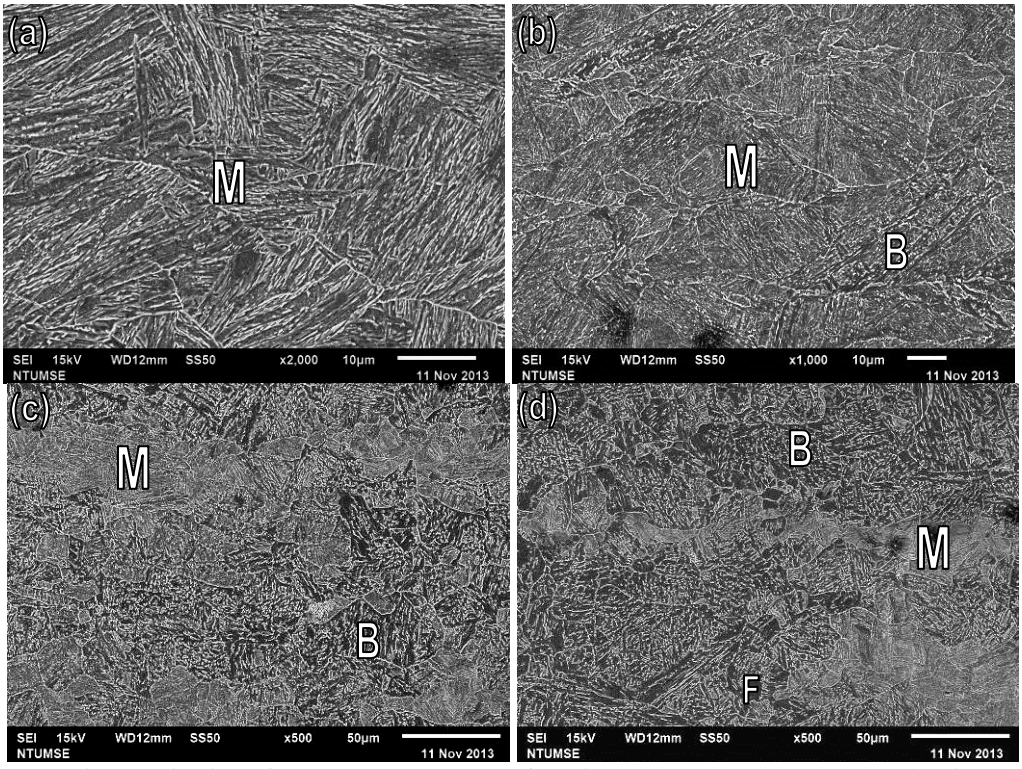

Fig. 4 Metallographic Examination of OS-B Steel at Depths of (a) 5 mm, (b) 10 mm, (c) 20 mm, (d) 25 mm (center) from the Direct Water Quenched Surface. (M: Martensite, B: Bainite, F: Ferrite)

Summary

TTT, CCT curves, Vickers depth profiles and microstructures of two direct water quenched steels for offshore application are evaluated in the experiment. Martensite is observed from the quenched surface. Increasing the depth below the quenched surface results in increasing the amount of bainite and ferrite due to insufficient hardenability of the steels and slower cooling rate at center of specimen. The scattered microhardness depth profiles are resulted from multiple phases in the center of specimen. The experimental results are consistent with TTT and CCT curves simulated by JMatPro software.

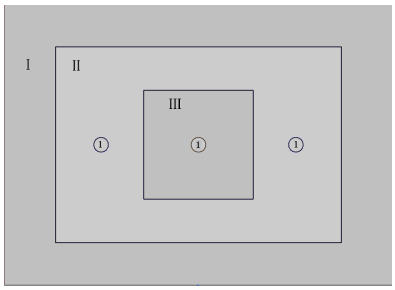
Keywords: water-cooled stool; finite element; unidirectional solidification; temperature field; numerical simulation



Abstract: To strengthen the bottom cooling is one of the key technologies of directionally solidified ingot process. Stool cooling scheme has a significant impact on the solidification process of the ingot. The study optimizes chassis cooling scheme according to the air gap between the ingot and the stool. With multiple sets of cooling system, water-cooled stool makes the basal water cooling adapt to air gap distribution through subregional cooling of different intensity control, and be uniform with it in the longitudinal direction solidification. The paper establishes mathematical model of unidirectional solidified ingot on temperature field of conventional water-cooled stool and improved one respectively. By the aid of finite element analysis method, numerical simulation of 45t ingot with algebraic model is carried out. In order to optimize parameters of ingot unidirectional solidification, temperature fields influenced by conventional water-cooled stool and improved one in the process of unidirectional solidification are simulated. The numerical results show that the optimized chassis cooling can result in the ingot in a longitudinal uniform solidification. The numerical simulation results can provide important reference for the optimization of unidirectional solidification process.

The solidification process of casting in which most of shrinkage, dispersed shrinkage and crack are produced is one of the most important processes in the production of casting [1]. There is a consistent request of lowering the manufacturing cost in industry. In the past, process improvement was achieved by trial and errors. The experiments demand a high effort and large resources. Using numerical simulation not only would allow for more economical and efficient operations. But also predictions on microstructure changes with respect to change in operation conditions can be easily made. This would help to reduce the formation of defects in a cast and thus improve quality of the finished product [2].

Production technology of directional solidified ingot is mainly reflected in three aspects which include stool cooling, lateral wall and surface insulation above the liquid. Among them, the inhibition of lateral wall heat transfer is the principal symbol which distincts from ordinary steel ingot, guarantees the heat flow and significantly reduces the ingot segregation; stool cooling scheme has a significant impact on the solidification process of the ingot. The rational chassis cooling can make the initial solidified shell unbroken contact with the chassis and improve the cooling rate of solidification process; the ingot can be in a uniform longitudinal solidification. A common practice is to use the thick and large chassis. The other is forced cooling, usually with water. YAMAGUCHI Toshiyuki et al. thinks that whole thick stool in the past had to be changed after the use of certain times, so the cost was too high, but if it is divided into two parts, only the upper one needs to be changed after damage so that the cost can be decreased, but the combination of upper and lower between the two plates is not tight and will form a heat insulation layer. Therefore, inventors set the cooling water loop on the upper part of the lower plate, and control the cooling intensity by the flow of cooling water. Only the upper part which is easier to be damaged needs to be replaced normally. In this way, not only the cost is reduced but also the cooling intensity

is ensured. Therefore, the inventors open groove or inclination on the insulation material which in the side wall, thereby limiting the reverse curls, strengthens the cooling, and increasing the directional solidification of ingot height, with a relative reduction in the volume. However, this approach may have the problem of forging [3].

This paper presents a new improved cooling chassis for directional solidification (geometric model of optimized water-cooled stool and the finite element model as shown in Fig.1 and Fig.2); the water cooling chassis consists of three blocks, laid inside the snake-shaped cooling pipe. Specific measure is to cool for subregion with different strength from the center to the periphery direction by adopting multiple sets of cooling system, hence has a greater effect cooling intensity in the center of the chassis and minor effect one around the chassis. At the same time, the study establishes the mathematical model on the temperature field of heavy steel ingot and compares with conventional water-cooled stool and simulates numerically in order to optimize the chassis cooling parameters.

Mmathematical Model for the Heat Transfer in The Solidification

Basic Assumptions

The simulation process needs to be set as close as possible to the actual conditions, but it is impossible to simulate all the phenomena and behavior considering the characteristics of heavy plate ingot solidification during the solidification process. Therefore, the following hypotheses for the computing model on the temperature field of a large ingot solidification process are made [4-7]:

1. The liquid metal starts to coagulate after instantaneous filling the cast. This assumption underlies some initial conditions. Regarding the generous plate steel spindle, this supposition will not cause too much error, because its solidification time is much longer than the casting time;

2. This paper adopts the view of E A Mizikar, without considering the liquid, solid phase flow, heat transfer can be compensated by ignoring internal convection through appropriate amplification liquid metal thermal conductivity;

3. As constant, density does not change with temperature;

4. The metal heat and the thermal conductivity use the effective specific heat and the effective thermal conductivity separately;

5. Calculations involving materials are isotropic;

6. Solidification is in equilibrium conditions;

7. The ingot deformation and volume changes can be ignored.

Controlling Equation

Mass conservation equation：

$$\frac{\partial \rho}{\partial \mathrm{t}}+\frac{\partial(\rho_{\mathrm{u}})}{\partial x}+\frac{\partial(\rho_{\mathrm{v}})}{\partial y}+\frac{\partial(\rho_{\mathrm{w}})}{\partial z}=0 \tag{1}$$

Energy conservation equation：

$$\rho \frac{\partial(\partial H)}{\partial t}+\rho \frac{\partial H}{\partial T}\left[u \frac{\partial T}{\partial x}+v \frac{\partial T}{\partial y}+w \frac{\partial T}{\partial z}\right]=\frac{\partial}{\partial x}(k \frac{\partial T}{\partial x})+\frac{\partial}{\partial y}(k \frac{\partial T}{\partial y})+\frac{\partial}{\partial z}(k \frac{\partial T}{\partial z}) \tag{2}$$

Changes of a specific position in casting can be defined as

$$H(T)=\int_0^T C_P dT+L[1-f_S] \tag{3}$$

Where ρ is the density(Kg · m^{-3})， t is the time(*s*)， *u*, *v* and *w* are velocity component in the direction of the *x*, *y* and *z* (m · s^{-1})，*H* is enthalpy (J · mol^{-1})，*T* is temperature(k)；*k* is permeability (W · m^{-1} · ℃$^{-1}$)； C_p is specific heat (J · Kg^{-1} · K^{-1})， *L* is latent heat(J · kg^{-1})， f_s is fraction solid.

Boundary Conditions and Initial Conditions

The determination of boundary conditions

For this study on 45t heavy plate ingot, ingot bottom surface in contact with water-cooled stool is transformed into the third boundary condition, while centrosymmetric surface of ingot and outside insulation are transformed into the second [8-10].

Upper surface of ingot： $$K\frac{\partial T}{\partial x}=q \tag{4}$$

Downward surface of ingot： $$q=h(T_b-T_f) \tag{5}$$

Ingot around: $$\frac{\partial T}{\partial x}=0 \tag{6}$$

Ingot centre： $$\frac{\partial T}{\partial x}\Big|_{x=d/2}=0 \tag{7}$$

x = d / 2 is half thickness of ingot.

Where： K —Thermal Conductivity Coefficient，W/m℃,

q —Heat Density，W/m2,

h —Heat Exchange Coefficient，W/m2℃,

T_b —Downward Surface Temperature of Ingot，℃,

T_f —Temperature of Cooling Water，℃.

Heavy plate ingot solidification process belongs to the one-dimension unsteady state heat conduction problem, for the initial conditions and three kinds of boundary conditions can be treated with the following form

$$A_T T+B_T Q=C_T \tag{8}$$

In the equation：

T —Temperature of side（wall），K,

Q —Heat flow density through the wall，W/m^2,

A_T， B_T， C_T —Constants according to the boundary conditions.

The determination of initial conditions

For casting process, the study ignores the influence of the filling process on the initial temperature field because the solidification time is considerably longer than the casting time of casting. So take

$$T\,(x,0)=T_C \tag{9}$$

$$T\ \text{Environment}=0 \tag{10}$$

In the equation： T_C — pouring temperature，℃.

Selected steel components for simulation are shown as Table 1, the solid–phase in temperature of 1393℃, the liquids in temperature of 1520℃, and thermo physical parameters curve of steel for calculation are shown in Fig.3. In the simulation process, the heat transfer coefficient of conventional water-cooled stool is set to 5000W/m**2/K, and the improved one which is divided into three parts are set to 20000W/m**2/K，10000W/m**2/K，5000W/m**2/K respectivly from inside to outside.

Table 1 Chemical Composition Of Calculation

C	Si	Mn	P	S	Ti	Ni	Cu	Mo

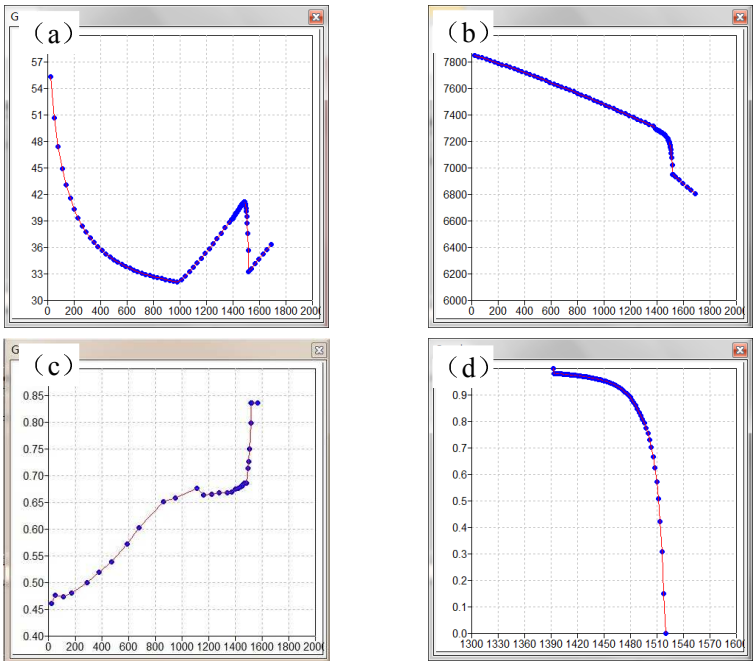

Fig.3 Thermo physical parameters curve of steel for calculation: a) conductivity b)density c) specific heat d)fraction solid

Temperature Field of Directional Solidification

Studying temperature field is a research interesting in casting and solidification processing. These results can provide guidance for production and further investigation. There are experimental methods and computer simulation methods in temperature field investigation. Among them, computer simulation is a very good, helpful and timesaving method. The ultimate goal of numerical simulation on casting solidification process is to optimize the process design and to realize the casting quality prediction. By using finite software ProCAST, temperature field influenced by conventional water-cooled stool and improved one in the process of unidirectional solidification is analyzed.

Fig.4 and Fig.5 show temperature field distribution on 45t directionally solidified ingot solidification with conventional water-cooled stool and improved one when simulation time is 8000s, 13000s, 20000s and 30000s respectively.

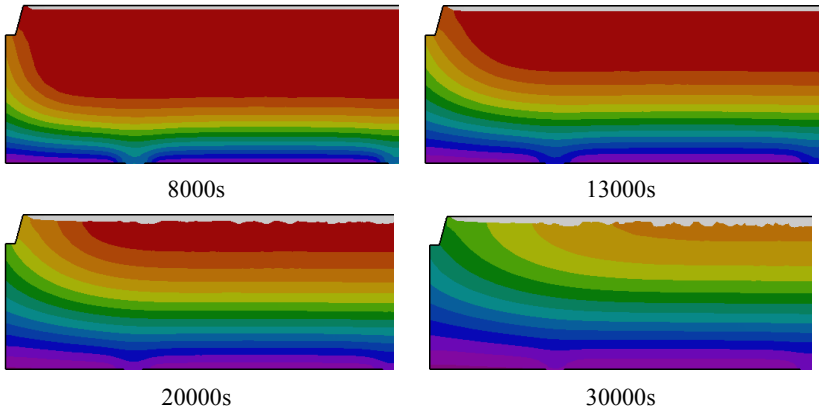

Fig.4 Temperature field distribution of directionally solidified ingot with conventional water-cooled stool

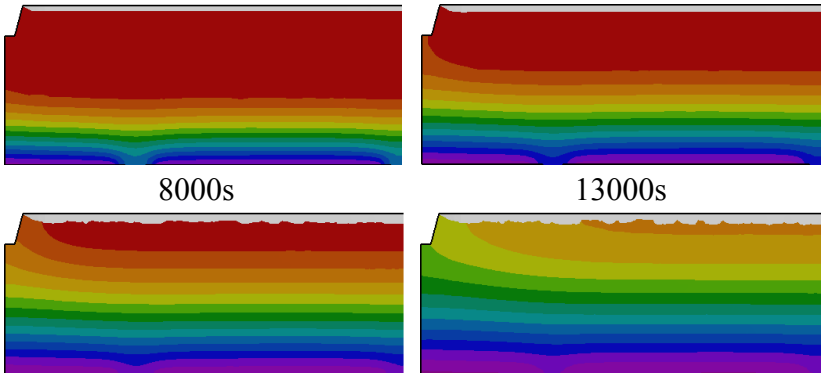

Fig.5 Temperature field distribution of directionally solidified ingot with improved water-cooled stool

From Fig.4 and Fig.5, we can see that the axial active heated temperature region gradually extends to the top from bottom of ingot along with the extension of solidification time. But solidification speeds of different parts are not identical, the bottom of ingot solidified firstly and finally the riser. Lower parts of ingot have a larger vertical temperature gradient at the initial stage of solidification. As time goes on, cooling effect decline obviously and vertical temperature gradient descends. While in the middle section, the liquid phase keeps invariant and then vertical temperature gradient increases but changes a little with temperature fall. The upper of ingot began at liquids, and temperature decreases as time goes by, and temperature gradient near the top increases. Directionally solidified ingot solidification with conventional water-cooled stool causes edge curve heavily. While improved one makes solidification front pushed smoothly and evenly to the top of the ingot with the solidification and promotes the directional solidification.

Conclusions

By subregional cooling of different intensity control with water-cooled stool which adopts multiple sets of cooling system, basal water cooling and air gap distribution are adapted to each other, and uniform solidification in the longitudinal direction is promoted. The two-phase zone between the solidified part and liquid steel is limited at the same time. The solidification front is pushed smoothly and evenly to the top of the ingot with the solidification. Solidification process becomes a natural refining process. The chemical composition of the body which is below the top is homogenized and inclusions can be refined and homogenized.

Keywords: Thermodynamics calculation, Calcium treatment, Sulfide inclusions, Gear steel

Abstract: Based on the thermodynamic calculation, the conditions of calcium treatment to sulfur gear steel are analyzed and the samples of rolled steel are studied. Results show that Calcium treatment to melting steel after RH refining can make the sulfide inclusions and calcium aluminates bind together and form the spindle shaped low melting compound inclusions. In the meanwhile, controlling of w(O) in steel below 0.0012% before calcium treatment is more beneficial to modify the Al_2O_3 and sulfide by the added calcium and to form the oxide-sulfide compound inclusions only if w(Al_S) in steel is adjusted to 0.015%~0.025% before continuous casting. The Ca wire should also be fed at higher temperature.

Introduction

High strength and good mechanical properties are two main characteristics of gear steel[1]. The mechanical properties can be improved by adding sulfur in gear steel. But the sulfide inclusions rating cannot exceed level 3 by the requirements in 20CrMo sulfur gear steel. So the shape of MnS should be modified by calcium treatment and MnS can also be bound together with Al2O3 or CaS to form spindle shaped with low melting point compound inclusions[2]. This type of inclusion is beneficial to the properties of steel[3]. In order to reduce the content of [O] in 20CrMo gear steel, the aluminum is used for deoxidization during tapping. Calcium treatment is used to modify the remained Al2O3. But improper calcium treatment will affect the casting properties of steel. In this paper, the controlling technology of calcium treatment of sulfur 20CrMo gear steel is analyzed and studied comprehensively by thermodynamic calculations.

Analysis on Thermodynamic of Calcium Treatment

The production process of 20CrMo gear steel is Converter, LF refine, RH refine and Continuous casting. The total content of [O] in 20CrMo sulfur gear steel should be controlled less than 12×10-6 and the aluminum is used for deoxidization in the production process. The calcium wire is fed after RH process and the sulfur wire is fed after the calcium treatment. The chemical composition of the steel is shown in Table1.

TABLE 1 CHEMICAL COMPOSITION OF STEEL %

Element	ω（C）	ω（Si）	ω（Mn）	ω（Cr）	ω（P）	ω（S）	ω（Mo）	ω（Al）
Mass fraction	0.16	0.27	0.56	0.94	0.022	0.021	0.1742	0.015

Element interaction coefficient is consulted to Refer 4 and activity coefficient of elements is calculated by formula of Refer 5.

TABLE 2 ACTIVITY COEFFICIENT OF ELEMENTS IN 1873K

Element	Mn	S	Ca	Al	O
Activity coefficient	1.25	0.85	0.000147	1.09	0.24

Thermodynamic of the Modification of Al2O3 by Calcium Treatment

Calcium is used mainly for improving castability of steel and the castability is improved by the reaction between calcium and Al_2O_3 particles in the steel. The Al_2O_3 would be modified into different types of calcium aluminates by adding calcium according to the different Ca content.

Al_2O_3 $CaO{\cdot}6Al_2O_3$ $CaO{\cdot}2Al_2O_3$ $CaO{\cdot}Al_2O_3$ $12CaO{\cdot}7Al_2O_3$ $3CaO{\cdot}Al_2O_3$ CaO

The chemical reaction can be expressed as follows.

$$3[Ca]+Al_2O_3=3CaO+2[Al] \qquad \Delta G^{\theta} = -706200 + 60.6T$$

$$K = \frac{([Al\%]f_{[Al]})^2 a^3_{CaO}}{([Ca\%]f_{[Ca]})^3 a_{Al_2O_3}}$$

In order to avoiding nozzle clogging, the low melting calcium aluminates is the aim inclusion to be expected. The characteristic of each calcium aluminates is showed in Table 3.

TABLE 3 CHARACTERISTICS OF CALCIUM ALUMINATES

Inclusion	Density（$g{\cdot}cm^3$）	Melting point（K）
$CaO{\cdot}Al_2O_3$	2.98	1878
$CaO{\cdot}2Al_2O_3$	2.91	2023
$CaO{\cdot}6Al_2O_3$	3.28	2123
$3CaO{\cdot}Al_2O_3$	3.04	1808
$12CaO{\cdot}7Al_2O_3$	2.83	1728

The activity value of CaO and Al_2O_3 in CaO-Al_2O_3 system of different models and experimental measurements are not uniform and showed in Refer 2. The Korousic classic theoretical model is more applicable for aluminum killed steel[6]. The relationship of [Ca] and [Al] in $CaO{\cdot}Al_2O_3$, $3CaO{\cdot}Al_2O_3$, $12CaO{\cdot}7Al_2O_3$ in 1873K are calculated with Korousic classic theoretical model.

TABLE 4 ACTIVITY VALUE OF CAO AND AL2O3 IN 1873K BY KOROUSIC MODEL

Calcium aluminate	a_{CaO}	a_{Al2O3}
$CaO{\cdot}Al_2O_3$	0.08	0.039
$3CaO{\cdot}Al_2O_3$	1	0.0050
$12CaO{\cdot}7Al_2O_3$	0.36	0.038

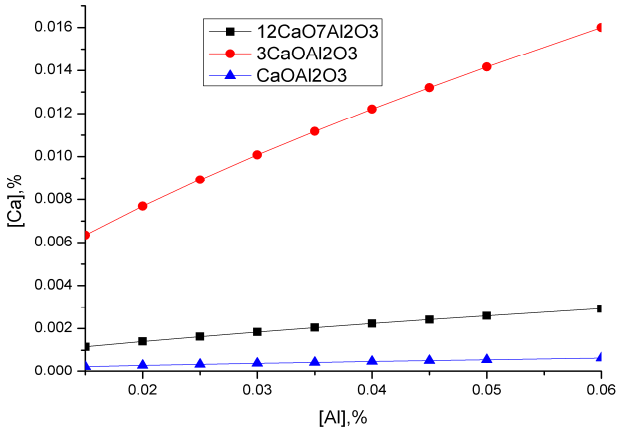

Fig. 1 Relationship Between [Ca] And [Al] In Different Calcium Aluminates In 1873k

To change the Al_2O_3 into $12CaO{\cdot}7Al_2O_3$ and $3CaO{\cdot}Al_2O_3$, the content of [Ca] should be controlled about 0.002% and 0.01% separately while the content of [Al] is 0.03%. The results also show that the Al_2O_3 can be changed into $CaO{\cdot}Al_2O_3$ only if the content of [Ca] is low. In order to get more low melting point inclusion($12CaO{\cdot}7Al_2O_3$), the content of [Ca] after the calcium treatment should be adjusted about 0.002% during the process.

Relationship between [O] and [S] by Calcium Treatment

Calcium is used mainly for improving castability of steel and it can also be used to change the sulfides. Ca is an element with extremely high affinity to oxygen and sulfur. And the content of [S] in 20CrMo gear steel is about 0.021%. In order to avoid the appearance of CaS, the S wires should be fed 5minutes late after Ca wires fed. The following reaction will occur while the calcium is fed into steel.

$$[Ca]+[O]=(CaO) \qquad \Delta G^{\theta}=-645421+146T$$

$$[Ca]+[S]=(CaS) \qquad \Delta G^{\theta}=-530312+118.63T$$

Because of the high melting point of CaO and CaS, the activity of them is 1. The average temperature of steel after RH process is about 1893K. So the equilibrium between the [Ca]-[O]-[S] at 1893K is shown in Fig.1.

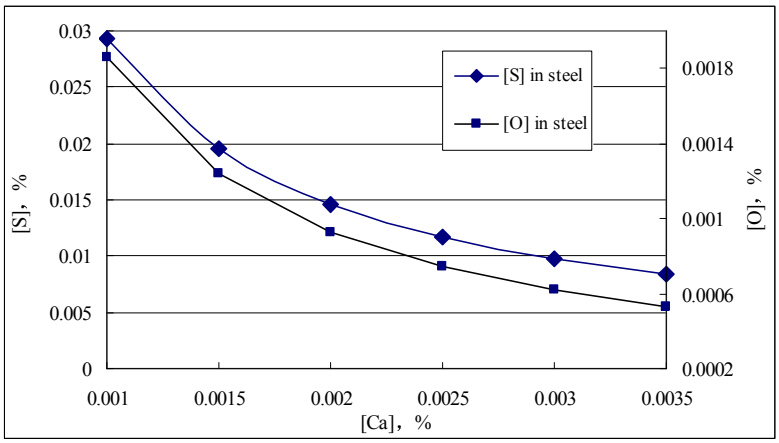

Fig.2 The Equilibrium between [S] and [O] and [Ca] at 1893K

According Fig.2, in order to avoid the simple CaS particle after calcium treatment, the content of [Ca] should be controlled less than 0.0015% before the S wire is fed. And in order to avoid the CaO after calcium treatment, the content of [O] should be controlled less than 0.0012%.

The Equilibrium of [Al] and [S] by Calcium Treatment

Since Ca has such a strong affinity to sulfur, it can react and transform sulfur existing in the melting steel to CaS. The reaction of [Al] and [S] in $CaO\text{-}Al_2O_3$ compound inclusion in aluminum killed steels after calcium treatment is shown below[6].

$$3CaO + 2[Al] + 3[S] = 3CaS + Al_2O_3 \qquad \Delta G^{\Theta} = -907104 + 317.7T$$

$$K = \frac{a_{Al_2O_3} a^3_{CaS}}{a^3_{CaO}([Al\%]f_{[Al]})^2([S\%]f_{[S]})^3}$$

The chemical reaction is carried on continuously by large amount of [Als] in steels. In order to reduce the number of high melting point inclusions, the content of [Als] should meet the demands of thermodynamics conditions to modify Al_2O_3 into $12CaO\cdot 7Al_2O_3$ while calcium treatment. The relationship is shown in Fig 3.

According to Fig.3, the reaction is influenced by temperature and the content of [Al] in steel. When the temperature is 1923K, 1873K, 1823K and the [Al] content is 0.02%, the balance content of [S] is separately 0.023%, 0.017% and 0.009%. The relationship shows that the balance content of [S] reduces with the temperature. In order to reduce the content of [S] and modify more low melting-point inclusions, the Ca treatment must be taken in high temperature. For the reason that MnS can not produce when the temperature is high, reaction in high temperature is beneficial for the combination between CaS and Al2O3. In the meanwhile, the segregation of S is reduced and the production of the reaction can also provide core for MnS to modify into spindle shaped inclusions. The average temperature in the product process after RH refining is 1893K and the temperature meet the demands of Ca treatment. According to the required content of [S] and the thermodynamics condition of $12CaO\cdot 7Al_2O_3$, the content of [Al] must be adjusted to 0.015%~0.025%.

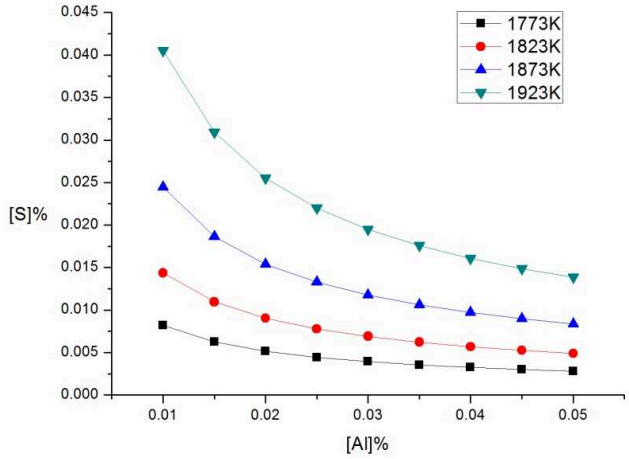

Fig 3. Relationship between [Al] and [S] in 12CaO·7Al2O3

Effect of the Inclusion Control in Rolled steel Using Calcium Treatment

The morphology of the inclusions is well controlled after the process and the number of inclusion is few and the inclusions are well distribution. There are also little long strip of MnS

inclusions to be found. But for the smelting conditions and other factors, a small amount of long strip inclusions can be found in some rolled steels. The samples of rolled steels are collected randomly and the inclusions are determined. The results of the test of rolled steels are showed in Table 5.

TABLE 5 THE TEST RESULTS OF 20CRMO ROLLED STEELS

No.	A type		B type		C type		D type	
	thick	thin	thick	thin	thick	thin	thick	thin
1	1.0	2.5	0.5	0.5	0	0	0	1.0
2	1.5	2.5	1.5	2.0	0	0	0	1.0
3	1.0	1.0	1.0	1.0	0	0	0	0.5
4	2.5	2.0	2.5	2.0	0	0	0	1.0
5	1.5	1.0	2.0	2.0	0	0	0	0.5
6	1.0	0.5	1.0	1.5	0	0	0	0.5

According to the requirements, the sulfide inclusions in 20CrMo rolled steels can't exceed 3 level. And the results show that the inclusions in steels are less that 2.5 level. Above all, the calcium treatment has been able to achieve good results on 20CrMo gear steel. And the occurrence of nozzle blocking has been decreased and the quality of the steel has been improved since calcium treatment. The morphology and composition of the compound inclusions are show in Fig.4.

Most of the inclusions in rolled steels are calcium aluminates compound inclusions with MnS around them. The results show that calcium treatment is more beneficial to modify the inclusions of Al_2O_3 and sulfide by adding calcium and to combine the oxide and sulfide into compound inclusion with oxide as its nucleus.

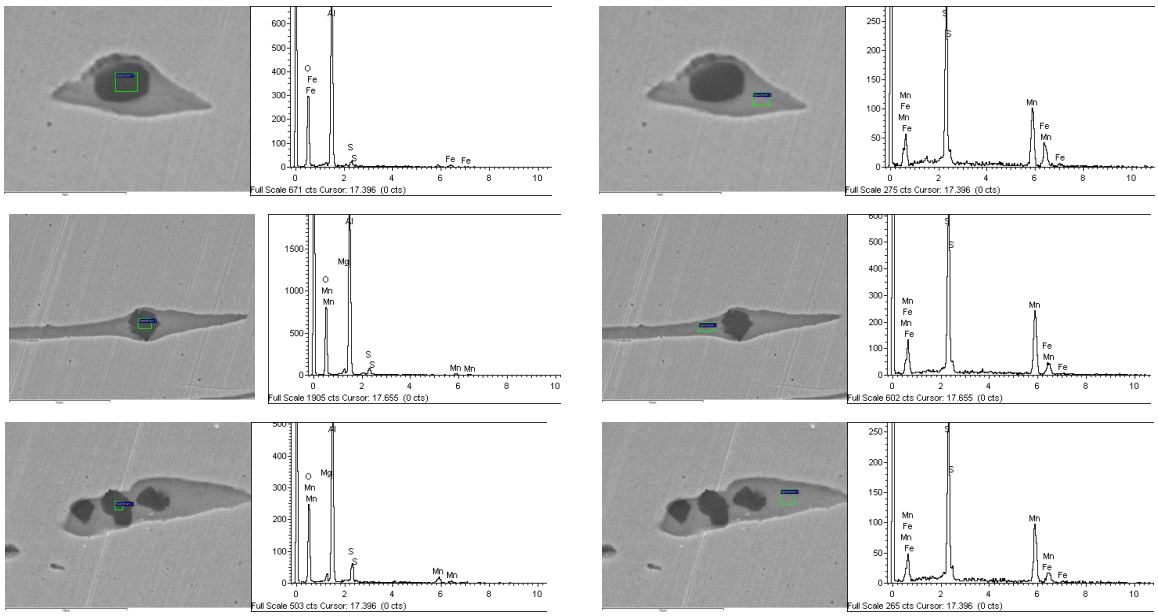

Fig.4 SEM and EDS of Compound Inclusions in Rolled Steels

Summary

To get $12CaO \cdot 7Al_2O_3$, the content of [Ca] should be adjusted about 0.002% during the process while the content of [Al] is 0.03%.

The content of [Ca] should be controlled less than 0.0015% before the S wire is fed.

The [Al] should also be controlled about 0.015%~0.025% to avoid nozzle blocking.

The sulfide inclusions in steel are well modified by calcium and the test results are meet the requirements.

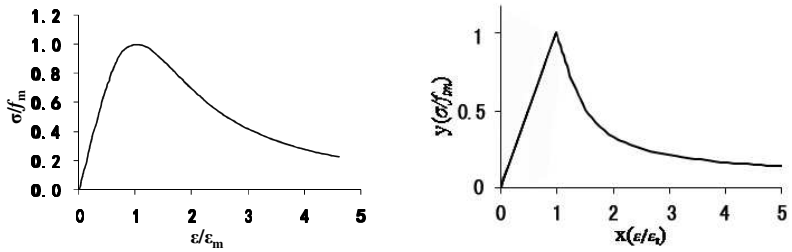
Keywords: BFRP (Basalt Fiber Reinforced Polymer); Masonry structure; Strengthening; Time-history analysis; Finite element method.

Abstract: The externally bonded FRP is an effective strengthening technique, which is mainly verified through laboratory tests. In this paper, numerical analysis models were established in ABAQUS respectively based on an experimental scaled three-story confined masonry structures before and after strengthened with BFRP. Then dynamical analysis considering material nonlinearity, geometric nonlinearity and contact nonlinearity was carried out on these two models. Here, representative volume element method was used to simplify the simulation of masonry. Besides, concrete damage plasticity model was adopted to simulate the structural damage and failure process. The reliability and accuracy of nonlinear dynamic finite analysis were validated by comparing the numerical simulation results and experimental results in terms of dynamic property, displacement and acceleration response and the maximum base shear.

Introduction

Externally bonded FRP for strengthening masonry buildings has been widely aroused many researchers' interest for its advantage of low weight-strength ratio, short installation periods, and low intervention on the structures. However, those researches on FRP strengthening technique mainly focus on laboratory experiments [1-3], and their primary strengthening object are masonry members (such as masonry units, walls, columns, arches and so on) [1-6], and the commonly used strengthening fibers are CFRP (carbon fiber reinforced polymer) , GFRP (glass fiber reinforced polymer) and AFRP (aramid fiber reinforced polymer) which are still not the best appropriate strengthening materials when it comes to strength action rate, thermal stability, heat-resistance and alkali resistance. BFRP (Basalt Fiber Reinforced Polymer) used in this paper is a new inorganic continuous fiber, which is much cheaper than the CFRP and has excellent physical and mechanical properties [7,8], while the application of FRP to masonry structures is still in its infancy and needs a thorough study urgently.



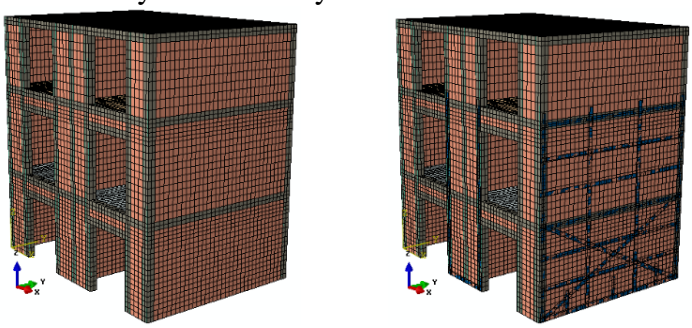
Numerical analysis and modeling are effective and convenient methods on the research of seismic performance of structure. Due to the complicity and difficulty of modeling brick and mortar as well as their contact interaction, it has been only used to analyze the strengthening effect of FRP on masonry members [9,10]. This paper establishes two numerical analysis models in ABAQUS respectively based on a experimental scaled three-story confined masonry structures before and after strengthened with BFRP[8], simplifying the modeling of masonry structure using representative volume element method which takes the brick and mortar as a whole. And then the numerical simulation results of dynamical analysis are compared with the experimental results in terms of dynamic property, displacement and acceleration response and the maximum base shear to verify the reliability and accuracy of nonlinear dynamic finite analysis.

Numerical modeling for (BFRP-strengthened) masonry structure

The detail structural specification of this (BFRP-strengthened) masonry structure refers to the shaking table tests in [8]. In the ABAQUS software, the modeling of masonry walls, structural columns and floor slabs are solid element using C3D8R, and the modeling of BFRP strips are membrane element using M3D4R. Through comparative analysis of various constitutive models, concrete damage plasticity model is chosen for masonry, which can be used for a good simulation of structural damage and failure process. For the masonry, the compression constitutive model in [11] is adopted, and the tensile stress-strain relationship is listed as follows:

$$\begin{cases} D=0 & 0\le\dfrac{\varepsilon}{\varepsilon_t}\le 1 \\ D=1-\sqrt{\dfrac{1}{\alpha_t(x-1)^{1.7}+x}} & \dfrac{\varepsilon}{\varepsilon_t}\ge 1 \end{cases}. \tag{1}$$

The constitutive curves of masonry compression and tensile relationship are shown in Fig.1.



(a) compression relationship (a) tensile relationship

Fig.1 Constitutive model for masonry

According to the principle of energy equivalence, the compression and tensile damage curve for masonry can be obtained.

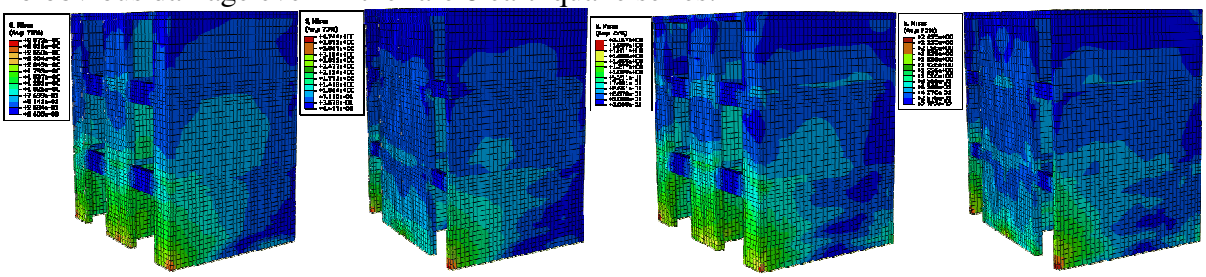
For the structural columns, concrete damage plasticity model is also chosen, and relative material parameters are decided according to the GB/T 50010-2010 [12]. The rebars embedded in the structural columns and ring beams are idealized as linear elastic model. The BFRP strips are taken as anisotropic linear elastic model. Tie constraint is applied to the interface between masonry walls and fiber strips. The meshed models are shown in Fig.2. The seismic waves (MYG004 removed) and input direction are the same as the laboratory test program [8]. Three seismic series (basic 7, rare 7 and rare 8) are considered in the dynamical analysis.

(a) pre-damaged model(A_{FEM}) (b) BFRP-strengthened model(B_{FEM})

Fig.2 Finite element analytical model

Results and discussion

Dynamic property



Mode analysis was carried out to these two finite element models. The natural frequencies of the first 9 modes can be obtained and compared to the experimental results (Table 1). The natural frequencies of the fist 3 modes agree well with the test results, and the relative standard deviation within 5%. The deviation increases with the mode. Due to the flexible feature and light self-weight of BFRP strips, the structural model strengthened with BFRP almost gets the same natural frequency as the pre-damaged model.

Table 1 Comparison of natural frequencies (Hz)

model	1st	2nd	3rd	4th	5th	6th	7th	8th	9th
A_{FEM}	6.428	8.607	14.768	23.370	26.203	34.196	36.107	48.134	54.129
$A_{experiment}$	6.445	8.105	15.332	25.563	/	/	/	/	/
B_{FEM}	6.451	8.641	14.791	23.432	26.279	34.259	36.197	48.236	54.155
$B_{experiment}$	6.250	8.105	14.551	26.563	/	/	/	/	/

Stress distribution of walls

Take El-Centro wave in rare 8 series for example, the stress distribution of these two models are shown in Fig.3. The pre-damaged model subjects to damaged at the place where principal compressional and tensile stress are lager. The damage mainly focuses on the horizontal crack on the wall and the crush of structural columns in the first floor, which agrees with the experimental damage phenomena. The BFRP strips cooperate with the masonry structure to resist earthquake, changing the stress distribution of the masonry wall. At the same earthquake moment, the maximum principle stress of B_{FEM} is 2.425MPa, which is 43% smaller than A_{FEM}. The BFRP-strengthened model shows no obvious damage even in the rare 8 earthquake series.

(a) A & 3 axis in A_{FEM} (b) B & 1 axis in A_{FEM} (c) A & 3 axis in B_{FEM} (d) B & 1 axis in B_{FEM}

Fig.2 Comparison of the maximum Mises stress distribution

Displacement response

The maximum displacement at each floor of these two models exhibits a trend of increase as the input acceleration increases. The maximum displacement is always obtained at the top floor. Models show different displacement response at different site waves, especially at the Ⅲ and Ⅳsite waves. Compared to the pre-damaged model, the BFRP-strengthened model shows the increase of 1.4%, 3.2% and 11.3%, respectively, in basic 7, rare 7 and rare 8 series. The simulation results are smaller than the experimental results due the effect of accumulative damage in the laboratory tests. In the rare 8 series (El-Centro), the displacement-time curves of these two models are shown in Fig.3, and Table.2 lists the detailed displacement value at each floor in the rare 8 series.

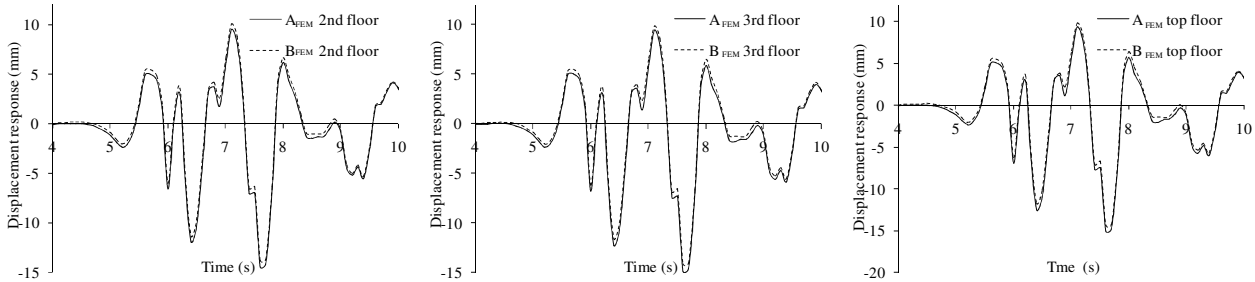


Fig.3 Displacement-time curve (El-Centro in rare 8 series)

Table 2 Comparison of displacement response (mm)

Input signal	Cases	Pre-damaged structure			BFRP-strengthened structure		
		2nd floor	3rd floor	Top floor	2nd floor	3rd floor	Top floor
EI-Centro	S	1.473	2.544	3.222	1.662	2.916	3.591
	E	2.860	2.964	4.120	2.798	3.330	4.648
Wenchuan	S	0.832	1.744	2.392	1.125	2.106	2.886

Pasadena	S	2.408	5.481	7.539	2.443	5.558	7.651
	E	5.159	5.621	7.946	5.330	6.101	8.518
SHW2	S	2.037	2.989	4.228	2.204	3.080	4.396
	E	3.540	3.529	4.840	3.969	3.337	4.427

Note: S=simulation, E=experiment.

Acceleration response

Due to different spectral characteristics of seismic waves, models have not the same response rule under different seismic wave input, while models show the same response rule under the same input with different peak accelerations. When the peak value of input acceleration is 0.10g or 0.22g, the models have no obvious crack and the numerical simulation results agree well with experimental results. After the input of rare 8 series, accumulative damage become predominant, so it makes the simulation results higher than experimental results. In the rare 8 series (El-Centro), the acceleration-time curves of these two models are shown in Fig.4, and Table.3 lists the detailed acceleration-amplifying coefficient at each floor in the rare 8series.

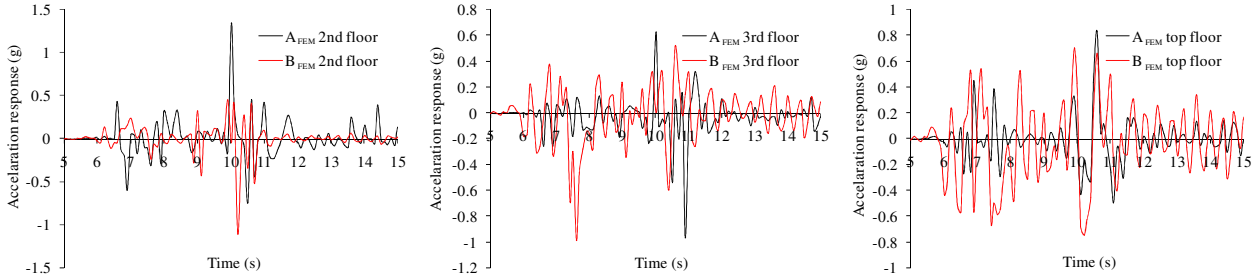

Fig.4 Acceleration-time curve (El-Centro in rare 8 series)

Table 3 Comparison of acceleration-amplifying coefficient

Input signal	Cases	Pre-damaged structure			BFRP-strengthened structure		
		2nd floor	3rd floor	Top floor	2nd floor	3rd floor	Top floor
EI-Centro	S	3.360	2.417	2.085	2.764	2.369	1.868
	E	0.912	0.861	1.143	1.005	0.917	1.254
Wenchuan	S	1.084	1.641	1.721	1.431	1.655	1.969
	E	1.093	1.074	1.426	1.047	1.065	1.552
Pasadena	S	2.854	1.460	1.769	2.259	1.432	1.491
	E	0.985	1.004	1.159	1.024	0.967	1.144
SHW2	S	3.766	3.235	2.851	3.524	2.933	2.623
	E	1.054	0.930	1.034	0.867	0.792	1.108

Maximum base shear

The value of the base shear reflects objectively the level of the earthquake action under certain seismic wave. Fig. 5 presents the maximum base shears of these two simulation models in the rare 8 series (El-Centro). The comparison of the maximum base shear in the rare 8 series is listed in Table 4. The simulation results in the maximum base shear are slightly smaller than the experiment results in most input cases. The base shear of B_{FEM} at other input moment is generally higher than that of A_{FRM}, verifying that BFRP-strengthening technique can obviously postpone the stiffness degradation and improve the energy-dissipating capacity.

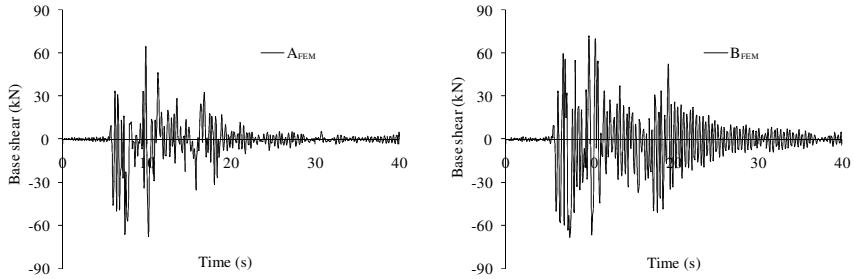

Fig.5 Base shear-time curve (El-Centro in rare 8 series)

Table 4 Comparison of the maximum base shear (kN)

Input signal	Pre-damaged structure		BFRP-strengthened structure	
	E	S	E	S
EI-Centro	98.525	82.247	97.411	83.475
Wenchuan	81.848	70.442	82.758	73.755
Pasadena	92.213	82.206	99.997	79.266
SHW2	81.928	88.047	80.041	88.545

Summary

BFRP-strengthening technique can significantly improve the energy-dissipating capacity and seismic performance due to the co-working action of BFRP strips and masonry structure. The strengthened model shows no obvious damage even in the rare 8 series, which agrees with experiment phenomena. The dynamic property, displacement and acceleration response and the maximum base shear of the numerical analysis models generally consistent with the laboratory results. Representative volume element method can effectively solve the complexity of masonry modeling and reasonably reflect the seismic response and phenomena, and verify the conclusions drawn from laboratory tests.

Key words: tricalcium silicate; MgO; structure; hydration

Abstract: The research investigates various methods to identify magnesium oxide influences on the crystal structure and hydration properties of tricalcium silicate. The f-CaO content of the clinkers were analyzed by chemical analysis. The complex disordered superstructure of the tricalcium silicate has been studied by a joint XRD, NMR and TEM. The results show that MgO exerts a remarkable influence on the polymorphisms of C_3S. Mg is not only substitutional atom but also interstitial atom in the crystal lattice of tricalcium silicate. The HRTEM pattern of C_3S doped with MgO is covered by the various irregular lattice. The addition of appropriate amount of MgO in raw meal can change the formation kinetic of C_3S, slightly perturb the environment of SiO_4^{4-} tetrahedral, modify the crystal structure of C_3S and affect the hydration activity. Doped with MgO in the raw meal can slow down the hydration rate of alite slightly in early stage.

Introduction

The major component of ordinary Portland cement (OPC) is a 50–75 wt. % solid solution of tricalcium silicate ($3CaO{\cdot}SiO_2$ =C_3S) with MgO, Al_2O_3 and Fe_2O_3 [1,2]. Seven structural modifications of C_3S have been identified [3-4]. The most common modifications are M1 or M3, and T2 occurs only rarely in cement clinker.

It is well known that the strength of cement from different localities differs a lot in spite of a high similarity of the contents of alite and other phases. Almost always, such differences are looked upon as a result of different concentrations of the minor oxides, especially MgO, SO_3 and alkali oxides. Alite is the principal hydraulic phase of clinker, having the decisive impact on the strength of Portland cement. Ca_3SiO_5 is characterized by an extensive polymorphism. The hydration activity of clinker is closely related with the different polymorphism of C_3S.

Many investigations[5-7] have been reported the effect of the addition of MgO on the formation of Ca_3SiO_5 minerals, but the results are inconsistent and even contradictory. In this study, the influence of MgO on the crystal structure and hydration characteristics of tricalcium silicate was investigated. The aim of the study was to investigate the influence of MgO on the synthesis, lattice parameters of the clinker phase and the effect on the hydration characteristics of dopped C_3S.

Experimental Procedure

Preparation of Specimen

Pure tricalcium silicate and its solid solutions with magnesium were made by solid-state reaction at 1500℃.The starting materials were analytical reagent grade calcium carbonate and quartz and magnesium oxide. Calcium carbonate and quartz in the stoichiometric ratio of 3:1 were ground to a fine powder and homogenized with MgO. The raw mixtures were mixed with 8% water and pressed into discs using a mould with the size of 25mm in diameter and 40mm in thickness. The discs were dried in an oven and burned at 1500℃ for 6 h in a platinum dish in the Nabertherm resistance furnace. The sintered pellets were ground to pass a 0.08mm sieve and reformed into pellets and fired at 1500C for 6 h again. The samples were all cooled rapidly by a electric fan. The final products were all powdered to pass the 0.08mm sieve. The concentration of MgO in raw meal and the abbreviation of samples are shown in table 1.

Table1 Concentration of MgO and abbreviation of samples[%]

Samples	C_{M0}	C_{M1}	C_{M2}	C_{M3}	C_{M4}	C_{M5}
w(MgO)	0	1	2	3	4	5

Results and discussion

The Content of F-CaO

As seen from Fig.1, the content of free lime in C_{M0} is 0.42%. The content of free lime in alite greatly rises along with the increase of the concentration of MgO up to 3.0%, the content of more than 3.0% MgO except. When the content of MgO exceeds 3.0%, the content of free lime in the alite remains approximately 1.3%. According to the molecular weight of CaO and MgO, Mg^{2+} could substitute for Ca^{2+} in the Ca_3SiO_5. Noticeably, Mg is not only substitutional atom but also interstitial atom.

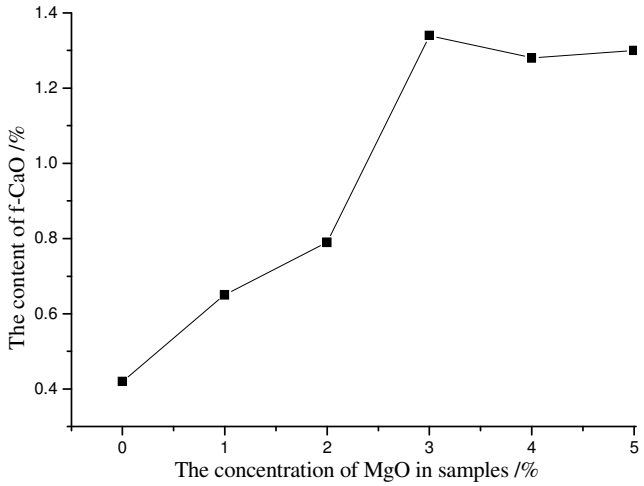

Fig.1 Effect of amount of MgO added on the content free lime of in samples

Mg^{2+} is known to substitute directly for Ca^{2+} in the Ca_3SiO_5 crystal lattice. According to J.Bensted [8], the limiting solid dissolved quantity of MgO in Ca_3SiO_5 was up to 2.2% at 1550℃. It is indicated that the free lime is released in clinker due to Mg^{2+} substitute for Ca^{2+} in the Ca_3SiO_5. When the amount of MgO added is over 3.0%, the solid dissolved MgO in Ca_3SiO_5 maintains a constant value.

Effect of MgO Added on C_3S Formation

Fig.2 presents the X-ray diffraction patterns for the pure tricalcium silicate and its solid solutions with magnesium sintered at 1500℃ for 6h twice. The diffraction peaks of $CaCO_3$ as well as SiO_2 in the patterns are not observed. This denotes that $CaCO_3$ has decomposed completely and the Si-O-Si bonds in SiO_2 have broken down. The primary diffraction peaks are C_3S mineral which have been marked out. The diffraction peaks of f-CaO(d= 0.2403 nm) are rather low, so the content of free CaO is little, the diffraction peak of free lime is visible in the specimen containing 3.0% MgO, which is in agreement with the results in Fig.1.

Seen from Fig.2, the XRD diffraction peaks with d values of 0.243nm and 0.2097nm belong to MgO, the peak of alite solid solutions with magnesium is all shifted toward the angles, it is shown that Mg substitute for Ca in Ca_3SiO_5 lead to decreasing the cell volume of Ca_3SiO_5. Apparently, the addition of MgO can affect the crystal structure of Ca_3SiO_5.

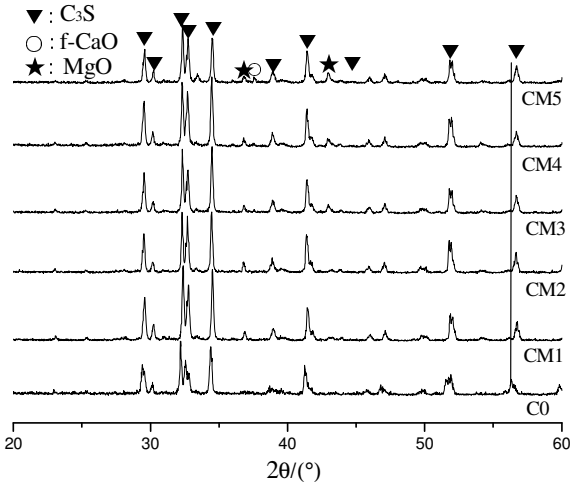

Fig.2.XRD pattern of the pure tricalcium silicate and its solid solutions with MgO

On the basis of the experiment, it is concluded that the addition of MgO can influence on the cell volume of Ca_3SiO_5.When the amount of MgO added is over 3.0%, Mg^{2+} may substitute for Ca^{2+} in Ca_3SiO_5 to release f-CaO. Doped with MgO in the raw meal can affect the structrue of Ca_3SiO_5.

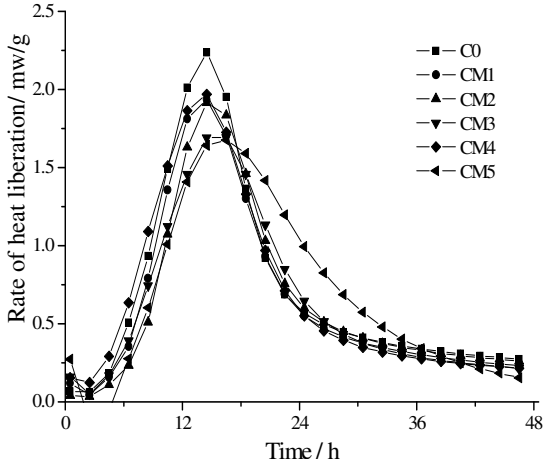

Fig. 3 Heat evolution curves of samples

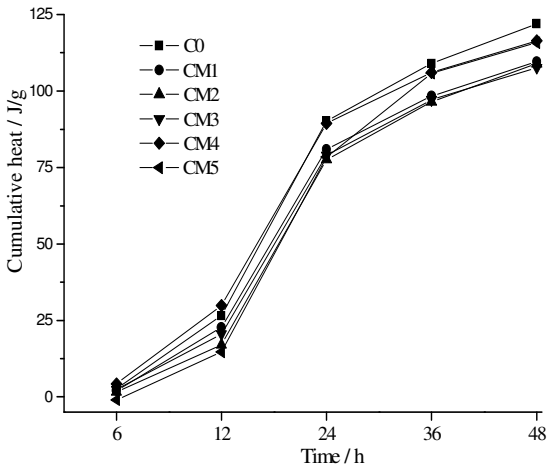

Fig. 4 Cumulative heat of hydration of samples

Heat of hydration

For pure C_3S and solid solutions, the heat evolution during the first 48 h of hydration is shown together with the cumulation heat of hydration over a period of 48 h in Fig.3 and 4, respectively.

Seen from Fig.3 and Fig.4, the effect of MgO added on the hydration behavior of C_3S is remarkable.The hydration rate shows that MgO slows down the hydration of C_3S slightly druing the first 48 h，but the cumulative heat of hydration is nearly the same in 48 h. This is in agreement with the result of Abdul-Maula and Dietmar Stephan[9].

Mechanisms

^{29}Si NMR Spectra of Pure C_3S and Solid Solution

By means of ^{29}Si solid-state NMR it is possible to detect all Si atoms in a sample, regardless of whether the atoms are part of a crystalline or amorphous compound. Furthermore, different chemical shifts make it possible to distinguish Si in the calcium silicates.

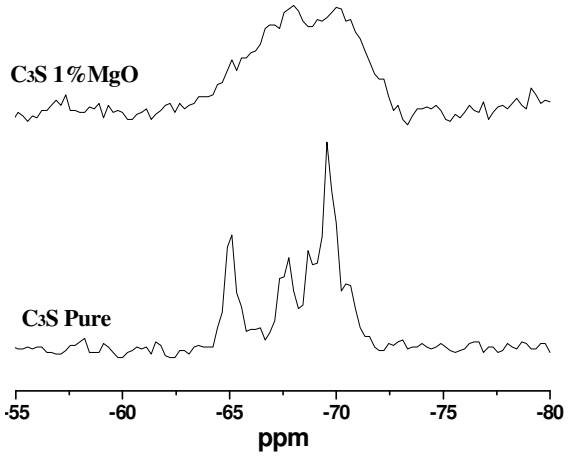

Fig. 5 ^{29}Si NMR of pure C_3S and C_3S doped with 1% MgO

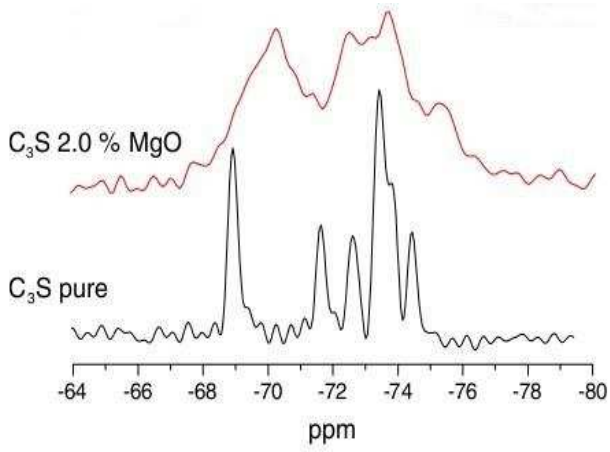

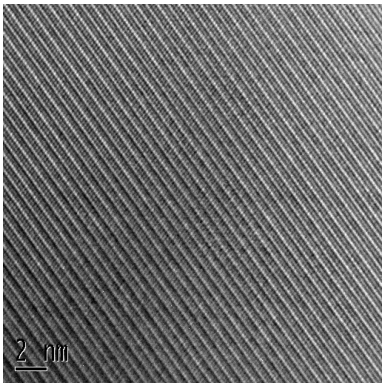

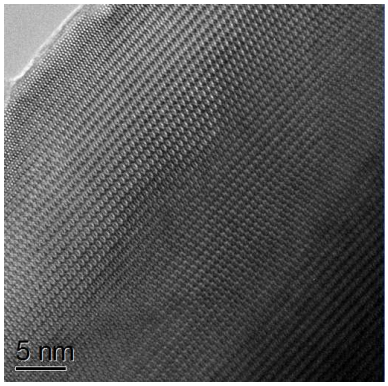

Fig.6 ^{29}Si NMR spectra of pure C_3S and C_3S doped with 2% MgO

Fig. 5 shows that the ^{29}Si MAS NMR spectra of undoped C_3S is compared to the spectra of C_3S with 1.0wt. % MgO. In Fig.6, the ^{29}Si MAS NMR spectra of undoped C_3S is compared with the spectra of C_3S with 2.0 wt.% MgO, which is synthesized using an innovative sol–gel process as precursor[10]. Seen from Fig.5 and Fig.6, the spectra of NMR are very similar, the C_3S doped with MgO give broad signals with complex line shape for the overlapping ^{29}Si resonances. The spectras of C_3S doped with MgO synthesized using solid-state or sol–gel process as precursor all shift to right to compare with the spectra of undoped C_3S. Seen from Fig.5, the area of the peaks at -65.0 and -69.6ppm is twice compared to the other peaks, which shows that these peaks belong to various Si with very different positions.

From the line broadening of the NMR spectra it can be presumed, that the doped elements slightly perturb the environment of SiO_4^{4-} tetrahedral. The sample containing an appropriate amount MgO is the only one with a monoclinic and not a triclinic structure[10]. The line broadening does not only occur for the monoclinic C_3S but also is a result of the incorporation of foreign ions already below the critical concentration for the phase transformation.

a: pure C_3S

b: C_3S doped with 1% MgO

Fig. 7 HRTEM of C_3S and C_3S doped with 1% MgO

TEM. The HRTEM pattern of pure C_3S and C_3S doped with 1% MgO are shown in Fig.7. Seen from Fig.7.a, the crystal lattice of pure C_3S is orderly and regular in the whole region, while the HRTEM pattern of C_3S doped with MgO covers the various irregular lattice in Fig.7.b, indicating several crystal defects, the crystal defect belong to modulated structure, which is consequent on the Mg^{2+} subsitiute for Ca^{2+} in C_3S to lead to vacancy of oxygen ion, as expressed by the following formula: $MgO \xrightarrow{C_3S} Mg_{Ca}+O_O$. It is concluded that the addition of appropriate amount of MgO in raw meal can change the formation kinetic of C_3S, affect the crystal structure of C_3S and alter the hydration activity.

Summary

The following conclusions can be drawn, concerning the crystal structure and hydration properties of tricalcium silicate doped with magnesium oxide:

(1) MgO exerts a remarkable influence on the polymorphism of C_3S. A slight Mg solid solution in the cement clinker is not only substitutional atom but also interstitial atom.

(2) MgO slows down the hydration rate of C_3S slightly during the early stage，but the cumulative heat of hydration is nearly the same in the early ages. The influence of magnesium on hydration properties of cement clinker mineral is significant.

(3) The addition of appropriate amount of MgO in raw meal can change the formation kinetic of C_3S, slightly perturb the environment of SiO_4^{4-} tetrahedral, modify the crystal structure of C_3S and affect the hydration activity.

Keywords: concrete; strain; multiple factors; damage model; mechanical analysis

Abstract. As the action mechanisms of various factors affecting concrete durability are different, it is difficult to understand the durability of concrete exposed to multiple factors using only mechanism analysis. Converting each action mechanism to an appropriate macroscopic mechanical effect can simplify complicated durability problems. Here we study concrete beams exposed to common environmental factors: cyclic freezing and thawing, bending stress and chloride attack. By converting each mechanism into a mechanical process and analyzing its effect on concrete, a damage model based on strain was established. Freezing-induced tensile stress is essentially a low-cycle fatigue tensile stress, as represented by a saw-tooth model. The maximum strains when the maximum freezing-induced tensile stress coupled with the four-point bending stress in every freeze-thaw cycle were measured, and found to increase with freeze-thaw cycling. Our damage model provides a new approach to predict the service life of concrete, and guidance for durability design of concrete.

Introduction

It is well known that the service life of concrete is largely determined by its durability in its environment. Research on concrete durability over the years has focused mainly on materials science, analyzing the physical and chemical mechanism of the degradation process. Results of this research have helped us understand the mechanisms responsible for many losses of concrete structure and function [1]. However, studying the mechanism of concrete durability only from the materials science viewpoint is not a full-scale approach, because concrete in practical engineering situations normally suffers from multiple environmental factors, each with its own action mechanism. Mechanism analysis is not an effective way to investigate the durability of concrete subjected to multiple factors. Converting the action mechanism to a mechanical effect, and then analyzing these mechanical effects at a macroscopic scale, is one way of dealing with this problem. Research on concrete durability should be based on practical engineering considerations, and the best progress will be made by combining materials science and mechanical analysis [2].

Concrete failure caused by non-mechanical factors is similar to that caused by loading. In freeze-thaw cycles, for example, a porous concrete matrix consisting of cement paste and aggregates is widely accepted to generate hydrostatic pressure [3] and crystallization pressure [4] resulting from the ~9 vol.% expansion of water upon freezing. Hydrostatic pressure and crystallization pressure may be considered as an 'inner tensile stress', which, together with the thermal stress, make up a freezing-induced tensile stress that will cause cracking and strain variations once it exceeds the tensile strength that concrete can bear. In this way, the freezing process can be considered as 'loading' and the thaw process as 'unloading' [1]. After long-term cyclic freeze-thaw action, concrete will suffer accumulated damage, causing larger connectivity of microcracks and, eventually, destruction. Based on the above, the mechanism of freeze-thaw damage is converted into mechanical actions. This conversion allows us to establish a mechanical model for the durability degradation process of concrete exposed to multiple factors.

In recent years, strain has increasingly been monitored as a measure of internal damage [5-9], and shown to increase progressively with the progress of deterioration. In this study we used strain to characterize the degree of deterioration in concrete beams in service, exposed to cyclic freeze-thaw, bending stress and chloride attack. We then converted each deterioration mechanism to a mechanical effect on the concrete, and analyzed the strain behavior of the concrete under the synergistic effects of multiple factors, in an attempt to establish a universal damage model of concrete (which could be used to predict the service life of concrete beams), and also to provide reference data for durability design of concrete.

Experimental Program

As well as the results described below, results from a previous paper [8] are examined in this work.

Raw Materials

The raw materials were a Reference Portland cement (strength grade P.I 42.5, composition given in Table 1) with specific surface area of 347 m3/kg and volume density of 3.10 g/cm3, fly ash (FA) with water demand ratio of 91% and ignition loss of 2.2%, blast-furnace slag (BFS) with density of 2.89 g/cm3, specific surface area of 439 m2/kg and activation index of 99%, river sand with the fineness modulus of 2.8 and silt content less than 1 wt.%, crushed gravel with particle sizes of 5–10 mm and 10–20 mm in a ratio of 4:6, polycarboxylate superplasticizer (water reducer) with 40 wt.% solids content, and triterpenoid-saponin air entraining agent (dosed at 0.01 wt.% of the cementitious material content).

Table 1 CHEMICAL COMPOSITION OF CEMENT, wt.%

Raw material	Chemical composition									
	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	NaO_2eq	Loss	f-CaO	Cl^-
Cement	22.02	4.00	3.48	62.12	2.58	2.72	0.53	1.75	0.87	0.011

Preparation of Specimens

The mix proportions and the physical properties of the concrete are listed in Tables 2 and 3, respectively. Prismatic concrete specimens with dimensions of 100×100×400 mm were employed. Electrical resistance strain gauges, as shown in Figure 1(a), and made as described in reference [9] were located at a depth of 0.5 cm on both sides of the concrete specimens, as shown in Figure 1(b). The specimens were demolded after 24 h, and were then put in a curing room at 20 ± 2 °C and ≥ 90% relative humidity. After 24 d of curing, the specimens were moved into the vacuum salt-saturation equipment, and were saturated with 3.5 wt.% sodium chloride solution saturating for periods between 24 and 28 d.

Test Method

(a) (b)

Fig. 1 Concrete Specimen with Strain Gauges

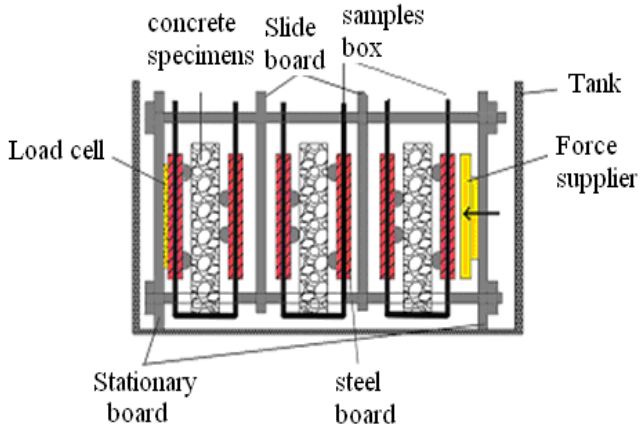

Fig. 2 Schematic of Test Samples in the Vertical Position

The concrete specimens were moved to the test chamber and placed in rubber sleeves filled with NaCl solution (3.5 wt.%) to a level 1–2 cm above the tops of the specimens. This concentration was selected because, according to reference [10], the greatest concrete damage under freeze-thaw cycles occurs in 3.5wt.% NaCl solution (which is also close to seawater concentration). Then the strain gauges were connected to a JC-4A automatic static strain data-logger. The concrete specimens were loaded a static constant four-point bending stress at a level of 0.35 or 0.5 by the force supplier, and the two sides of the concrete that contained the embedded strain gauges were placed next to the steel boards, as shown in Figure 2 and Table 3. Next, the freeze-thaw cycles were started, and strain variations were measured and recorded using a data-logger and computer. The freeze-thaw cycling was carried out according to Standard for test methods of long-term performance and durability of ordinary concrete GB/T50082-2009. The highest and lowest temperatures of the specimen centers were controlled to (-18±2) and (5±2) °C, respectively. An example of the actual measured temperatures of the thermal exchange fluid and specimen centers is shown in Figure 3.

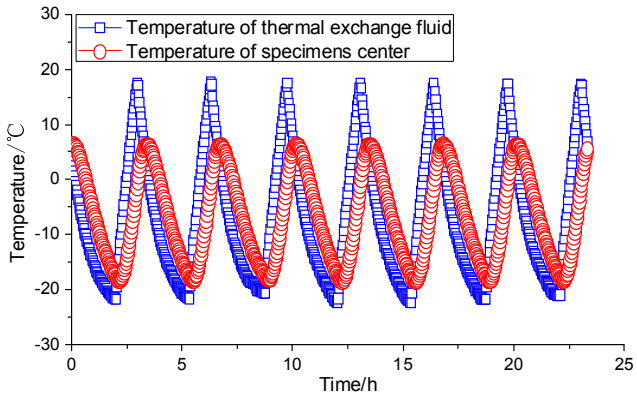

Fig. 3 Temperature Profile for Freeze-thaw Cycles

Experimental Results

Taking concrete specimen BI, for example, the maximum strains all appear near the lowest temperature (-18 °C) in every freeze-thaw cycle. Using the maximum strain in the first cycle as the initial value, Figure 4 shows that the maximum strains on the compression zone edge and the tension

zone edge both increase with the progress of freeze-thaw cycles, and that there is part of the curve where the rate of increase is constant. The increasing maximum strains are caused by the generation of residual strains. The strains at the tension zone edge are all larger in the same cycle and increase faster than those on the compression zone edge, because the tension zone of concrete is stretched by the maximum freezing-induced tensile stress coupled with the bending stress, while the compression zone edge is compressed by the bending stress, which partly counteracts the stretching from the maximum freezing-induced tensile stress. Freezing-induced tensile stress σF is a macroscopic overall stress, which includes stresses caused by hydraulic pressure, crystallization pressure, thermal expansion, thermal contraction, thermal gradients and so on (shown as Equation (1)), and, macroscopically, concrete is elongated by this overall force.

$$\sigma_F=\sigma_P+\sigma_T+\sigma_G+\ldots \quad (1)$$

where σP is the stress caused by hydraulic pressure and crystallization pressure; σT is the thermal-expansion and thermal-contraction-induced stress; and σG is the stress caused by thermal gradients. The values of εTm0 and εCm0 listed in Table 4 can be obtained from Figure 4. εTm0 is the initial maximum strain at the tension zone edge when the four-point bending stress is coupled with the maximum freezing-induced tensile stress (N = 0); εCm0 is the initial maximum strain of the compression zone edge when the four-point bending stress is coupled with the maximum freezing-induced tensile stress (N = 0).

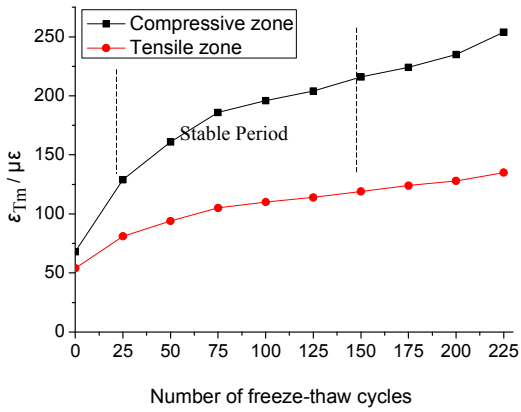

Fig. 4 Relationship Between Maximum Strain of BI and the Number of Cycles

The freeze-thaw damage mechanism of concrete involves several specific stages: the acceleration period, slow growth period and accelerated destruction period. Each stage is discussed in more detail below.

Acceleration period: The maximum strains increase rapidly because of the generation of new microcracks, the propagation of the tips of the original microcracks and the increasing water saturation, which can increase the freezing-induced tensile stress in concrete.

Slow growth period: The maximum strains seem to increase at a lower speed. Because of the damage accumulated during the acceleration period, the microcracks in concrete start to connect, and their connectivity can relieve some of the effects of the freezing-induced tensile stress. The major driving force for the increasing deformation during this period may be moisture migration in the concrete. This period occupies a large part of the whole process, and corresponds to the linear portion of the strain-cycling curve.

Accelerated destruction period: The connectivity of the cracks in the concrete increases greatly, allowing a large amount of the external solution to enter into the looser concrete and thus to generate a more destructive freezing-induced tensile stress. In this stage, the maximum strains again increase rapidly, until the concrete is completely destroyed.

The figures showing the experimental results of samples BII and Cao's C30 and C50 samples are not included here, but the values obtained from analysis of this other data are also listed in Table 4.

Establishment of Damage Model

Proposed Model for Maximum Freezing-induced Tensile Stress

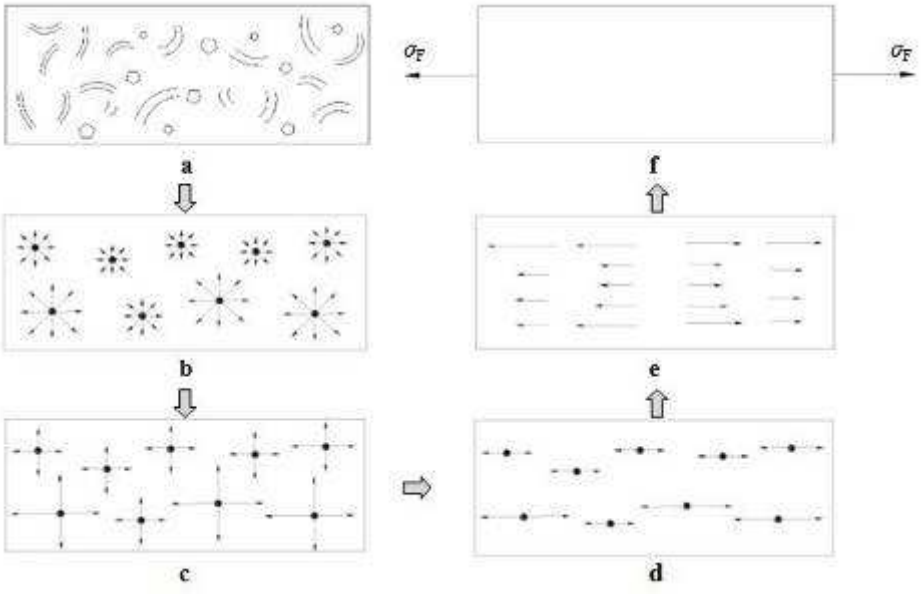

Fig. 5 Model Showing Horizontal Axial Maximum Freezing-Induced Tensile Stress on a Cross-section of Concrete

Figure 5 shows a schematic of the model where the maximum freeze-induced tensile stress is regarded as a horizontal axial stress. This model applies to particular points in time, whenever the freezing-induced tensile stress reaches its maximum value in every freeze-thaw cycle. The strains at these particular moments are the peak strains measured in every freeze-thaw cycle and all appear near the lowest temperature (-18 °C). There are some pores in concrete (Figure 5a), and every pore can be considered as a mass point. These pores each experience the maximum freezing-induced tensile stress in all directions (Figure 5b) during the progress of the freeze-thaw cycles, and this maximum freezing-induced tensile stress can be decomposed into a horizontal axial stress and a vertical axial stress (Figure 5c). Because we are measuring only the horizontal axial stress, we can neglect vertical stresses, as shown in Figure 5d. The increasing maximum strain of the concrete is largely due to variations in the pores, and has little to do with the compacted concrete matrix. Considering all the pores on the cross-section of concrete as a whole, no matter how the positions of these stresses change, provided that these stresses equivalently act on the cross-section of concrete, the degree of damage for this whole will be constant, according to the damage-equivalent hypothesis in the rain-flow counting method [11]. Therefore the maximum freezing-induced tensile stresses can be separated, forming tensile stress as shown in Figure 5e. For the whole piece of concrete, this is equivalent to applying a tensile stress to both ends of concrete in the horizontal axial direction (Figure 5f).

Maximum Freezing-induced Tensile Stress Coupled with Static Constant Four-point Bending Stress

In concrete, the freezing process is equivalent to loading, and the thawing process equivalent to unloading, so freezing-induced tensile stress is similar to a low-cycle fatigue tensile stress, and we can assume that it can be simply represented by a saw-tooth model [1], as shown in Figure 6. We have chosen to couple the freezing-induced tensile stress with a static four-point bending stress applied from above, so that damage will be localized in the central portion of the concrete specimen. The maximum in freezing-induced tensile stress σFm coupled with the four-point bending stress occurs at the tension zone edge, and the maximum compressive stress is at the compression zone edge of the concrete, as shown in Figure 7; we assume that their magnitudes are constant.

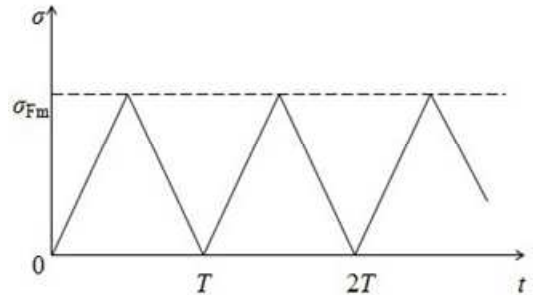

Fig.6 Model of Freezing-induced Tensile Stress

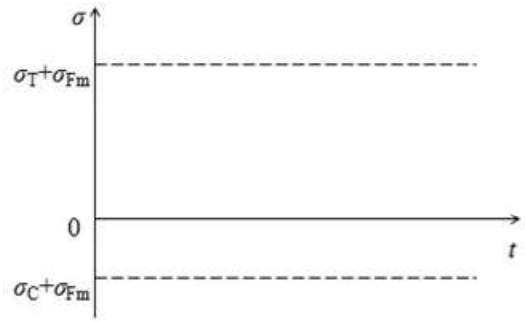

Fig. 7 Maximum Freezing-Induced Tensile Stress σFm Coupled with Four-point Bending Stress

Proposed Model

To apply these ideas to establish a damage model for concrete under synergistic effects of multiple factors, we modify the simple damage mechanics model for the fatigue of concrete proposed by Alliche and Francois [12] , according to Bernouilli's hypothesis. First, we assume that thermal gradients are not created between the center and the surface of the concrete. The elastic modulus of concrete changes with temperature, but in the present paper, since the minimum temperature for each cycle is essentially the same (near -18 °C), we can assume that these slight differences can be ignored. As shown in Figure 8, it is clear that the absolute value of the strain on the abscissa axis is equal to that on the compression zone edge, so the abscissa axis can be regarded as an equivalent compression stress line. When the four-point bending stress is coupled with the maximum freezing-induced tensile stress, the compression zone of concrete is above the axis, and the tension zone is below. We can also assume that damage appears only in the tension zone. The vertical coordinate of any point on the cross-section of the concrete can be expressed by ζ:

$$\zeta = \frac{z}{h\text{-}k} \tag{2}$$

where h is the height of the concrete; k is the distance between the equivalent compression stress line and the bottom of the concrete, and is related to the magnitude of the maximum freezing-induced tensile stress and bending stress; and z is the distance from the bottom of the concrete to the point. The initial value of ζn = 0.5, and then the neutral axis will move up with increasing freeze-thaw cycles, meaning that ζn > 0.5. The equilibrium equations for the normal stress and for the moment are:

$$\int_0^1 \sigma_{\mathrm{T+Fm}}(\zeta) b(h-k)\,\mathrm{d}\zeta = 0 \tag{3}$$

$$\int_0^1 \sigma_{\mathrm{T+Fm}}(\zeta) b(h-k)^2 \zeta\,\mathrm{d}\zeta = M \tag{4}$$

$$M = -\frac{Eb(h-k)^2}{6}\varepsilon'_{\mathrm{Tm0}} \tag{5}$$

where b is the thickness of the concrete; E is its elastic modulus; ε'Tm0 is the initial maximum strain (ζ = 0) of the equivalent compression stress line when the four-point bending stress is first coupled with the maximum freezing-induced tensile stress (N = 0), and can be calculated by the following formula, according to Figure 8:

$$\varepsilon'_{\mathrm{Tm0}} = \left|\varepsilon_{\mathrm{Cm0}}\right| = K_1 \varepsilon_{\mathrm{Tm0}} \tag{6}$$

where K1 is an undetermined constant; εTm0 is the initial maximum strain (ζ = 0) at the tension zone edge when the four-point bending stress is coupled with the maximum freezing-induced tensile stress (N = 0); and εCm0 is the initial maximum strain of the compression zone edge when the four-point bending stress is coupled with the maximum freezing-induced tensile stress (N = 0).

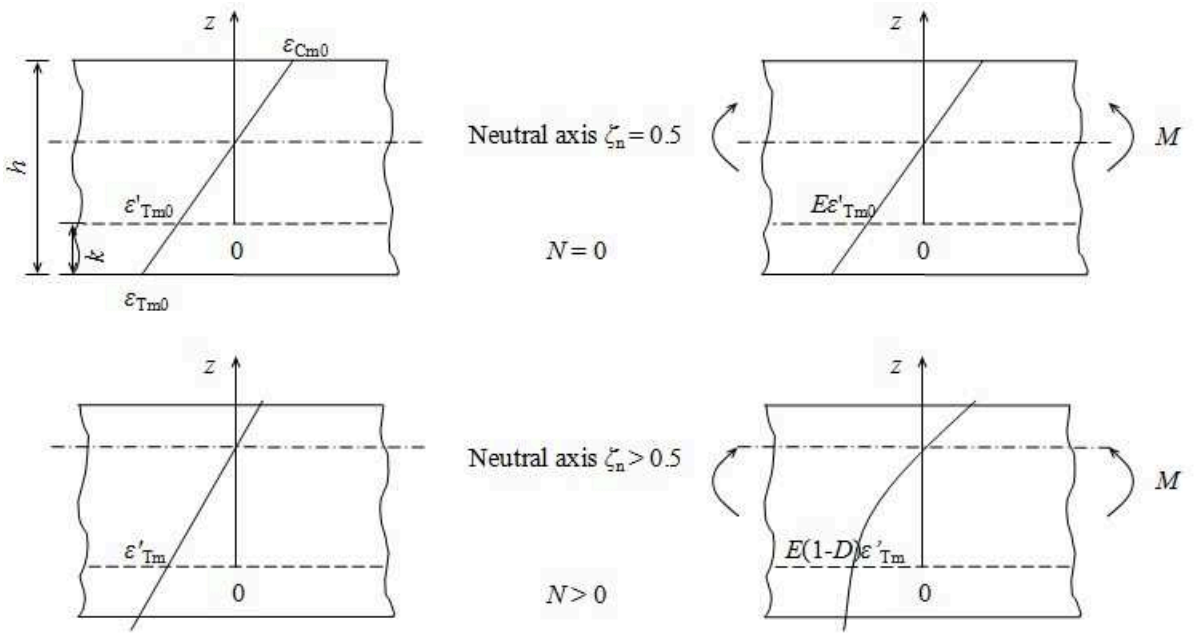

Fig. 8 Schematic of Evolution of Strain and Stress Under Freeze-Thaw Cycles Coupled with Bending Stress

The theoretical derivation shown here is similar to that in reference [12]. Finally, we obtain the relationship between strain and number of cycles N:

$$\frac{24}{13}\left(\frac{\Delta\varepsilon_{\mathrm{Tm}}}{\Delta N}\right)_0 \frac{N}{\varepsilon_{\mathrm{Tm0}}} = -\frac{9}{2}\ln 2\zeta_{\mathrm{n}} - \frac{63}{4\zeta_{\mathrm{n}}} + \frac{69}{8\zeta_{\mathrm{n}}^2} - \frac{2}{\zeta_{\mathrm{n}}^3} + 13 \tag{7}$$

$$\frac{1}{3}D'_{\mathrm{m}} = \frac{1}{\zeta_{\mathrm{n}}} - \frac{1}{2\zeta_{\mathrm{n}}^2} \tag{8}$$

$$D'_{\mathrm{m}} = K_1 D_{\mathrm{m}} \tag{9}$$

$$K_1 = \left|\frac{\varepsilon_{\mathrm{Cm0}}}{\varepsilon_{\mathrm{Tm0}}}\right| \tag{10}$$

where Dm is the maximum damage degree at the tension zone edge; D'm is the maximum damage degree at the equivalent compression stress line. In fact, the magnitude of the maximum freezing-induced tensile stress is not constant. In each cycle, the maximum measured strain occurs near the lowest temperature. The elastic modulus at this point may vary slightly from cycle to cycle, because of differences in temperature and thermal gradients. Thermal gradients are created between the center and the surface of concrete, which influence the freezing-induced tensile stress and the elastic modulus under freeze-thaw cycles. Therefore, we should introduce some correction factors to modify Equation (7):

$$\frac{24}{13}k_\sigma k_{\mathrm{E}} k_{\mathrm{G}} k_{\mathrm{u}}\left(\frac{\Delta\varepsilon_{\mathrm{Tm}}}{\Delta N}\right)_0 \frac{N}{\varepsilon_{\mathrm{Tm0}}} = -\frac{9}{2}\ln 2\zeta_{\mathrm{n}} - \frac{63}{4\zeta_{\mathrm{n}}} + \frac{69}{8\zeta_{\mathrm{n}}^2} - \frac{2}{\zeta_{\mathrm{n}}^3} + 13 \tag{11}$$

where kσ, kE, kG and ku are the correction factors: kσ is used to correct the magnitude of the maximum freezing-induced tensile stress; kE is used to correct the elastic modulus for the effects of slight changes in temperature; kσ is used to correct for thermal gradients; and ku is used to correct for the influence of other unknown factors. $\left(\frac{\Delta\varepsilon_{\mathrm{Tm}}}{\Delta N}\right)_0$ is the initial rate of variation of εTm and this value

must be obtained from the stable period of the experimental results. If Dm is given, D'm can be calculated by Eq. (10) and Eq. (9), and then we can obtain ζn from Eq. (8). The concrete that was loaded in bending experiences brittle fracture starting at the tension zone, so Dm is usually assigned a value of 1. $\left(\frac{\Delta\varepsilon_{\mathrm{Tm}}}{\Delta N}\right)_0$, εTm0 and εCm0 can all be obtained from the experimental measurements. Finally, we can predict the final number of freeze-thaw cycles required for failure, NF.

Verification of Model

Table 4 shows the experimental results from the concrete specimens, the computed results and the values of kσkEkGku. We can conclude that the deformation of the concrete specimens with higher strength grades is smaller than that of those with lower strength grades, when the concretes are made from the same raw materials. For concrete specimens with the same mix proportions but different loading stress levels, the specimens with the larger loading stress level experience larger deformations in the tension zone and smaller deformations in the compression zone.

Table 4 Measured results and comparison with computed life

NO.	$\varepsilon_{\mathrm{Tm0}}$ (με)	$\varepsilon_{\mathrm{Cm0}}$ (με)	$\left(\frac{\Delta\varepsilon_{\mathrm{Tm}}}{\Delta N}\right)_0$ (10^{-6})	N_{F} Measured	N_{F} in Eq. (7) Computed	$k_\sigma k_{\mathrm{E}} k_{\mathrm{G}} k_{\mathrm{u}}$	N_{F} in Eq. (12) Computed
Cao's C30	113.2	-75.2	0.73	175	40	0.229	160
Cao's C50	84.7	-61.0	0.44	225	59	0.262	236
BI	68.1	-54.5	0.40	225	57	0.253	228
BII	73.9	-50.4	0.52	175	43	0.246	172

The computed values of kσkEkGku are almost the same for all samples, so we can determine an overall value of 0.25, and then obtain Eq. (12) from Eq. (11):

$$\frac{6}{13}\left(\frac{\Delta\varepsilon_{\mathrm{Tm}}}{\Delta N}\right)_0 \frac{N}{\varepsilon_{\mathrm{Tm0}}} = -\frac{9}{2}\ln 2\zeta_{\mathrm{n}} - \frac{63}{4\zeta_{\mathrm{n}}} + \frac{69}{8\zeta_{\mathrm{n}}^2} - \frac{2}{\zeta_{\mathrm{n}}^3} + 13 \tag{12}$$

This verification of the damage model shows that there is good agreement between the values of NF computed using Eq. (12) and the measured results. Therefore, the damage model can accurately characterize the degree of damage resulting from freeze-thaw cycling coupled with a constant four-point bending stress and chloride attack.

Conclusions

The combined effects of freeze-thaw cycling, bending stress and salt exposure on concrete beams were evaluated in this study. By converting the freeze-thaw mechanism into mechanical effects on the concrete and then evaluating the synergistic effects of multiple factors, a multiple-factor damage model was proposed to characterize the relationship between strain and freeze-thaw cycles. The damage to concrete under freeze-thaw cycles and salt exposure was converted into a freezing-induced tensile stress action, which is a macroscopic overall stress. The freezing process is equivalent to loading and thawing equivalent to unloading, so freezing-induced tensile stress is similar to a low-cycle fatigue tensile stress and could be simply represented by a saw-tooth model.

Our mechanical analysis targeted the times where the maximum freezing-induced tensile stress was coupled with four-point bending stress in every freeze-thaw cycle. These times are where the peaks of the measured strains in every freeze-thaw cycle occur, and appear near the lowest temperature (-18 °C) in every cycle. The measured maximum strains on the compression zone edge and the tension zone edge of concrete both increase with the progress of freeze-thaw cycles. A

multiple-factor mechanical damage model based on strain, which more closely resembles the complicated situations found in engineering practice, was established. We showed that the model is suitable for predicting the life of concrete exposed to a combination of freeze-thaw damage, bending stress and chloride attack.

Keywords: FAST engineering, cable net structure, active reflector, mechanical analysis

Abstract: The reflector of Five-hundred-meter Aperture Spherical radio Telescope (FAST) is supported by cable-net structure, so that to enable its reflector surface to form a paraboloid from a sphere in real time through active control. However, such form-changing operation would lead to about 500MPa stress range for the cable-net structure. Such stress range is nearly twice as much of that defined by the relative standard. So the cable-net structure is the most critical and expendable part of FAST reflector system. So, the service life of FAST would directly depend on the residual fatigue life of its cable-net structure. The present paper would make an effort to find a more appropriate deformation strategy to decrease the stress amplitude of the cable during form-changing operation.

Introduction

The project of Five-hundred-meter Aperture Spherical radio Telescope (abbreviated as FAST), belongs to the national "11th Five-Year Plan" Key scientific projects, has been approved for construction by the National Development and Reform Commission in July 10, 2007.[1] FAST working frequency can cover the range of 70MHz to 3GHz. The design resolution and point accuracy are respectively 2.9′ and 8″.[1,2] In order to achieve such technical specifications, the root mean square value of the out plane error of its reflector shape should be no more than 5mm.

According to the geometric optical principle of FAST (illustrated as Figure. 1), the supporting structure of its reflector system should be capable of formation of a paraboloid surface from a sphere in real time through active control, that is the most prominent special requirement beyond those of conventional structures. The crossed nodes of the cable-net are used as control points(see Fig.2). Each of them is tied to a control actuator by down tied cable. By controlling the actuator using the feedback from the measurement and control system, the position of these cross nodes can be adjusted to form an illuminated aperture with 300m diameters. And this illuminated aperture can move along spherical surface according to the zenith angle of the target objects (see S1 and S2 in Figure 1). Later, an extensive numerical comparative analysis has been performed among several different grid types, such as three-dimensional grids, kiewitt grids and geodesic triangle grids. Finally, the last one is determined because of its more uniform of cable stress and cable length.[3,4]

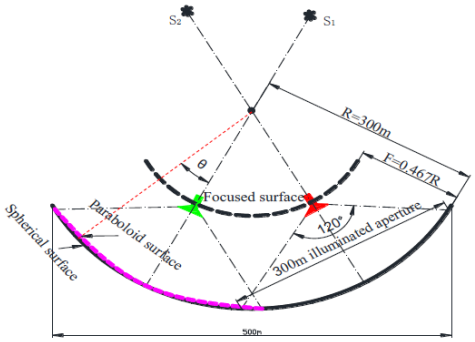

Fig. 1. The geometric optical principle of FAST

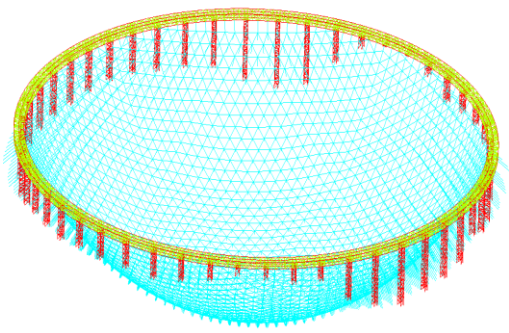

Fig. 2. Concept of the adaptive cable-net structure

From above-mentioned description, it can be easily seen that the long-term observation process of FAST would lead to long-term frequent shape-changing operation of cable-net structure. Previous research results have shown that such shape-changing operation would lead to about 500MPa stress

range[4]. Such stress range is nearly twice as that required by the relative standard.[5] So, the cable-net structure would be the most critical and expendable part of the FAST reflector system. Thus, the service life of FAST would be directly related to fatigue life of its cable-net structure.

In order to improve the reliability of FAST and to extend its service life, the present work, based on the preliminary design, would make an effort to decrease the stress range of the cable caused by shape-changing operation.

The stress range optimization

The main influence factor analysis

There are about 4600 triangular elements supported by the cable-net. The cable-net is consisting of about 7000 steel cables and about 2300 cross nodes. Each cross node is tied to one actuator on the ground. The length of cables is from 10.3m to 12.3m. All cables are disconnected with each other, which enable us to adjust their cross sections according to their loads.

In general, the illuminated aperture is a paraboloid surface, whose profile can be expressed by

$$x^2 = 2py + c \tag{1}$$

The variables and parameters of this problem can be summarized as follow: the weight of reflector element w, the density of the cable ρ, the elastic modulus of cable E, the area of cable cross section A_i, the geometric parameters of illuminated aperture p and c, the diameter of the illuminated aperture d, the radius of the cable-net structure R, the diameter of the ring beam D. So, the stress amplitude can be expressed by

$$\Delta\sigma = f\left(w, E, \rho, A_i, p, c, D, d, R\right) \tag{2}$$

In our preliminary design, w, d, R, D, A_i have already been determined as a certain value. The weight of reflector element w is about $17Kg/m^2$, the diameter of the illuminated aperture d is 300m, the radius of the cable-net R is 300m, and the diameter of the ring beam D is 500m, and all cable's cross section A_i have also been determined according its load. For steel cable, ρ is about 7850Kg/m3. Thus, Eq(2) can be simplified as

$$\Delta\sigma = f\left(E, p, c, d\right) \tag{3}$$

Among these four governing parameters, two of them, namely E and d have independent dimensions. By applying the π theorem in dimensional analysis (Barenblatt 1996), we obtain

$$\frac{\Delta\sigma}{E} = f\left(\frac{p}{d}, \frac{c}{d^2}\right) \tag{4}$$

Furthermore, the nodes of the outer edge of the cable-net are fixed to the ring beam, and their position cannot be adjusted by the actuator like other cross nodes can do (See Fig. 2). In order to expand the observation zenith angle of FAST as large as possible, outer edge of illuminated aperture should coincide with basic spherical surface. Only then can outer edge of illuminated aperture arrive at the outer edge of the cable-net. With such constraint, we can derive that

$$c = 22500 + 2p\sqrt{67500} \tag{5}$$

Then, the Eq(3) can be further simplified as

$$\frac{\Delta\sigma}{E} = f\left(\frac{p}{d}\right) \tag{6}$$

For the steel cable, the elastic modulus is about 200GPa, thus the only variable remained in this implicit function is *p/d*, which is the focal ratio of this telescope.

From Eq(6) we can know that the fatigue stress range of FAST cable is most dependent on the focal ratio of this telescope. The different focal ratio would lead to the different relative position between the illuminated aperture and the base plane, which is directly related to internal forces of cable-net and stroke of actuator.

In our early work, three kinds of deformation strategies, namely the strategy Ⅰ, the strategy Ⅱ, and strategy Ⅲ, have been proposed. The relative positions of these three strategies to the spherical base plane are shown in Figure. 3. Among of these strategies, the strategy Ⅰ and Ⅱ are respectively corresponding to the shortest actuator stroke and the minimum deviation from the illuminate aperture to the base spherical surface. The actuator stroke of the strategy Ⅰ is about 0.67m, and the maximum deviation distance of the strategy Ⅱ is about 0.47m. As for the strategy Ⅲ, it is derived based on equal arclength principle, in which the profile arclength of the illuminated aperture is equal to that of the spherical base plane within the 300m diameters of the illuminated aperture. The focal ratios corresponded to these three strategies are respectively 0.4665, 0.4611, and 0.4613.

In the preliminary design of FAST cable-net structure, the deformation strategy Ⅰ was recommended as the prefer control scheme just because of its shortest actuator stroke. Obviously, it is unreasonable to omit the fatigue problem in the deformation strategy optimization, especially for the present case of about 500MPa stress range.

So the present work would make an effort in establishing the relation between the focal ratio and the deformation stress range. And then, by considering both factors of the actuator stroke and the stress range of the cable, we would re-recommend deformation strategy for FAST future observation.

Numerical analysis

In the present paper, ANSYS software is applied for simulation, and link10 is used to simulate the response of the cable. When it does not work, the FAST cable-net should hold spherical shape under combined loads of gravity, initial stress, and down tied cable. In order to derive such state, the inverse iteration method is applied. As for the observation state, the deformation procedure of forming the illuminated aperture from spherical shape can be simulated by the conventional iteration method.

For the FAST condition, the maxmium distance between the spherical and the paraboloid surface is no more than 1m. As we known, the angular velocity of celestial body is about 15 degrees per hour. Accodingly, the radial velocity of the cross node during FAST tracking observation is less than 1mm/s. So, the deformation procedure of the reflecter system in the tracking observation can be taken as quasi-static state procedure. Base on this conclusion, we can replace a continuous observation procedure with a set of sequential discrete observation states. By comparing with the time history analysis method, this method would be capable of saving a lot of calculation time.

For FAST observation, the illuminated aperture is restricted within the scope of the cable-net. Consequently, we can easily deduce the movement range of the illuminated aperture center, which has been illustrated by Fig. 4. This region contains 550 cross nodes, the interval of any two adjacent ones is no more than 13m which corresponds about only one degree-center angle of 300m radius of reflector.

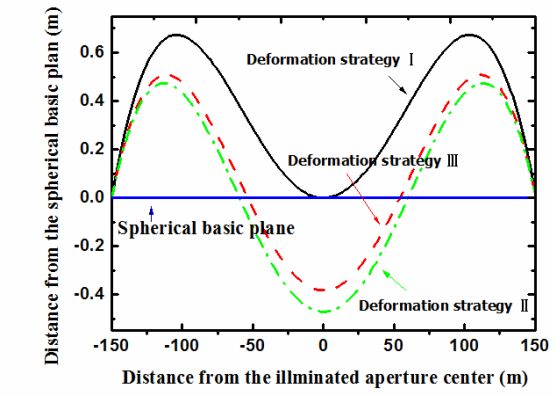

Fig. 3. The relative positions between the paraboloid and base spherical surface for three previous proposed deformation strategies.

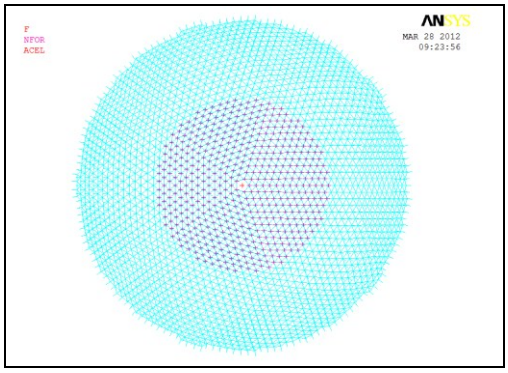

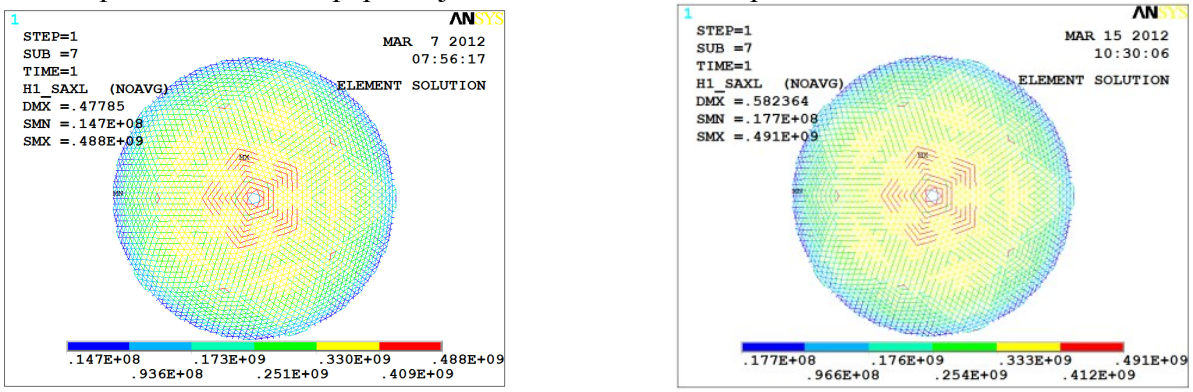

Fig. 4. Illustration of range of cross nodes used as discrete points to describe continuous trajectory path of the center of the illuminated aperture

In the present work, these 550 cross nodes are taken as the discrete points, which is used to describe the continuous trajectory path of the center of the illuminated aperture. Thus, any possible observation state during FAST observation can be approximately recognized as one of 550

observation states, whose centers are corresponding to these 550 cross nodes. By using the finite element analysis method, we can simulate these 550 observation states. With the simulation results, stress data of all cables under those 550 cases can be saved as two-dimensional array data. By processing this two-dimensional array data, the maximum stress range of each cable during FAST observation can be easily derived.

However, using the discrete observation states to describe the continuous observation procedure would bring errors in our evaluation. Magnitude of these errors would be directly depended on how dense discrete points used. Obviously, more dense discrete points would lead to more accurate estimated result. So, comparative analysis has been performed on the deformation strategy Ⅱ respectively by using above 550 discrete points and more dense discrete points. For the later, the discrete points contains not only the cross-nodes but also the mid-points of the cables and median-points of the triangle elements, thus there are more than 2200 deformation states need to be simulated for one deformation strategy.

The calculation results derived by above two sets of the discrete points are respectively shown in Fig. 5 a and b. It is can be readily seen that the peak stress ranges derived by using 550 discrete points and 2200 discrete points are respectively 488MPa and 491MPa, difference between them is no more than 1%. So, we can assume that using 550 cross nodes has enough accuracy for engineering design. The subsequent work of this paper is just based on this assumption.

a) Simulation result achieved by 550 discrete points b) Simulation result achieved by 2200 discrete points

Fig. 5. Comparison of the simulation results of the deformation strategy Ⅱ respectively derived by using 550 discrete points and 2200 discrete points

Utilizing the same procedure, the distribution of the stress range for other two types of deformation strategies can be derived. The peak stress range of the strategy Ⅰ and strategy Ⅲ are respectively 547MPa and 482MPa. By using the least square method, the relation of the focal ratio and the peak stress range can be fitted by quadratic polynomial, from which we can predict that the focal ratio value corresponding to the minimum stress range is about 0.4633. The corresponding profile shape of the illuminated aperture can be determined by Eq(1) and Eq(5).

We input this new deformation strategy into the above analysis procedure, we can derive that the maximum stress range of this deformation strategy is 488MPa, which is same to that of the focal ratio of 0.4613. Then, by repeating the above steps with interpolation of this new data point, the focal ratio of 0.4621 can be further determined. The further simulation result has shown that the maximum stress range corresponding to the focal ratio of 0.4621 is 459MPa, which is about 90MPa beneath that of deformation strategy Ⅰ and 30MPa beneath that of the strategy Ⅱ.

However, it is difficult to say whether 0.4621 is the optimum focal ratio for the fatigue problem of the cable-net. For this reason, other two strategies with 0.4620 and 0.4622 of focal ratios have also been investigated in the present work. And the simulation results have shown that the peak stress ranges leaded by these two deformation strategies are respectively 462MPa and 460MPa, both of them are slightly higher than that caused by the deformation strategy with focal ratio of 0.4621. So, we have reasons to believe that the deformation strategy with focal ratio of 0.4621 is very close to the deformation strategy corresponding to the minimum stress range.

It also should be noted that the actuator stroke of this strategy is 0.89m, which is also 50mm beneath the strategy Ⅱ. By comparing the stress range and actuator stroke of these deformation strategies (see Table. 1), we would recommend the strategy with focal ratio of 0.4621 for FAST application.

TABLE. 1. COMPARISON OF THE FATIGUE STRESS RANGE OF THE CABLE AND THE STROKE OF THE ACTUATOR CAUSED BY DIFFERENT DEFORMATION STRATEGIES.

Focal ratio	0.4603	0.4611	0.4613	0.4620	0.4621	0.4622	0.4633	0.4665
Stress range (MPa)	12	488	482	462	459	460	488	547
Actuator stroke (m)	0.9890	0.9450	0.9341	0.8966	0.8914	0.8861	0.8291	0. 6741

Conclusion

During FAST observation procedure, the stress range borne by its cable is more than twice as that provided by the relative standard. In order to improve the reliability of FAST, the present work has performed an extensive numerical and experimental investigation to decrease the stress range of the cable caused by shape-changing operation. Then, the focal ratio is the key influence factor of the stress range of FAST cable-net structure caused by shape changing operation. And 0.4621 is suggested as the most appropriate focal ratio, which would lead to about 30MPa reduction of the stress range and 50mm reduction of actuator stroke.

Key words: jute fiber; compressive strength; pull-out force; saturated alkali treatment

Abstract: In this study, jute fibers and polypropylene fiber (PP) were added into cement-based mortar to improve their compressive strength. Results obtained have shown that the compressive strength of the motar was perfect with jute fiber of 19mm length at the fiber contents of 0.8 $kg \cdot m^{-3}$. The reinforcing mechanism of fiber in the motar was analyzed by means of comparing of the mortar compressive properties under different circumstances, and the testing results of scanning electron microscope (SEM) and the addition of filament in experiments.

Introduction

Fibers have the potential to be used as reinforcement to overcome the inherent deficiencies in cementitious materials. In recent years, there has been sustained interest in utilizing natural fibers in cement composites and in manufacturing products based on them with a view to have alternate building materials, which are energy-efficient, economical and eco-friendly.

It has been recognized that fiber reinforcement is an effective way to enhance the performance of cement-based materials in many ways [1]. Mortar is a kind of quasi brittle material which is easy to be crack and has very low crack resistance [2]. However, jute fibers could be added to improve its compressive strength, flexural strength and early-age crack resistance [3]. The degree of the improvement depends upon both the volume and the type of fibers used [4]. In this study, the mechanical properties such as crack resistance of fiber- reinforced mortar based on the change of length and volumes of jute and PP fibers were studied and discussed.

Experimental materials and equipment

Materials

"Conch" brand PO32.5 cement, sand fineness modulus of 2.5, Running water, Gypsum powder, Dispersibility powder. The needed fiber in the experiment was tested by electronic single fiber strength machines. Each sample was tested 20 times, and the average data was finally obtained. The mechanism of the fiber specimen was carried out on a LLY - 06 B/PC electronic single fiber strength machines, the results in Table 1.

TABLE 1 THE MECHANICAL PROPERTIES OF FIBER

Sample	designation	lineal weight [dtex]	breaking strength [cN/dtex]	breaking elongation [%]	initial modulus [cN/dtex]
Untreated jute	Jute A	29.73	3.95	6.35	15.71
Saturated alkali treatment 12h	Jute B	26.72	2.83	14.42	10.54
PP fiber	PP	3.45	1.91	84.48	1.95

The experimental parameters and experimental steps

Fiber length in the test is chosen according to the market application.The selected length of jute fiber was 10 mm, 19 mm and 30 mm. And the selected length of the pp was 10 mm and 12 mm. The fiber content in the mortar was 0.4 $kg \cdot m^{-3}$, 0.8 $kg \cdot m^{-3}$ and 1.2 $kg \cdot m^{-3}$. In this experiment, mortar strength grade was designed with reference to JGJT plastering mortar, 220-2010 technical regulations. The cube moulds with dimensions of 70.7 mm ×70.7 mm ×70.7 mm were used. Pull-out force tesing of single fiber was carried out in accordance with the self-designed experimental platform. During the mortar manufactured process, the demoulding time of specimen should be completely same, and the mortar specimen should be conserved to avoid being effected by other objective factors.

First of all, the specified size of the compression casting mold should be prepared during the trial production of mortar specimen, and daub on the inner wall of the mold with a layer of lubricating oil, in order to prevent the specimen from accounting for the wall. Then, pour plenty of water into the mixer, and weighed fibers, stired them well. Add cement, yellow sand and dispersibility powder in the mortar mixer, according to the designed proportion . Start the machine to dry mixing for 1-2 minutes, then add stirred water and fiber and stir for another 2-3 minutes. Pour mixed mortar into the prepared triple mold and vibrate it on shaking table, in order to reduce bubbles of mortar. The specimens were stored in the laboratory for 24 hours with the storage temperature 20 ± 1 ℃. After stripping mortar specimens, maintenance them in the 101 B constant temperature and humidity curing box for 7 days, curing temperature 20 ± 1 ℃.

Test results and performance analysis

Fiber reinforced cement compressive strength performance test

The mortar specimens were tested which has reached standard curing time with the JYE-200 type compression testing machine manufactured in the city of WuXi. Each set of the sample was tested for three times[5]. And take the average of the final result. Convert the measured results for strength. The intensity of conversion calculation formula is shown below:

$$f_{cc} = F / A$$

where, fcc was the compressive strength(MPa), F was the maximum crushing load (N), A was the area

of the compression face(mm^2). The change trend of the compressive strength was shown in the Figure.1, Figure.2, and Figure.3 .

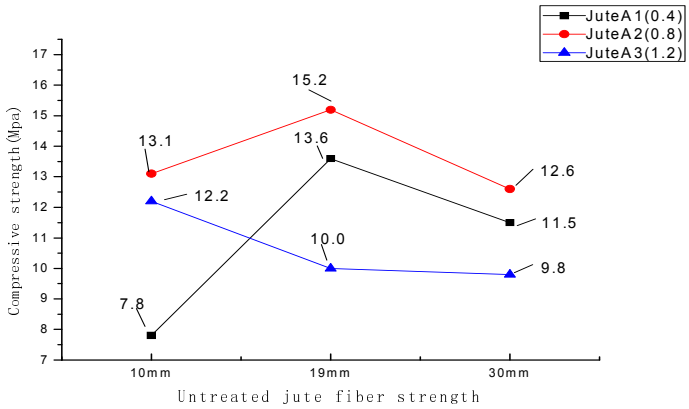

Figure.1 The Compressive Strength of Untreated Jute with Different Lengths, Different Content

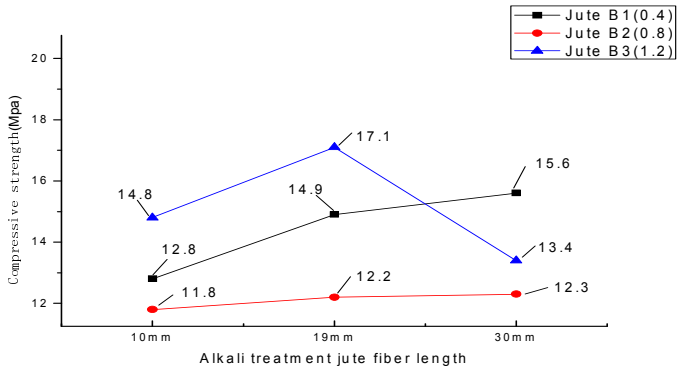

Figure.2 The Compressive Strength of Jute Saturated Alkali Treatment of 12h with Different Lengths, Different Content

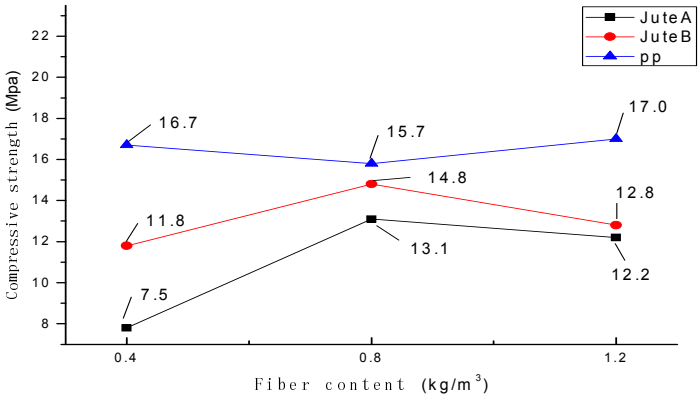

Figure.3 The Compressive Strength of Different Fiber with 10mm

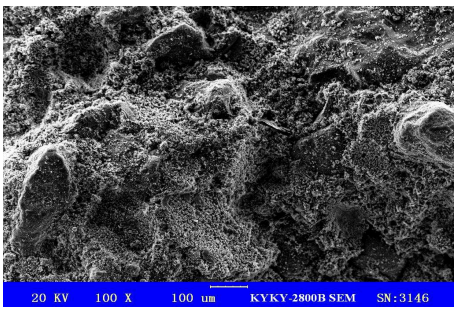
According to the graph, it was recognized that the compressive strength of the specimen as the fiber length changed when the untreated jute (Figure.1) content is 0.4 kg·m^{-3}or 0.8 kg·m^{-3}. And the specimen reached the highest compressive strength when the fiber length was 19mm. When the fiber content was 1.2 kg·m^{-3} and the fiber length was 30mm, the specimen reached the highest compressive strength. When Jute was treated with saturated alkali for 12 hours (Figure.2), as the fiber length increases, the compressive strength increased and then decreased in the case of high content. On the other hand, the compressive strength showed a gradual upward trend in the case of low content. The reasons why mortar intensity changes was that the length of untreated jute fiber was appropriate. Appropriate length may be contribute to increasing in the strength when the content was a certain value. However, the fibers would hold together because of uneven dispersion as the fiber length increased. And some areas under the action of the force would be very brittle due to mortar internal porosity increases when the fiber content was 1.2 kg·m^{-3}. The fibers ,which were treated with saturated alkaline solute ,added to the mortar. It made the strength to get some improvement relative to the untreated jute fibers. However, when the fiber length was 30mm, the strength would be greatly decreased. The reason was that the fiber and the cementitious material in the mortar bonded better. It was caused by a certain degree of degumming of fiber's surface after alkaline treatment. The compressive strength of mortar was improved by jute fiber which owned the role of bridging. However, the phenomenon of fibers hold together was further deteriorated because fiber length was constantly on the rise and friction of fibers was increased . The compressive strength was decreased sharply. When the length of fiber was 10mm (Figure.3), the compressive

strength of the mortar which mixed PP fiber showed a greater advantage .Compared with different fibers, the critical point of compressive strength had been found when the fiber content was 0.8 $kg \cdot m^{-3}$ .This found provided a good reference to the practical application of several fibers .

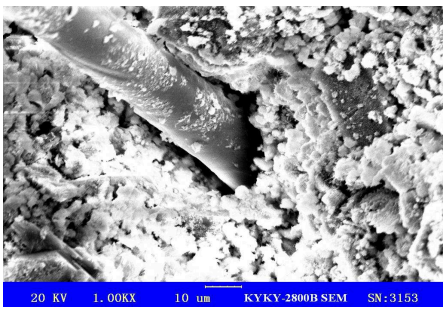
TABLE 2 THE COMPRESSIVE STRENGTH OF MORTAR REINFORCED BY FIBER WITH 19MM LENGTH UNDER DIFFERENT DOSING CONTENT

Sample	Dosing content [$kg \cdot m^{-3}$]	Fiber Length [mm]	Crushing load [KN]	compressive strength [Mpa]	strength growth rate [%]
Sample 1	-	-	57.5	11.5	-
Sample 2	0.8	19	75.98	15.2	32.17
Sample 3	0.8	19	60.98	12.2	6.09
Sample 4	0.8	12	111.97	22.4	94.78



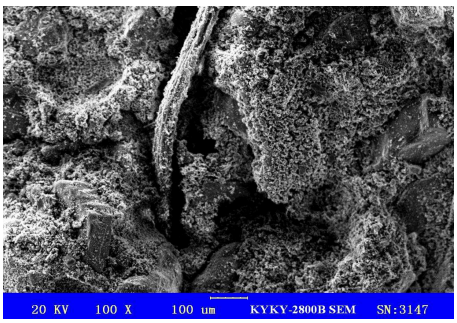
The strength of the specimen growth rate compared with the plain cement mortar strength

Sample 1-plain mortar, sample 2-mortar reinforced by untreated jute, sample 3-mortar reinforced by jute saturated alkali treatment,sample 4-mortar reinforced by PP fiber.



According to pre-experimental research, it was found that when the dosing content of fiber is 0.8 $kg \cdot m^{-3}$, the compressive strength of mortar changes obviously. Considering the PP fiber dosing content in mortar on the current market, the compressive strength of mortar before and after adding fiber is compared. The results are shown in Table 2. Comparing with the plain mortar, the compressive strength of mortar reinforced by fibers has increased. But after adding the fibers treated by saturated alkali solution, it would result in the lower growth rate since there is some loss of fiber strength.

Mortar specimens fracture surface



For further description of the fiber's form existence in mortar, we pick up a number of pieces of the fractured specimens are soaked in absolute ethanol for 1h, then placing them in 101 AB thermostatic drum wind drying oven. Finally, the small pieces of specimens were observed under the KYKY2800 type B scanning electron microscope (SEM). The results were show in Figure.4.

（c） mortar with jute saturated alkali treatment

（d）mortar with pp fiber

Figure 4 The SEM images of Mortar specimen fracture

Pull experiment of single fiber

Combined with results of compressive strength test, one experiment platform is simulated which can be used to show the role of fiber during the process of fracture in the experiment. ALD spiral frame and SH-500 digital force gauge were chose to compose the platform. In order to explore the effect of the fiber in the mortar, the fiber pull-out force under the same mortar mix ratio, different fiber length and fiber volume of 0.8 $kg \cdot m^{-3}$ is tested to explore the effect of the fiber in the mortar. Several fibers mixed with cement mortar is selected, the pull-out force of single fiber after 5h solidification under normal temperature and pressure is tested. The experimental results are shown in table 3. It was found that the fiber length has a strong influence on the fiber pull-out force required in the experiment. The suitable length of jute fiber is 19mm, while suitable length of PP fiber is 12mm.

TABLE 3 THE TEST OF DIFFERENT FIBER PULL-OUT FORCE

Sample	Fiber pull-out force（N）		
	10mm	19mm	30mm
Untreated jute	0.417	0.511	0.307
Saturated alkali treatment jute	0.215	0.330	0.288
PP fiber	0.205	0.299	-

Conclusions

(1)The compressive strength of mortar were discreteness, but a certain tendency could be obtained. The compressive strength of mortar specimens was largely influenced by the content and length of fiber. In terms of jute fiber, when the volume for 0.8 $kg/m^3$and the fiber length for 19 mm, the compressive strength of reached highest.

(2)For untreated jute with different fiber length, the specimen compressive strength declined after rising, when the fiber volumes were 0.4 $kg \cdot m^{-3}$ and 0.8 $kg \cdot m^{-3}$.But it showed larger variation when the fiber volume is 1.2 $kg \cdot m^{-3}$,while the saturated alkaline treatment of 12h jute showed a slowly increasing trend.

(3) The bonding effect of jute fiber and mortar base material was better than the bonding effect of untreated jute and mortar.

(4)The pull force of single fiber was consistent with compressive strength. The pull force was relatively high when fiber length was 19 mm. But the test standard should be further perfect.

Keywords: shock absorber; low-cycle fatigue; fatigue test; life prediction

Abstract: In this paper, by experiments on the low-cycle fatigue life of groups of base metal test specimens under constant total strain control, the number of cycles to fracture failure are obtained. The measured S-N curve of base metal is established and the fitted formulas based on three low cycle fatigue life prediction models are caculated according to the test data. The relationship between the low-cycle fatigue life and strain amplitude are concluded. The results of observation show that the elastic strain effect can be negligible in the range of strain amplitudes used for the study of low-cycle fatigue (0.01-0.08). In addition, the calculation suggests that the three-parameter power function is suitable for the low-cycle fatigue life prediction of the base metal because its prediction accuracy is higher than other methods. The research provides technology supports for life prediction and engineering application of the shock absorber.

Introduction

Seismic design and technique can be divided into two aspects: isolation techniques and ductility design. The two methods have been used in seismic design code of bridge in Japan, United States and New Zealand.[1-2] The study and application of isolation technology in our country start later especially in bridge engineering.[3] In the counstruction of the high speed railway, the stiffness of the bridge pier improves greatly and the design horizontal seismic force increases further. So it is imperative to find new way to solve the problem of aseismatic design in railway bridge.

Based on the idea of bearing function separation and according to the demand of the seismic design of high speed railway bridge, a new type of shock absorber which possesses the stable hysteretic capacity and sufficient plastic deformation capacity has been proposed by Professor Li Chenggen and Gao Ri in China recently. The design idea is to change the fixed bearing into the movable so that the vertical and horizontal function can be separated.In the serviceability state, the vertical support reaction and rotation at beam ends are still realized by the bearing, but the horizontal force and horizontal displacement, which transferred from the beam, are supported and controlled by the shock absorber. When earthquake occurs,the horizontal force of the beam will be transferred via the absorber to the piers. From the Fig.1 it can be seen that the absorber is a typical of cantilever beam structure, which belongs to bending-shear member statically.

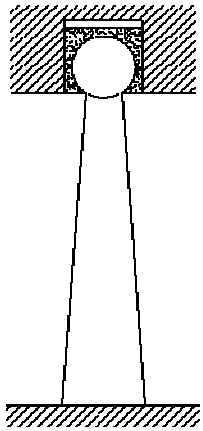

Fig.1 Structure of the shock absorber

Under the earthquake and strong wind effect, due to the low ultimate strength and small maximum ductility, parts of structure destroy quickly at the early stage while the majority fail for the low cycle fatigue. The current study on the fatigue failure of civil engineering are concentrated in high cycle fatigue such as the cumulative damage and fatigue life evaluation. However, little work has been carried out for the low cycle fatigue failure under the earthquake effect. The shock absorber that fabricates entirely from a new type of metal has not yet been thoroughly investigated and the relative literatures are few in China and foreign countries, let alone the study on low cycle fatigue. The subject is concerned chiefly with the study of the low cycle fatigue life of the shock absorber base metal.

Through the experiments on some specimens, the number of cycles to fracture failure are obtained and the measured S -N curve of the base metal is established. Combined with experimental data, we creat fitted curves based on three low cycle fatigue life prediction models and compare the prediction accuracy of three prediction models by caculating the fitting parameter determination coefficient square R^2 and the sum of squares due to error (SSE).

Unidirectional Tensile Test

The cylindrical specimens with gauge length of 20 mm and diameter of 8 mm were used (Fig.2). Three specimens were employed to carry out the unidirectional tensile test. The stress-strain curve is obtained from the experiment, as shown in Fig.3.It can been seen that the stress increases rapidly with the increasing of deformation, but the increased stress value decreases gradually with the increment of the deformation. When the stress reaches its maximum, the stress decreases with the deformation increasing. In addition, the mechanical properties of the base metal are given in Table 1.

Low Cycle Fatigue Test Condition

The fatigue tests were conducted on the MTS Hydraulic Servo Fatigue Machine in ambient air at room temperature according to the "GB/T15248-2008: The test method for axial loading constant amplitude low-cycle fatigue of matallic materials". Triangular waveform was used for all the fatigue tests and the frequency was 0.2 Hz. The tests were carried out under uniaxial tension loading with total strain control at given strain amplitudes of 0.01, 0.02, 0.04, 0.06, 0.08 and a strain ratio of 0. The failure criterion of low-cycle fatigue was based on the specimen's fracture. The number of specimens corresponding to different total strains are shown in the Table 2.

Results and Discussion

The measured S-N curve

According to the experimental conditions above, we obtained the number of cycles to fracture failure. The experimental data choice was based on the Grubbs criterion and the significance level was 0.05. The final measured sresults are shown in the Table 3.

TABLE 3 CYCLES-TO-FAILURE

	1	2	3	4	5	6	7	measured results
0.01	902	782	968	916	303	267	900	376
0.02	95	94	129	71	68			58
0.04	28	--	24	32	16			14
0.06	11	18	17					8
0.08	7	10	14					4

Note:" --" means that the datum is rejected.

It is necessary to put forward feasible analytical method for the computation of the fatigue life. The S-N curve can reflect the fatigue strength property of the material and it is the foundation for fatigue design. So, we must establish S-N curve for estimating the low-cylce fatigue life of the base metal. According to the determination method of S-N curve that provided by Zhang Guodong[4], the measured S-N curve is shown in Fig.4 .

Under the constant total strain effect, the relationship between the low-cycle fatigue life and total strain are concluded as follows:

(1)In the small range of strain amplitud(0-0.02), the fatigue life reduce rapidly with the increasing strain amplitude;

(2)the fatigue life decreases slowly in the large range of strain amplitud (>0.04);

(3)when the strain amplitud is between 0.07 and 0.08, the fatigue life is almost the same.

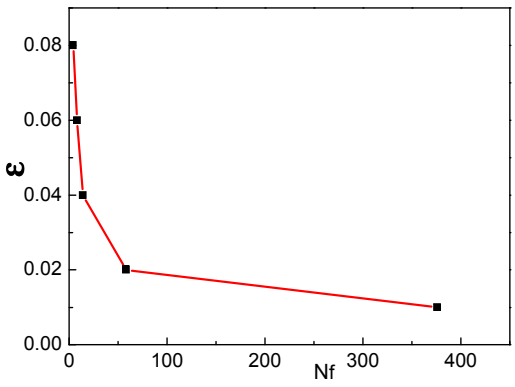

Fig.4 The measured S-N curve

The low-cycle fatigue life prediction models and analysis

In this section,test results are analyzed by considering the applicability of several various predictive strain fatigue life models. Each model can be plotted in a from with the values of model coefficients being obtained from a least-squares regression analysis. By comparing the fitting parameter determination coefficient square R^2 and the sum of squares due to error (SSE), the best prediction model can be determined. N_f and $2N_f$ mean the number of cycles and reversals, respectively.

(1) Manson-Coffin prediction formula

In the basic low-cycle fatigue life prediction models,the initial Manson-Coffin equation is widely applicable.[5] At high strain amplitudes (>0.01), where plastic stains are significant, elastic strain effects are negligible. Eqn.(1) shows the relation between plastic strain $\Delta\varepsilon_p$ and low-cycle fatigue life data.

$$\Delta\varepsilon_p = \varepsilon_f^{'} N_f^c \tag{1}$$

Where $\varepsilon_f^{'}$ and c represent the fatigue ductility coefficient and the fatigue ductility index, respectively. It is merely suitable for the short life span areas.

Many scholars' study show that the total strain amplitude can describe the fatigue properties of material on a larger and wider scope, even including the high cylce fatigue.[6] The total strain consisting of elastic strain and plastic strain is represented by the following equation:

$$\Delta\varepsilon_t/2 = \Delta\varepsilon_e/2 + \Delta\varepsilon_p/2 \tag{2}$$

Where, $\Delta\varepsilon_t$ means the total strain, $\Delta\varepsilon_e$ means the elastic strain. In addition, $\Delta\varepsilon_e$ and $\Delta\varepsilon_p$ can be obtained by the hysteresis loops at half life.

$$\Delta\varepsilon_t/2 = \frac{\sigma_f'}{E}(2N_f)^b \tag{3}$$

Where, σ_f' refers to fatigue strength coefficient, b refers to fatigue strength index, E refers to elastic modulus.

So the fatigue life of a material subjiected to a given strain range could be estimated by superposition of the elastic and plastic strain components given by another variation of Manson-Coffin relationship as:

$$\Delta\varepsilon_t/2 = \frac{\sigma_f'}{E}(2N_f)^b + \varepsilon_f'(2N_f)^c \tag{4}$$

The total strain-fatigue life curve, approaches the plastic-strain life cure at large strain amplitudes and approches the elastic-strain life at low strain amplitudes.

Based on the formula (1) and (4), the fitted curves combined with the experimental data are represented as the Fig.5 and Fig.6, respectively.

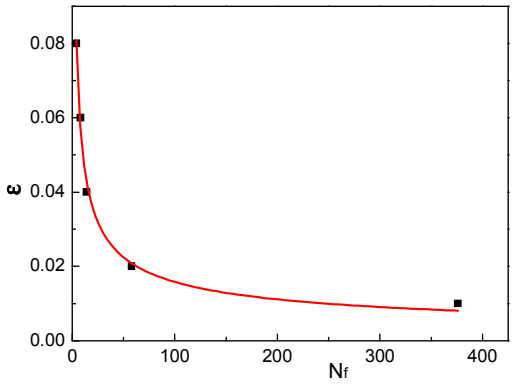

Fig.5 The fitted S-N curve based on Eqn.(1)

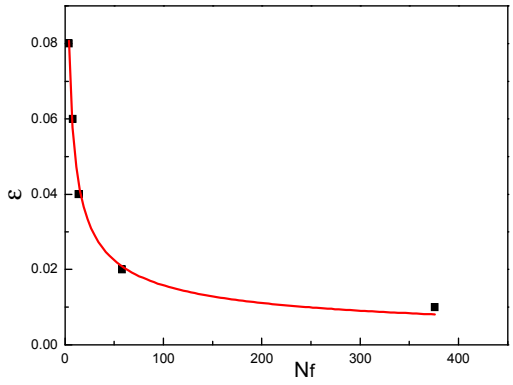

Fig.6 The fitted S-N curve based on Eqn.(4)

It can be seen that the two fitted curves are very close to the experimental data, suggesting that the predicted fatigue life coincides well with the experimental data. Through the optimum fitting, there are two equations can be obtained as followings:

$$\Delta\varepsilon_p = 0.16297\left(N_f\right)^{-0.50669} \tag{5}$$

$$\Delta\varepsilon_t/2 = 4.8544E(-17)(2N_f)^{-0.50669} + 0.29715(2N_f)^{-0.50669} \tag{6}$$

The results are reported along with the the fitting parameter determination coefficient square R^2 and the sum of squares due to error (SSE) in Table 4.

TABLE 4 COEFFICIENT OF MULTIPLE DETERMINATION AND SUM OF SQUARES DUE TO ERROR IN THE FITTING FORMULATIONS

	R^2	SSE
Eqn. (5)	0.99073	2.28125E-5
Eqn. (6)	0.99304	2.28125E-5

From the Table 4, although the SSE of two equtaions are the same, the R^2 of Eqn.(6) is better than that (5). So the modified Manson-Coffin formula prediction accuracy is higher than the later. Through analsis of the Eqn.(6), the first term is so small that it can be negligible compared with the second. This provides further evidence that the elastic strain can be ignored for the range of strain amplitudes used for the study of low-cycle fatigue (0.01-0.08).

(2) Three-parameter power function for low-cycle fatigue

By analysising and studying for a lot of $\varepsilon - N$ curve experimental data, Fu Huimin proposed three-parameter power function, as represented in Eqn.(7). MIL-HDBK-5J has adopted this method in dealing with low-cycle fatigue recently.[7]

$$N_f\left(\Delta\varepsilon_t-\Delta\varepsilon_0\right)^m=C \tag{7}$$

Where, $\Delta\varepsilon_0$, m and C are undetermined consants.

The fitted curve and equation of this model to the experimental data are shown as followings.

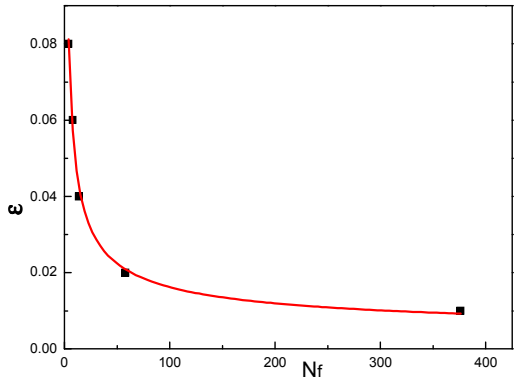

Fig.6 The fitted S-N curve based on Eqn.(8)

$$N_f\left(\Delta\varepsilon_t-0.00273\right)^{1.82786}=0.03814 \tag{8}$$

In this plot, the predicted fatigue life coincides perfectly with the test data. The value of R^2 is 0.9874 and SSE is 2.06562E-5. Compared with the initial Manson-Coffin model, the sum of squares due to error (SSE) is much less than the later although the R^2 is lower. It is indicated that the three-parameter power function is more suitable for the low-cycle life prediction of the base metal.

Conclusion

Through the unidirectional tensile test and low-cycle fatigue experiment, the mechanical properties of the base metal and the count loops to failure are obatained. The measured S-N curve is established according to the experimental data. At the low strain range, the low-cycle fatigue life decreases significantly with sharper gradient with increasing the strain amplitude in the range from 0 to 0.04. However, for the strain amplitude higher than 0.06, the low-cycle fatigue life decreases gradually with increase in the strain amplitude.

There is satisfactory agreement between the three fatigue life prediction models and the experimental life. It is evident that the effect of elastic strain can be neglected compared with the effect of plastic strain in low-cycle fatigue life (0.01-0.08). With the comparison of these three kinds of forecasting methods, the fitting parameter determination coefficient square of modified Manson-Coffin formula is higher than other two methods. But taking account of the sum of squares due to error, the three-parameter power function is more suitable for the low-cycle life prediction of the base metal. Furthermore, the research provides technology supports for life prediction and engineering application of the shock absorber.

Keywords: wet–dry cycles; pore structure; simulated seawater environment; performance deterioration

Abstract: In this paper, we present the corrosion behavior of F30S30 concrete used for a bridge cap which was investigated in simulated seawater with 2.0% NaCl, 0.35% $MgCl_2$, and 0.25% Na_2SO_4 under wet–dry cycles. This behavior was compared with those in 3.5% NaCl, 5.0% Na_2SO_4, and 3.5% NaCl + 5% Na_2SO_4 solutions. Results show that the change in pore structure obtained through X-ray computed tomography could reflect the amount of corrosion products and the degree of destruction. The variety and quantity of corrosion products varied with the corrosive environment. The damage mechanisms of concrete also changed according to the corrosive environment. The effects of Mg^{2+} and SO_4^{2-} were superimposed on each other for the simulated seawater environment, thereby posing a serious threat to the structure, primarily through damage and coarsening of the pore structure caused by Mg^{2+}.

Introduction

In the field of concrete research, corrosion is an important problem when concrete components are operating in seawater, particularly in the splash zone or in water-level change areas **[1].** Seawater normally includes chlorides, sulfates, and magnesium salts. Concrete components working in the splash zone or water-level change areas often undergo corrosion and seawater erosion with wet–dry cycles.

Wet–dry alternation with high chlorine salt content threatened the durability of concrete. Sosa [2] analyzed the concrete contour and steel–concrete interface of samples exposed to the atmospheric zone, alternate drying–wetting, and underwater area. Tittarelli [3] exposed specimens to wet–dry cycles in a 10% NaCl aqueous solution, and then, analyzed the effect of silane-based hydrophobic admixture on the corrosion of galvanized reinforcing steel in concrete. Santiago [4] presented two models that deal with chloride-induced corrosion and subsequent cracking of the concrete cover in reinforced concrete structures. Espinosa [5] analyzed mechanical stress during the crystallization of KNO_3 and Na_2SO_4 in the pores of two bricks with different porosities using strain measurements. Yigiter [6] studied investigative factors, such as cement type, water-cement ratio, and cement

content, on seawater resistance of concrete using mechanical strength tests, chloride penetration depth measurements, and scanning electron microscopy–energy-dispersive X-ray spectroscopy (SEM–EDS). Oh [7] conducted comprehensive tests using variables that include water-binder ratio, cement type, type and amount of mineral admixtures (silica fume, fly ash, and blast-furnace slag), and maximum size of aggregates and air entrainment, to develop a high-performance concrete with high resistance to chloride penetration and high durability. Gruber [8] discussed laboratory evaluations to assess long-term performance of concrete with high-reactivity metakaolin produced in North America in resisting chloride penetration and expansion reduction caused by alkali–silica reactivity.

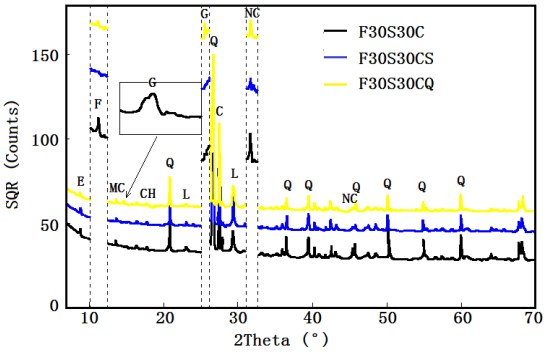
Although the law of concrete with different dosages of mineral admixture, durability under different environments, variation of concrete permeability under different load conditions, and size effect of concrete on chloride resistance have been studied, their specific applications in engineering have not been reported. Chongqi Bridge is located at the Yangtze River estuary, which intersects with the Yellow Sea. The pier cap and the lower part of the bridge undergo alternating wet–dry cycles, and the maximum salinity in the water reaches 25 g/L. The present study investigates the corrosion behavior of F30S30 concrete in the complex environment described earlier.

Experiments

The specimen size was 100 mm × 100 mm × 400 mm. F30S30 concrete specimens were composed of 30 mass% fly ash and 30 mass% ground slags. The ratio of water to cement was 0.35, and the ratio of cement to sand was 2.90. The specimens were allowed to dry naturally for 12 h to 15 h after 28 d of standard curing. Afterward, four surfaces of the specimen, except for two opposite sides, were coated with epoxy resin. As a result, chloride ions could only enter through the two opposite sides in corrosive solutions.

The wet–dry cycle tests for the specimens were conducted using different corrosive solutions. In accordance with the wet–dry cycles of high-performance concrete [9,10] and the highest salinity of an engineering environment during dry season, the following corrosive solutions were selected: (1) 3.5% sodium chloride (NaCl) solution (C), (2) 5.0% sodium sulfate (Na_2SO_4) solution (S), (3) 3.5% NaCl + 5% Na_2SO_4 solution (CS), and (4) 2.0% NaCl + 0.35% $MgCl_2$ + 0.25% Na_2SO_4 simulated seawater solution (CQ). The specific implementation of the wet–dry cycle test was as follows: soaking for 8 h in one solution, followed by drying for 1 h in natural environment, then drying at 60 ± 2 °C in an oven for 38 h, and finally cooling for 1 h in natural environment. These wet–dry cycles were repeated for 360 d.

The deterioration of concrete after every seven cycles was analyzed by testing the ultrasonic propagation velocity of the specimens. Chloride ion content after the wet–dry cycles was measured using the chemical titration method based on SL352-2006 hydraulic concrete testing procedures.

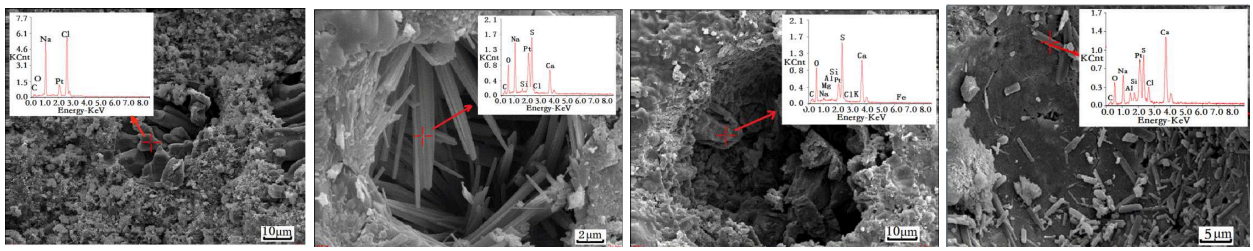


In addition, all specimens were examined using Y.CT Precision system (YXLON International, Germany). The detector of the computed tomography (CT) system was a flat-panel type with 1 024 × 1 024 detector elements and 1 080 projections. The voltage and current of the X-ray tube were set to 185 kV and 0.33 mA, respectively, and the object rotation angle was 360°. For the specimens in this study, the 3D voxel size was 0.063 mm × 0.063 mm × 0.063 mm. Phase structures were analyzed by X-ray diffraction (XRD, D8, Germany), and the experimental samples used were 40 μm powder in diameter. The surface morphology and chemical elements of the corrosion products after a certain number of cycles were obtained by SEM.

Results and Discussion

Analysis and morphology of corrosion products

The XRD patterns of F30S30 concrete specimens after 360 d of wet–dry cycles in three different solutions (C, CS, and CQ) are shown in Fig. 1. Ettringite ($C_3A{\cdot}3CaSO_4{\cdot}32H_2O$) and $MgCO_3{\cdot}3H_2O$ were found in all samples. The former is the product of the hydration reaction between C_3A and sulfate. Friedel salts (F salt: $C_3A{\cdot}CaCl_2{\cdot}10H_2O$) was detected in the samples immersed in C solution but not in the samples immersed in CS solution. This result showed that the presence of sulfate salt hindered the formation of F salt. However, an extremely low peak of F salt appeared in CQ simulated seawater solution. This result indicates that sulfate is more active than chloride and hydroxide ions in C_3A, and that the obstruction of sulfate salts in generating F salt is only effective under certain conditions.



By contrast, chloride, sulfate, and magnesium were detected in the sample immersed in CQ simulated seawater solution. Furthermore, $CaSO_4{\cdot}0.5H_2O$ (d = 3.009Å/100, 2.804 Å/85, 6.010 Å/70, 3.480 Å/55, and 1.850/55) was obtained from the sample immersed in CQ simulated seawater solution.

E：Ettringite; F: Friedel's salts; G: $CaSO_4{\cdot}0.5H_2O$; MC: $MgCO_3{\cdot}3H_2O$; CH: $Ca(OH)_2$; Q: α-SiO_2; L: $CaCO_3$; C: α-C_2SH; NC: NaCl, NS:Na_2SO_4

Fig. 1 XRD patterns of the F30S30 concrete samples after 360 days in three different solutions (C, CS and CQ)

The SEM images and EDS patterns of the samples after 360 d of wet–dry cycles in C, CS, and CQ solutions are shown in Fig. 2. The morphology of NaCl crystals in the sample tested in C solution is presented in Fig. 2a. The figure shows that several holes appeared in F30S30 concrete, and that NaCl crystals filled these holes. The crystallization of NaCl crystals could also be predicted to lead to extremely high pressure in the concrete, which might cause it to crack as crystallization continues to a certain degree. The morphology of the needle-like Na_2SO_4 crystals found in the sample tested in CS solution is presented in Fig. 2b. Under this condition, Na_2SO_4 crystals grew intertwined and almost filled the holes completely. The EDS patterns showed that the short and thick stubs (Fig. 2c) were $CaSO_4$ crystals. Furthermore, several ettringite crystals were found in the sample after 360 d of wet–dry cycles in CQ simulated seawater (Fig. 2d) based on XRD results. Daimond [11] believed that ettringite appears as thin rods 3 μm to 4 μm long, whereas the morphology of the secondary ettringite generated by the external sulfate attack is related to growth conditions. The crystallization speed was significantly faster in a complex environment, thus causing the secondary ettringite to form into slender rods with unobvious edges.

(a) in C solution (b) in CS solution (c) and (d) in CQ simulated seawater

Fig. 2 SEM images and EDS patterns of the F30S30 concrete samples after 360d of wet–dry cycles in the three different solutions

Penetration content of Cl^{-1} and Deterioration Degree

The content distribution of Cl^{-1} along the depth of the samples tested in different solutions for 28, 90, 180, and 360 d of wet–dry cycles is shown in Fig. 3. Cl^{-1} contents in the surface area were highest in all three tested conditions, and they clearly decreased with increasing depth. In particular, when testing time was more than 90 d, Cl^{-1} content distribution at the depth of 14 mm to 18 mm of the samples in CS and CQ solutions tended to exhibit an immobile tendency and its value was approximately 0.2%. Cl^{-1} content in the sample tested in C solution for 360 d wet–dry cycles had a relatively high value but only reached a limited value of 0.8% at the region more than 20 mm from the surface. These data are consistent with the results of the reference [4].

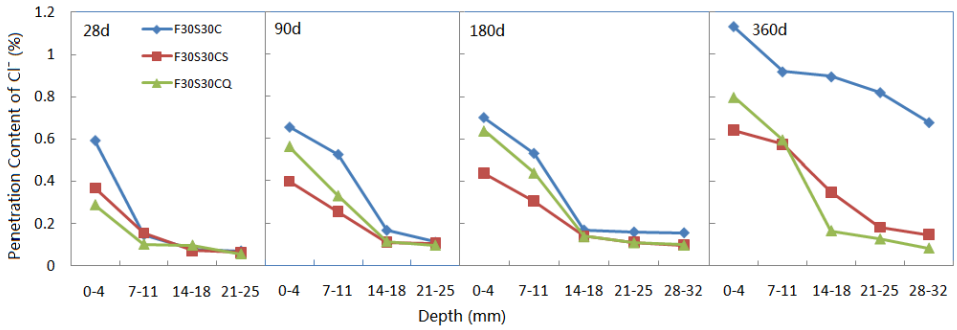


Fig. 3 Cl^- concentration versus depth and ages curve

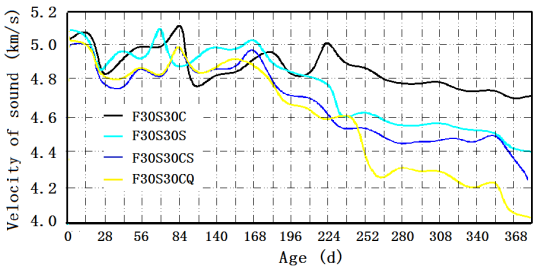
Cl^- content in the concrete samples was unsaturated under the conditions of wet–dry cycles in the present study. The capillary action introduced by unsaturated concrete accelerated the migration of Cl^- to the internal areas of the concrete. However, when SO_4^{2-} was also present and diffused into concrete, SO_4^{2-} would decrease the concentration of free Cl^- on the concrete surface and hinder the natural diffusion of Cl^-. This result explains why Cl^- content was clearly lower in samples tested in CS and CQ solutions than that in C solution after 360 d of wet–dry cycles.



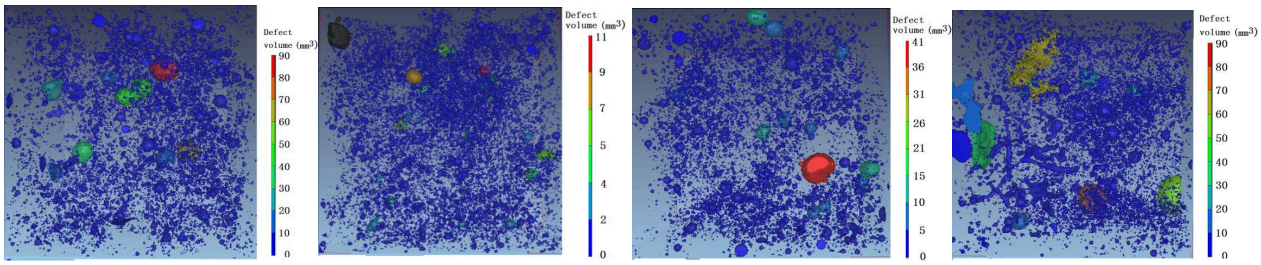


Fig. 4 Effect of time on the ultrasonic velocity in different solutions

The changes in ultrasonic velocity of F30S30 concrete samples after various numbers of wet–dry cycles in four different solutions are presented in Fig. 4. The data show that the velocities of sound clearly declined in the three samples tested in S, CS, and CQ solutions after approximately 200 h. The CQ solution exhibited the most serious result.

Changes in Pore Structures

The 3D renderings of holes in the original F30S30 concrete and that in the sample after 360 d of wet–dry cycles in three different solutions are shown in Fig. 5. Numerous holes were found within the original concrete, including a small number of big holes (Fig. 5a). After 360 d of wet–dry cycles in C or CS solution, the size of the holes within the concrete did not change significantly (Figs. 5b and 5c). However, the shape of the holes changed significantly after 360 d of wet–dry cycles in CQ simulated seawater, as shown in Fig. 5d. In addition, adjacent holes clearly joined and became large irregular holes, whereas several small holes connected to each other and formed long pipelines (Fig. 5d).

(a) Before testing (b) In C solution (c) In CS solution (d) In CQ simulated seawater

Fig. 5 3D renderings of holes

The porosity of the initial sample and the samples tested in C, CS, and CQ solutions after 360 d were 1.76%, 1.19%, 1.20%, and 2.19%, respectively, based on the X-ray CT (X-CT) scan results. Porosity slightly decreased in samples tested in C and CS solutions after 360 d. By contrast, porosity slightly increased in CQ simulated seawater solution. The distributions of pore size in F30S30 concrete before and after the tests are shown in Fig. 6. After the wet–dry cycles in C environment, the number of pores smaller than 0.2 mm markedly increased, whereas the number of pores larger than 0.2 mm decreased. For the specimen tested in CQ simulated seawater, 0.007 mm was the dividing point in the increasing and decreasing trends. For the specimen tested in CS solution, the pore number significantly decreased.

For an individual hole, the pore volume decreased when the corrosion products attached to the pore walls; whereas the pore volume increased when the corrosion products peeled off. After corrosion occurred in C environment for a certain period, the corrosion products attached to the pore walls caused certain pores to become smaller. Thus, the number of smaller pores increased. For large holes, the products peeled off or several pores joined together, thus causing a decrease in the number of holes or an increase in porosity. A high degree of peeling of corrosion products and increase in porosity both occurred in the samples after 360 d of wet–dry cycles in CQ simulated seawater (Figs. 5d and 6).

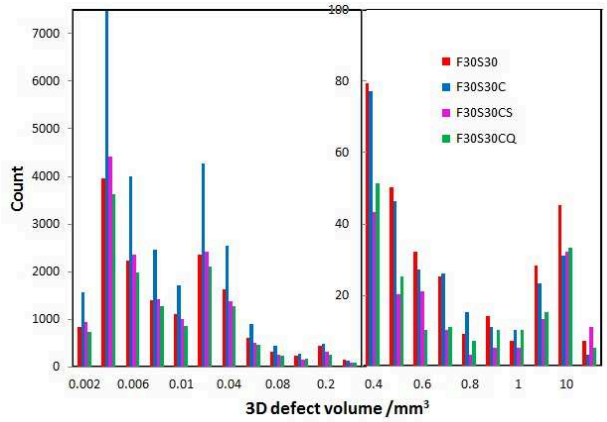

Fig. 6 Distributions of the pore size

In summary, the erosion mechanisms of Cl^- and its damage to the concrete were as follows: (1) the dissolution of $Ca(OH)_2$ and precipitation of calcium; (2) the formation of expansion compounds, such as calcium chloride and magnesium chloride; and (3) Ettringite could be generated under a sulfate environment in concrete, and its volume expanded with age. Shrinkage and tensile stress occurred under dry conditions, thus causing microcracks that allow sulfate ions to penetrate more easily into the concrete.

In CQ simulated seawater, Cl^- and SO_4^{2-} diffused together inside the concrete and reacted with aluminum to generate Friedl and Aft salts, respectively [12]. Meanwhile, Mg^{2+} and SO_4^{2-} superimposed on each other, thus resulting in serious complex erosion. $Mg(OH)_2$ formed on the surface of the concrete, whereas the dense layer was destroyed after the formation, and a new reaction was repeated. The wet–dry cycle accelerated the corrosion reaction rate described earlier. SO_4^{2-} diffused inside the concrete and reacted with the hydration product to generate ettringite or gypsum. These products initially attached to the pore walls and peeled off later. The spalling caused by Mg^{2+} in concrete was more severe than the spalling caused by SO_4^{2-}. Hence, Mg^{2+} caused major deterioration of concrete in the form of spalling.

Conclusions

The following conclusions can be drawn based on the extensive and careful examination of F30S30 concrete used in the Chongqi Bridge cap.

(1) The SEM images and EDS results show that corrosion products emerged from the holes. Crystal pressure potentially causes microcracks. Hence, the change in pore structure can reflect the amount of corrosion products and the degree of destruction.
(2) In the present study, the X-CT test method was used to study the changes in pore structures. The resulting data are consistent with other test results. Pore volume decreased when corrosion products attached to the pore walls. By contrast, individual pore volume and total porosity both increased when corrosion products peeled off.
(3) The effects of Mg^{2+} and SO_4^{2-} were superimposed on each other for CQ simulated seawater solution. These two factors pose a serious threat to the concrete structure, primarily in the form of spalling and coarsening of pore structures caused by Mg^{2+}.

Keywords: Marine engineering concrete; bending stress; NaCl solution; Na_2SO_4 solution; Simulated seawater; Damage and degradation

Abstract: The loaded specimens were put in fresh water, 3.5%NaCl solution, 5.0%Na_2SO_4 solution, and simulated sea water with different concentrations respectively, and then the damage process under wetting and drying cycle was investigated. The ultrasonic non-metal testing technology, X-CT scanned image, free chloride and sulfate ions chemical titration were used to investigate the degradation of the marine concrete under the coupling effect of Chemistry and Mechanics. The effect of solutions, wetting and drying cycle and bending stress to the durability of marine concrete were further studied. The results indicate that different salt solution affects marine concrete at different degrees: sulfate salt is more corrosive than chloride salt, simulated seawater is similar to 5.0%Na_2SO_4 solution, while five-time simulated seawater is the most corrosive; wetting and drying cycle remarkably accelerates the penetration of corrosive ions, which results in the concrete damage, compared to the corrosive environment, concrete is damaged violently under the coupling effect of Chemistry-Mechanics and tensile stress has greater influence on the damage.

Introduction

The durability of the concrete generally refers to the property or ability to resist physical, chemical or mechanical factors. It directly decides the service life of the concrete structure. In decades, researches showed that marine concrete, especially in marine splash zone and tide zone, were damaged seriously with service life far shorter than expected [1,2]. It can be explained by the complex environment, not only concrete is corroded by the soluble salt rich in the seawater such as chloride and sulfate salt [3,4], but also the corrosion is accelerated by the wetting and drying cycle severely in the tide zone [5,6]. The amount of the internal micro cracks will increase when concrete is loaded, and these micro cracks will expand and connect the cracks which already existed so that attacking medium would transport into the concrete structure easily [7,8]. Coupling of all above factors could accelerate the damage process of concrete remarkably. Therefore, it is significant and practical study the damage mechanism of concrete under coupling effect of chemistry-mechanics.

Experimental Detail

Raw Materials and Mix Proportions

Chinese standard 52.5 R (I) Portland cement equivalent to ASTM Type I Ordinary Portland cement supplied by Wuhan huaxin Cement Corporation in China was used. type I low calcium fly ash; type S95 blast furnace slag grounded to fine powder; river sand with fineness modulus of 2.6 and coarse aggregate of crushed limestone with particle size of 5 ~20 mm were used; Water-reducing rate of polycarboxylic acid type water-reducer JM-PCA(Ⅳ) was 35%; Ordinary tap water. The main chemical compositions of cement and mineral admixtures are shown in Table 1.

Marine concrete need to endure the corrosion of seawater, so mix 30% fly ash and 30% slag powder to replace cement of equivalent quantity. Details are shown in Table 2.

TABLE1 THE MAIN CHEMICAL COMPOSITIONS OF RAW MATERIALS

Parameters	ω（CaO)	ω（SiO2)	ω（Al2O3)	ω（Fe2O3)	ω（MgO)	ω（SO3)
Cement	65.03	21.38	4.71	3.68	2.53	0.53
Fly ash	3.49	52.42	33.25	4.53	1.07	/
Slag	36.35	33.48	12.21	1.41	10.60	0.66

C50FS	0.40	0.30	0.30	0.33	1.50	2.50	0.51	2390

Test mechanical properties of the specimens after standard curing for 90 days: the compressive strength was 57.6MPa and the flexural strength was 8.7MPa.

Experiment Methods

Concrete specimens were cast in molds of 70 mm×70 mm×280mm, with a Φ10 rebar in center. Then removed from the molds after 24 h, and cured in the condition of 20 ± 3 ℃ and 95% of relative humidity for 90d. Two opposing sides were set as the exposed surface, and the remaining sides brushing epoxy resin before the test. Four sets of salt solution were chosen to compare with fresh water, as listed in Table 3. Simulated seawater, which was made according to 25 g/L high salinity and contained main ingredients of seawater, consisted of 2.00%NaCl, 0.25%Na_2SO_4 and 0.35%$MgCl_2$, five-time simulated seawater consisted of 10.00%NaCl, 1.25%Na_2SO_4 and 1.75%$MgCl_2$. The specimen was immerged in solution for 8h, followed by drying for 38h in an oven under 60±2℃, and then cooled in natural condition for 2h. A whole wetting and drying cycle needs 48h.

TABLE 3 THE SALT SOLUTION USED IN THE EXPERIMENT

Label	A	B	C	D	E
Solution type	Fresh water	3.5%NaCl	5.0%Na_2SO_4	Simulated seawater	Five-time simulated seawater

Use a four-point bending spring-loaded device for long-term constant load on concrete specimens (as shown in Fig.1), the bending stress ratio was 0.35 and every 3 specimens as a group under the same loading device. Specimens were taken out every 20 cycles and tested by NMB-4A nonmetallic ultrasonic detector to detect the speed changes of ultrasonic wave, and then converted these data into dynamic elastic modulus (Fig.2).

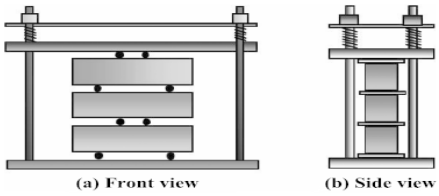

Fig.1 Schematic Diagram of Loading Equipment

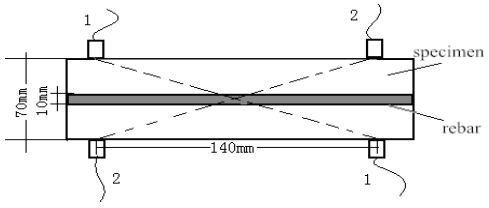

Fig. 2 Schematic Diagram of Ultrasonic Testing

Cut along the vertical direction of the exposed surface, remove the coarse aggregate, and then ground the samples with a mortar and pestle until the powder could pass through the Φ0.63mm square hole sieve. The chloride ion content of the concrete specimens was analyzed according to the "Hydraulic concrete testing procedures" (JTJ270-98) as well as the sulfate ion content of the

concrete specimens was analyzed according to the "Gravimetric method of sulfate content in water" (GB11899-89). The specimens were divided into five layers to cut: 0-3mm, 6-9mm, 12-15mm, 18-21mm, 24-27mm.

Results and Discussion

The Impact of Different Salt Solutions on the Degradation of Concrete

The dynamic elastic modulus of concrete specimens under the action of wetting and drying cycle with bending load in different salt solutions was tested every 20 cycles, and the results are shown in Fig.3.

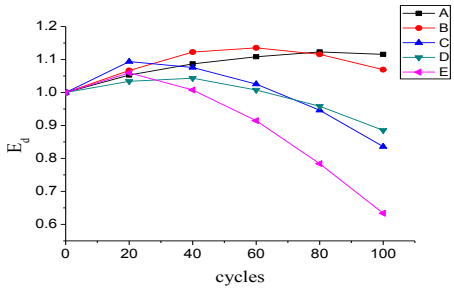

Fig.3 The Relative Dynamic Elastic Modulus of Concrete in Different Salt Solution

Following conclusions could be given from the results:

1) The relative dynamic modulus of elasticity of the specimens in fresh water gradually increased at first, and tended to be stable after 80 cycles;

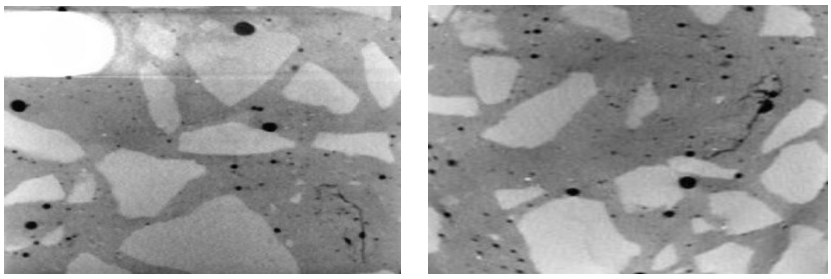
2) The indicator in 3.5%NaCl solution increased during the first 60 cycles, and declined after that;

3) In 5.0% Na_2SO_4 solution, the dynamic modulus of elasticity of tested-piece increased rapidly during the first 20 circulations and then declined violently after that, So it was 40 circulations earlier than that in 3.5%NaCl solution. It is because the chloride ion damages ferroconcrete by swelling and rusting the surface of rebar and it takes a long time before it gets inside the concrete and accumulates to a certain concentration. However, sulfate and hydration products of cement can react to produce swelling materials such as ettringite and gypsum, which is a fast process. That explains why the specimen in 3.5%NaCl solution damaged more slowly than in 5.0% Na_2SO_4 solution;

4) In five-time simulated seawater, the indicator declined fastest, this is mainly resulted from Mg^{2+} in the simulated seawater. The Mg^{2+} may transform to $Mg(OH)_2$ on the surface of concrete, but the wetting and drying cycle promoted the corrosion reaction, so the compact layer would be damaged soon after it is formed. The reaction, producing not-sticky gel S_2H and MSH, could happened quickly, which resulted in the concrete surface peeling off constantly, thus the damage becoming more and more seriously;

5) Relatively, the specimen of concrete was most damaged in the five-time simulated seawater, followed by 5.0% Na_2SO_4 solution, simulated seawater, 3.5%NaCl solution and the fresh water.

X-CT images of the concrete specimens after 100 wetting and drying cycles are shown in Fig.4. The images show the inside of the concrete after it had been corroded 100 times under the effect of wetting and drying cycle in the simulated seawater. It can be seen that the surface and inside of the concrete already have micro cracks, most of which are existed along tiny openings, and expanding gradually. At last they interconnect and then damage will be produced.



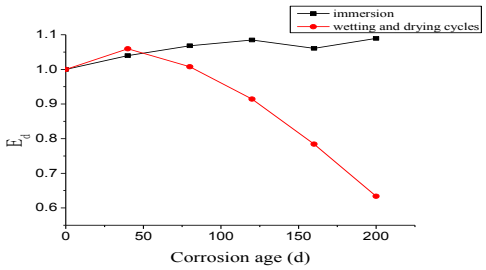


Fig.4 X-Ct Images of the Concrete Specimens after 100 Wetting and Drying Cycles

The Impact of Different Corrosive Environment on the Degradation of Concrete

The specimens of concrete were immerged or under wetting and drying cycles in five-time simulated seawater. The dynamic modulus of elasticity of them were tested every 40d and the result is shown in Fig.5. Meanwhile, the content of free chloride ion after 200d's corrosion was also tested, result of which is listed in Fig.6.

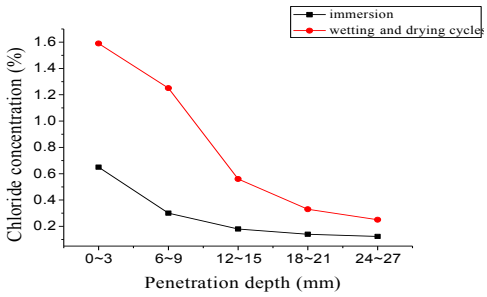

Fig.5 The Relative Dynamic Elastic Modulus of Concrete Fig.6 The Distribution of Chloride Concentration

It can be concluded from the Fig.5 that the relative dynamic modulus of elasticity of the immerged specimens rises gradually at first, and tends to be steady at the 120th day, while the data of specimens under wetting and drying cycle declined violently after 40 days. At the 120th day, the relative dynamic modulus of elasticity decreased by 36.6%. Fig.6 shows that the chloride ion in both environments declined gradually from surface to inside of the concrete as chloride ion invades concrete from surface. However, the surface of specimens under wetting and drying cycle contains more chloride ion than that being immerged. That is because chloride ion on concrete surface in wetting and drying cycle works with great complexity. In the surface, it was mainly because of the absorption of capillaries to accelerate transmission. But inside the concrete, the transmission was still dominated by diffusion. The wetting and drying cycle accelerated the declining of the dynamic modulus of elasticity of the concrete and invasion of chloride ion inside it.

The Impact of Different Load Stress on the Degradation of Concrete

Bending load test under the condition of the five-time simulated seawater was applied in the concrete's specimen and chloride ion in different stress zones was tested every 100 wetting and drying cycles (as showed in Fig.7). Distribution of sulfate ion in different stress zones is listed in Fig.8.

The graphics indicate that, the content of chloride ion and sulfate ion declined with the depth into the concrete and finally became steady. There were more chloride ion and sulfate ion, and their penetration ability was better in tension zone than that in compression zone. That is because the tensile stress produced by the stress area brought quicker expansion of micro cracks, which accelerated the penetration of chloride ion and sulfate ion. On the contrary, the pressure stress in the compression zone limited micro cracks so that the two ions had difficulties in penetrating the concrete and their transmission was restrained.

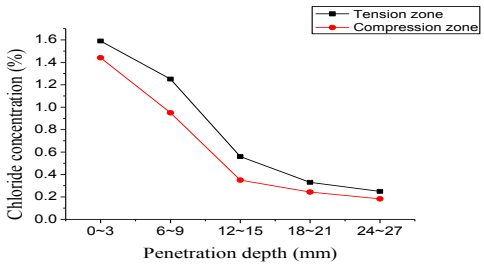

Fig.7 The Concentration of the Chloride Ion

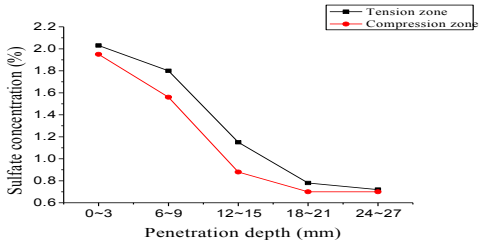

Fig.8 The Concentration of the Sulfate Ion

Conclusions

(1) Under the coupling effect of wetting and drying cycle and bending load, different salt solution affects the durability of marine concrete at different degrees: sulfate salt is more corrosive than chloride salt, simulated seawater is similar to 5.0%Na_2SO_4 solution, while five-time simulated seawater is the most corrosive.

(2) Compared with the immersion corrosive environment, wetting and drying cycle formed capillary suction, which greatly accelerated the diffusion speed of the chloride and sulfate ion.

(3) When under the bending load, there is more chloride and sulfate ion and a deeper penetration depth in tension region than in compression zone, which indicates that the concrete take more damage and degradation under the coupling effect of chemistry-mechanics and the tensile stress has greater influence on the damage.

Keywords: Polymer; Waterproof coating; Cement

Abstract: Polymer modified cementitious waterproof coating is an important construction material. In this paper, starting from the classification and choice of waterproof coatings, the importance, advantages and application prospects of the polymer cement waterproof coatings were discussed. The approaches for solving the existing problems and limitations of polymer modified cementitious waterproof coatings were put forward.

Introduction

In accordance with the Outline of the China's 12th Five-year Plan, during the 12th Five-Year Plan period, the country's population will be controlled within 1.39 billion, and China's urbanization rate will increase 1% each year. Large population keeps continuous demand for housing, and the increasing per capita net income can transform the hidden housing into real demand, and thus activating development of waterproof material industry. With the fast-paced urbanization, 450 million farmers enter the cities and towns, the government will make good efforts to build guaranteed house.

During the 12th Five-Year Plan period, asphalt based waterproof membrane will be eliminated. The average annual growth rate of major waterproof materials will remain increase at the rate of over 10 %, and the output of major waterproof materials is expected to reach 1,600 million square meters by 2015 to meet the ballooning waterproof market demand. It is predicted that at the end of the 12th five-year, the enterprises on waterproof materials with the sales revenue over 5,000 million yuan will appear, dozens of which will be more than 10,00 million yuan.

In 2012, production of Chinese waterproof building materials reached 1,356 million square meters, rose by 12.70% compared with 2011, in which new waterproof materials accounted for 90% , and the share will continuously increases. Among them, SBS/APP modified asphalt waterproof coiled material has the largest proportion, 26.37%. Waterproof coating and polymer waterproof coiled material ranked second and third, 22.77% and 15.58% respectively. The main reason is the pull from the real estate market in the first half and affordable housing construction in the second half.

Based on years of experience on waterproof material development, this paper mainly introduced the performance and characteristics of polymer waterproof coatings and put forward the strategies for application and research of this materials.

Classification of Build Waterproof Coatings [1-4]

In the field of construction engineering, waterproof coatings are generally divided into the following four categories:

(1) Synthetic polymer waterproof coatings: polyurethane waterproof coatings, silicon rubber waterproof coatings, acrylic waterproof coating, polyvinyl chloride elastic waterproof coating, PVC waterproof coating, polyurea elastic coatings and methyl methacrylate coatings.

(2) Polymer modified asphalt waterproof coatings: solvent-based rubber asphalt waterproof coatings, butyl rubber modified asphalt waterproof coatings, styrene-butadiene rubber modified asphalt waterproof coatings, APP modified asphalt waterproof coatings, emulsion / solvent type SBS modified asphalt waterproof coatings, water soluble neoprene asphalt waterproof coatings and solvent neoprene asphalt waterproof coatings.

(3) Polymer modified cementitious waterproof coatings: polymer emulsions modified build waterproof coatings, polymer modified cementitious waterproof coatings. Polymer modified cementitious waterproof coatings are divided into type I (polymer) and type II (cement) (Type I is used for non long-term immersion environment / type II for long-term immersion environment building waterproof engineering).

Inorganic waterproof coatings: cement-based capillary crystalline waterproof coatings and mineral admixture or admixture cement-based waterproof coatings.

Among these four kinds of waterproof coatings, synthetic polymer coating has excellent waterproof performance. Because of its strict requirement on the surface moisture content, moisture ratio should be less than 7%, so the yield decreased. Market share of polymer modified asphalt waterproof coating and inorganic waterproof coating are low. The market share of polymer modified cementitious waterproof coatings have been in increase these years.

Selection of Waterproof Coatings

The following requirements should be met in selection of different types of waterproof coatings in application.

(1) Chooses appropriate inorganic coatings or organic coatings with excellent binding force with wet inter-area for wet base, or adopts composite coating which was first coated with cement-based inorganic coatings and than with organic coating.

(2) Corrosive underground environment need organic waterproof coatings with good corrosion resistance as rigid preventive layer.

(3) Polymer modified cementitious waterproof coatings type II is often used in underground waterproof engineering.

Polymer modified cementitious waterproof coating is a kind of two-component waterborne waterproof coating, which is developed by mixing polymer emulsion such as acrylate, cement and additives. The coating consists of two-component composition, polymer and cement. Therefore it has the dual characteristic of rigid and flexible materials, the good elongation and waterproof performance of polymer coating, and high strength and excellent binding force with wet interarea of hydraulic binding material. It meets the requirements of different engineering on flexibility and strength by adjusting the proportion of polymer emulsion and cement. The coating uses water as the dispersant, there is no problem of environmental pollution and human health problems.

Characteristics of Polymer Modified Cementitious Waterproof Coatings

Polymer modified cementitious waterproof coatings have the following advantages.

Non-Toxic, Tasteless and Environmental Friendly

Polymer modified cementitious waterproof coatings do no harm to the construction workers and has no pollution to the environment. In 2012, China's total housing construction area was 5734 millions square meters, and completed 990 millions square meters, of which 790 million square meters for residential (National Bureau of Statistics report 20130118). In residential construction decoration, about 70% of families choose the balcony, kitchen, basement floor to perform waterproof again. The area of kitchen and toilet is generally small, and most of them exists negative and positive angles and pipelines. The choice of waterproof materials should consider the size of kitchen and toilet, the number of negative and positive angles, tube piercing and sanitation, the wet base, etc., as well as the connection structure of floor and wall. Polymer modified cementitious waterproof coating has significant advantages: one is suitable for the change of primary shapes and benefit for pipeline laying, the other is excellent water resistance and the overall coating without seam.

Two-Component, Easy For Use

Unlike reactive two-component synthetic polymer waterproof coating, most of them use thinner, which will evaporate in the construction and curing process and do damage to the environment and human health. With the enhancing awareness of environment protection, the workers, site administrators, designer and users gradually realized environmental advantage of polymer modified cementitious waterproof coating.

Low Cost and High Performance

Polymer modified cementitious waterproof coating can be used for wet inter-area, the total construction period can be shortened effectively and the construction costs be reduced significantly. Synthetic polymer coating has strict requirements for the base. When the content of water in interarea is more than 7%, in the case of the waterproof layer completed before the next procedure finished, it will produce bulge in the sunlight. In such case, the subsequent construction could pierce the waterproof layer, thus waterproof layer lost integrity and waterproof function. When using polymer modified cementitious waterproof coating, it can be done only after the former procedure. Compared with other materials, one waterproof engineering item can save construction time of about 5 days with polymer modified cementitious waterproof coatings.

Obvious Synergistic Effect of Polymer Emulsion and Cement

There exists synergetic effect between polymer emulsion and cement film forming process, which has good aging resistance and mechanical performance. The cost of product protection of later stage is low. Organic polymer emulsion lost water to be elastic film with adhesivity and continuity after using of polymer modified cementitious waterproof coating. Cement, grading quartz powder, coarse whiting absorbed the water in the emulsion and hardened, flexible polymer film layer and the cement inter-fingered each other, forming solid elastic three-dimensional network structure waterproof layer. Flexible polymer filled in the gap of cement stone, which made the cement stone more compact and elastic. The film has good elongation. Cement stone filled in the polymer, which made the polymer possess better durability. Polymer modified cementitious waterproof coating is a kind of coating waterproof layer with high strength, toughness, high durability. With the existence of net structure of cement stone and polymer film, the coating don't need protective layer during the construction of small area, the thickness of the protective layer can be decreased during the construction of large area, thereby reduces the construction cost.

Lower Construction Cost

The price difference between polyurethane waterproof coating and polymer modified cementitious waterproof coating is about 3300 yuan per ton. By using the later, every square meter can save 6.6-10 yuan, which includes no thinner expense of synthetic polymer coating. Thus, the owners and the contractors give more and more attention on polymer cement waterproof coating.

Existing Problems of Polymer Modified Cementitious Waterproof Coatings

(1) There are two major types of polymer modified cementitious waterproof coatings on the market, acrylic emulsion and poly (ethylene-vinyl acetate) copolymer emulsion (EVA). However, there is no water resistance test of the material in routine testing, causing a lot chaos and the low-end development trend. A fast detection method for such materials should be set up as soon as possible.

(2) Compared with synthetic polymer coatings, the extension rate of polymer modified cementitious waterproof coatings are lower and deformability higher. It should necessary to develop new coatings, improving the elongation and broadening the application range.

(3) High-end additional functions and value are low. It should consider adding the root resistance agent, flame retardant etc. to the materials, broadening the application in planting roof, fireproof and waterproof coating fields.

(4) Construction temperature is relatively strict for polymer modified cementitious waterproof coatings, usually above 5℃. It is imperative to break through the inherent thinking on cement, and explore the new coating could be used at lower temperature.

Conclusion

It can be estimated that waterproof coatings are developing from solvent type to emulsion and reaction type, from low-end products to products of high elasticity, high durability and functionality. That is to say, waterproof coatings will play more and more important role in the construction industry and show good prospects for the future. With the increasing concern on environmental protection and construction operation quality, polymer modified cementitious waterproofing coatings will draw much more attention and find more application in construction and building industry.

Keywords: EPS mixed lightweight soil; optimum proportion; unconfined compressive strength; SEM test

Abstract. In order to study the inorganic composite curing agents of lime, gypsum, fly ash on the strength properties of EPS lightweight soil using recycled sludge, the unconfined compressive strength test and scanning electron microscope test are done to investigate the strength properties of EPS lightweight soil. The effect and scope of each curing agent is investigated and determined by means of single-doped unconfined compressive strength test, and the optimum proportion of the curing agent is further determined by the method of orthogonal unconfined compressive strength test, of which the stabilized effectiveness of the lightweight soil is compared with those only using cement as curing agent. Finally, the SEM test is done to study the microstructure and pore characteristics of the lightweight soil mixed with EPS adding with or without curing agent. The test results and curing agent can be used as conference when stabilizing soft soil and treatment of discarded clay.

Introduction

Currently, with the rapid economic growth, China is in the rapid developing period. The development of urban real estate, construction of ocean and coastal projects, expansion of roads and bridges projects, etc., is requiring a lot of engineering soil. Generally, the source of engineering soil is from farmland's excavation, sand and stones of ocean, exploitation of mines, etc., which led to many negative effects, such as soil erosion, landslides and reduction of farmland. Meanwhile, the process of infrastructure and Canal dredging projects will generate a lot of wasted soil and silt, which pollute the environment and land resources again. How to use engineering discarded soil and silt and to make it meet the requirements of engineering soil, has become a popular and urgent issue.

EPS mixed lightweight soil is a kind of lightweight soil which is composed of raw material soil, EPS granules, curing agent and water, etc., and stirred and solidified to form curtain strength. Its research and development can not only reduce environmental pollution, but also can make the project discarded soil and canal silt be converted into a renewable civil resource and reused again. With the growing shortage of consuming resources and the increase of environmental protection awareness, lightweight technology of soil is gaining more and more attention and recognition. However, the strength and deformation of EPS mixed lightweight soil, is still far from the level of wide range of practical engineering applications, as well as construction period, which needs further investigation.

Many scholars and engineers pay more attention on the strength and deformation of lightweight soil at home and abroad. For example, Zhang[1], Huang[2] and Zhang[3], etc. analyzed the influence of the composition and dosage of inorganic curing agents to the strength of solidified soil. Ji[4], Wang[5] and Fan[6], etc. studied the microstructure of cement stabilized soil and lightweight soil by means of XRD and SEM microscopic experiments. Based on the previous research work, this paper use Hangzhou Canal silt as raw soil and study characteristics of EPS mixed lightweight soil and investigated the effect of inorganic curing agent of lime, gypsum and fly ash on the strength of lightweight soil by means of unconfined compressive strength test and scanning electron microscope test.

Curing materials

Soil samples The main raw curing material used in the test is soil samples, EPS spherical particles, curing agents and water. The soil samples are taken from the canal of Hangzhou, of which the main physical and mechanical indexes are shown in table 1.

Table 1 The basic physical and mechanical indexes of canal silt

natural density ρ/(g/cm^3)	water content w/%	specific gravity d_s	void ratio e	liquid limit w_L/%	plastic limit w_P/%
1.62	57.5	2.60	1.489	53.0	28.3

EPS spherical particles The lightweight material used is a in the test is spherical EPS beads produced by Hangzhou Plastic Packaging Material Co. Ltd. , with the density and bulk density of 0.030g/cm^3 and 0.016g/cm^3, respectively. EPS particle content is quantified by the volume fraction α_{eps} of EPS particle in the sample, which is the ratio between the volume of EPS particles in the sample (V_{eps}) and the total sample volume (V):

$$\alpha_{eps} = \frac{V_{eps}}{V} \times 100\% \tag{1}$$

The content of EPS particle used in this test is 15%, 25% and 35%, respectively.

Curing agent The cement, lime, gypsum and fly ash are chosen as curing agent. The cement is chosen from the 42.5# ordinary portland cement produced by Qianchao Cement Plant, Hangzhou.

The cement content(β_c) is the ratio between the quality of cement (m_c)and the quality of canal silt(m_s):

$$\beta_c = \frac{m_c}{m_s} \times 100\% \tag{2}$$

The gypsum is produced by Shanghai Baoping Building Materials Co. Ltd. The lime is produced by Yongfu County of Guangxi Jin Yingtai Co. Ltd. The fly ash is produced by Jiaxing Power Plant, Zhejiang. The content of lime, gypsum and fly ash used in the test is:

$$\beta_b = \frac{m_b}{m_s} \times 100\% \tag{3}$$

where β_b is the content of lime, gypsum and fly ash, m_b is the quality of lime, gypsum and fly ash and ms is the quality of canal silt.

Experimental results

Single-doped test Firstly, the test is taken by only adding cement to the lightweight soil for Hangzhou Canal silt. Then, using soil sample of 15% cement content as the reference volume in the single-doped test, of which the content of lime, gypsum and fly ash is selected as five levels, and the content of EPS particle is chosen as 15%, 25% and 35%. A total of 45 groups, each group prepared three parallel samples, a total of 135 specimens are prepared. Taken the average intensity of the sample curing for 28 days of each factor as Y-coordinate, and the content level of each factor as X-coordinate, the relationship between sample intensity index and changes in the level of each factor is shown in Fig. 1-2.

Fig. 1 is the relationship between the unconfined compressive strength and lime content of lightweight soil under different volume fraction of EPS particles. From Fig. 1, it can be seen that: at certain lime content, the compressive strength of the sample decreases with the increase of EPS particle volume fraction. At certain EPS particle volume fraction, the strength of the sample increases with the increase of lime content, then begins to decrease after passing the peak value. When the lime content is 5%, the compressive strength of the sample reaches the maximum value.

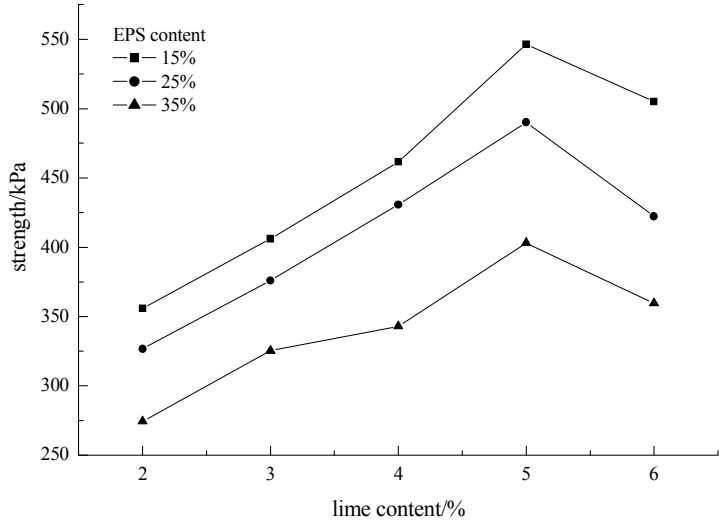

Fig. 1 The relationship between strength and lime content for different EPS content

Fig. 2 is the relationship between the unconfined compressive strength and fly ash content of the lightweight soil. From the figure, it can be seen that the confined compressive strength of the lightweight soil increases with the increase of the fly ash content and decreases with the increase of EPS particle volume fraction. When the fly ash content is 12%, the compressive strength of the sample reaches the maximum value.

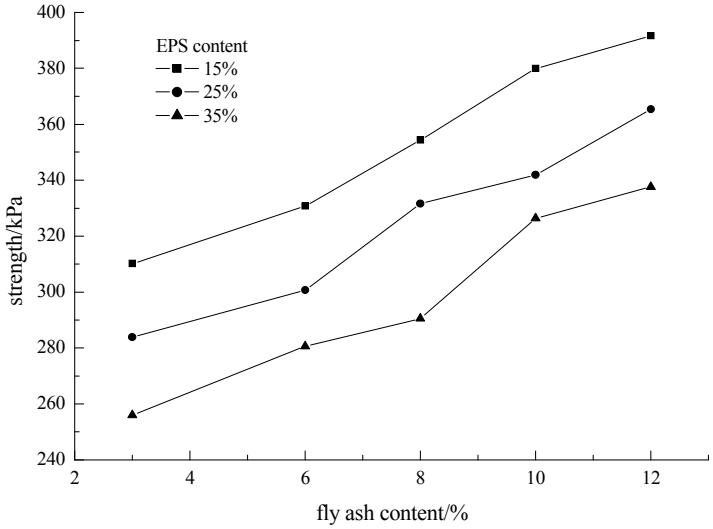

Fig. 2 The relationship between strength and fly ash content for different EPS content

Orthogonal test Based on the single-doped test, the test uses pure soil sample as a reference volume of orthogonal test, and four factors and three levels of the content of lime, gypsum and fly ash are selected, a total of 9 groups, 28 days of curing age, each group preparing three parallel samples, and with the content of EPS particle of 15%, 25% and 35%, a total of 81 specimens are prepared and tested.

The optimal level and the best combination of experimental factors must be determined firstly, of which the optimal level means the level of each factor which makes the strength index to achieve the best. To determine the optimal level of factors, each level's impact of this factor on strength index must be determined. The orthogonal experiment compressive strength is shown in table 2. The 4 number in K_1 line respectively means 1 level of four factors corresponding to the sum of the unconfined compressive strength in the test. Using the same method, it can obtain K_2 and K_3. The 4 number in each line of k_1, k_2 and k_3, respectively, are K_1, K_2 and K_3 corresponding to each number divided by 3, which is the average value of each level. Dosage level with maximum average value is the optimal level of this factor. Taken lime as example, the k_2 is maximum, so 2 level is the best for

lime, and lime content is 15%. Similarly, the optimum dosage level of cement is 18%, the optimum dosage of lime is 5%, the optimum dosage of gypsum is 2%, and the optimum dosage level of fly ash is 12%.

To Determine the primary and secondary order for each factor, the impact of various factors on strength index is different and its importance varies each other. In the same column, the maximum number of k_1, k_2 and k_3 minus the minimum number of the k_1, k_2 and k_3, and the value is called range (R_j). According to the size range of R, the factors' influence of importance on experimental index can be determined. The larger the gap between each data of range R, indicating that the differences between levels of the factor is bigger, which plays more important role in the test, otherwise the factor plays the secondary influence. According to the data of table 2, it can get the sequence of 4 factors from the main influence to the secondary influence. The order is cement, fly ash, gypsum and finally lime.

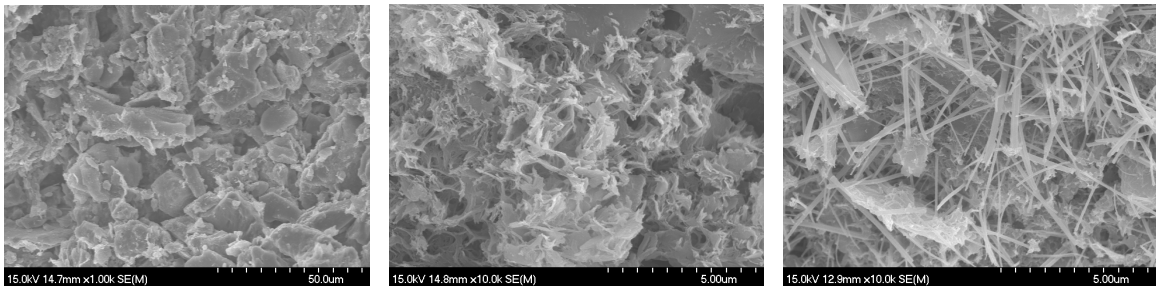

Table 2 Analysis of orthogonal test results (35% EPS)

	cement	lime	gypsum	fly ash
K_1	1218	1648	2137	1352
K_2	1879	1905	1662	1836
K_3	2345	1889	1568	2254
k_1	406	549	712	451
k_2	626	635	554	612
k_3	782	630	523	751
R	376	86	190	301

The maximum value and change trends of R are consistent when the content of EPS particle changes in the range of 15%, 25%, 35%, indicating that the factors' impact on the role of strength index has nothing to do with EPS particle content.

Microstructure of lightweight soil In the SEM test, the lightweight soil with 25% EPS particle content is set as reference volume, and three kinds of soil samples are prepared to investigate the similarities and differences from the microstructure viewpoint: original soil samples, lightweight soil samples of 15% cement content, and lightweight soil samples of optimal combination curing agent and 15% cement content. The results are shown in Fig. 3.

From Fig. 3(a), it can be seen that the blocky and platy aggregates are the elementary cells of Canal silt microstructure. These aggregates are connected by surface contact or edge-to-surface contact. Voids in undisturbed soil are dense and widely distributed. Generally, there are two kinds of voids: big voids which are formed between clay aggregates and small voids between mineral particles inside of clay aggregates. Features of the microstructure are small contact area, poor stability and large void ratio.

(a) (b) (c)

Fig. 3 SEM photos of raw soil and solidified soil
(a) undisturbed soil; (b) without optimal curing agent; (c) with optimal curing agent

Fig. 3(b) and 3(c) is the SEM photos of solidified soil. From the figure, it can be seen that: if the lightweight soil is stabilized without optimal combination curing agent, the clay aggregates are connected by cement hydration products of C-S-H and Aft with fibrous, hexagonal plate lap to form a

network structure. Cement hydration products filling or inserting the voids of soil aggregates, wrapping clay aggregates or bonding clay aggregates nearby together. Therefore, cement hydration products' effects of filling, wraping, bonding can improve strength properties of Canal silt. But there are still a lot of voids among clay aggregates which is caused by unhydrated cement, and hence exists faulty.

If the samples of lightweight soil is stabilized with optimal combination curing agent, there not only exists additional strengthen structure caused by cement hydration products, but also produce a lot of network shaped beam fiber among internal voids and gaps where cement hydration products cannot act, which makes the structure of soil samples further improved, so that the ability to resist damage and deformation of the samples increased.

Summary

By means of unconfined compressive strength test and scanning electron microscope test, the characteristics of EPS mixed lightweight soil is investigated and the effect of curing agent on the strength of stabilized soil is analyzed. From the analysis, the conclusions can be drawn as follows:

(a) Under the same EPS particle volume fraction, the unconfined compressive strength of lightweight soils increases with the increasing content of cement. The compressive strength of the sample decreases with the increasing volume fraction of EPS particle for same cement content.

(b) For 15% cement content, when the content of lime, gypsum and fly ash is same, the unconfined compressive strength of the sample decreases with increasing volume fraction of EPS particle. If the content of lime, gypsum and fly ash is 5%, 2%, 12% respectively, the compressive strength of the sample reaches maximum value for same EPS particle volume fraction.

(c) The best combination of experimental factors is obtained through orthogonal experiment: cement content is 18%, lime content is 5%, gypsum content is 2% and fly ash content is 12%. The sequence of 4 factors from the main influence to the secondary influence is cement, fly ash, gypsum, lime.

(d) From the view point of microstructure, the lightweight soil with optimal curing agent, the internal voids and gaps between voids are appearing a large number of network shaped beam fiber, which makes the network structure of soil samples further improved, so that the ability of anti damage and deformation of the samples is increased.

Keywords：coarse-grained soil; triaxial tests; engineering characteristics; strength and deformat

Abstract：Using large-scale shearing device, isotropiclly consolidated-drained triaxial test under different confining pressures are performed for overburden material of ShuangJiangKou earthdam which relative density is 0.9. The engineering characteristics of coarse-grained soil such as strength and deformation is studied. The results show the peak strength of coarse-grained soil under isotropically increase with the confining pressure and there is a relationship of linear between the peak strength of coarse-grained soil and initial modulus. The volume strain value of isotropically consolidated-drained triaxial shear test increase with increase of confining pressure, and the dilatancy decrease increase with increase of confining pressure. The secant modulus E_{s1} and the tangent modulus E_{t1} obtained by the tests both increase with increase with increase of confining pressure, and the values of E_{s1}/E_i and E_{t1}/E_i are all smaller than one. The failure poisson ratio v_{if} obtained by the tests both decrease with increase with increase of confining pressure, and there is a relationship of power function between vif and σ_3/P_a .

Introduce

Coarse-grained soil usually refers to cohesionless mixed soil composed by coarse particles such as rubble, gravel, stone chip and stone power, etc and the mixed soil which is mixed by cohesive soil and many coarse particles[1]. The engineering properties of Coarse-grained soil behave with good compacting effect, strong perviousness, large packing density, high shear strength, small settlement deformation, high bearing power etc[1]. So it is widely used in hydraulic engineering, traffic engineering and civil engineering.

During the past few decades, A Large number of research on engineering characteristics of coarse-grained soil have been carried out by many scholars abroad, and have obtained certain achievements[2-12].

However, Because the engineering characteristics of coarse-grained soil is more complicated. Research on strength and deformation of coarse-grained soil under many complex stress state need fully be studied.

Therefore, Using large-scale shearing device, Isotropic consolidated-drained triaxial tests under different confining pressures are performed for overburden material of Shuangjiangkou earth dam whose relative density is 0.9. The dissertation studied on the engineering characteristics of coarse-grained soil such as strength and deformation. The result of research will provide the base of tests and theoretical basis for the similar projects.

Test Equipment and Test Soil

Isotropic consolidated-drained triaxial tests is performed for overburden material of Shuangjiangkou earth dam on Dadu River whose relative density is 0.9. Large-scale shearing device

is adopted, which is 300 mm in diameter and 600 mm in height and 60 mm in the most major granular diameter.

The overburden material of Shuangjiangkou earth dam on Dadu River is sand gravel, whose particle is tact, angularity is less, strength is high and permeability is strong. The nature grading is reduced scale by the hybrid method of the document [13] and the size grading curve is showed as the figure 1. The biggest dry density is obtained by the vibratory compaction experiment of surface and the least dry density is obtained by the loose-filled experiment. The biggest dry density is 2.29g/cm3 and the least dry density is 1.93g/cm3. The dry density of sample preparation is 2.25g/cm3, and the initial void ratio is 0.251.

The samples are made by the compaction test and is compacted in five layers. The saturating samples are made by the water head saturated and pumping saturated method. The loading is controlled by the method of radial strain control in loading stage and the shear rate is 0.9mm/min. The confining pressure of different test are all respectively 200, 500, 1200, 2000and 2500kPa.

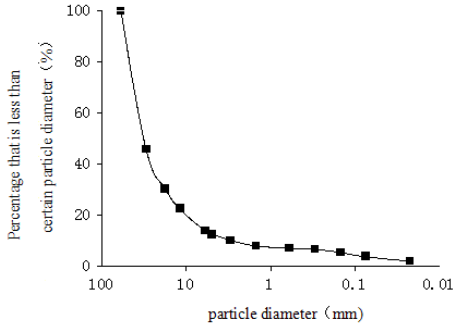

Figure 1 Size grading curve of coarse-grained soil

Test Result Analysis

Stress-strain-strength Characteristics

The curves of $(\sigma_1-\sigma_3)\sim\varepsilon_a$ of consolidated-drained triaxial test in different confining pressure are given in figure 2. Figure 2 shows that the curves of $(\sigma_1-\sigma_3)\sim\varepsilon_a$ of consolidated-drained triaxial test shows hyperbola type and slight strain softening. Figure 2 also shows that there are obvious peak of strength in the curve of consolidated-drained triaxial test, and the peak of strength increases with the increase of confining pressure. he peak strengths under different confining pressure are arranged and listed in the table 1. .

Table 1 shows that the peak strength is 9727kPa when confining pressure is 2500kPa, which has increase amplitude of 8609kPa than when confining pressure is 200kPa, has increase amplitude of 7294kPa than when confining pressure is 500kkPa, has increase amplitude of 4670kPa than when confining pressure is 1200kPa and has increase amplitude of 1600kPa than when confining pressure is 2000kPa.

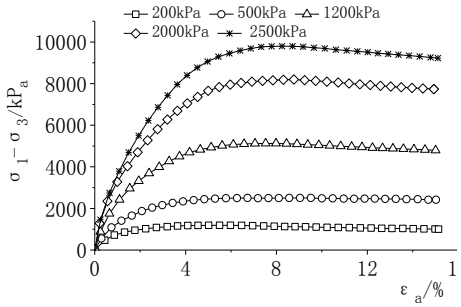

Figure 2 Curves of $\sigma_1-\sigma_3\sim\varepsilon_a$ of consolidated-drained triaxial test

Table 1 The peak strengths under different confining pressure

peak strength	200 /kPa	500 /kPa	1200 /kPa	2000 /kPa	2500 /kPa
$(\sigma_1-\sigma_3)_f$	1188	2503	5127	8197	9797

The initial modulus E_i is sorted out and the curve of $E_i \sim (\sigma_1-\sigma_3)_f$ is accumulated as the figure 3. The figure 3 shows that the E_i increase with the increase of $(\sigma_1-\sigma_3)_f$, and there is a relationship of linear between the peak strength of coarse-grained soil and initial modulus, which may be formulated by the expression

$$(\sigma_1-\sigma_3)_f = aE_i + b \tag{1}$$

Where a and b are both parameters of material. In this experiment, the parameters obtained by fitted is respectively 0.0599 and 41.59. The relative coefficient R^2 is 0.98.

Volume Strain Characteristics

The curves of $\varepsilon_v \sim \varepsilon_a$ of consolidated-drained triaxial test in different confining pressure are given in figure 4. Figure 4 shows that the volume deformation value(volume compression) under lower confining pressure is more bigger than that under higher confining pressure. For example, the volume deformation value(volume compression) when the confining pressure is 2500kP$_a$ is more bigger percentage 1.72 than the volume deformation value when the confining pressure is 200kP$_a$.

Figure 5 also shows that dilatancy of sample increase with the decrease of confining pressure. One point is worth mentioning, that is, the axial strain ε_a from volume compression to volume expansion increase with the increase of confining pressure. For example, the axial strain ε_a from volume compression to volume expansion when confining pressure is 2500kP$_a$ is more bigger percentage 4.47 than that when the confining pressure is 200kP$_a$.

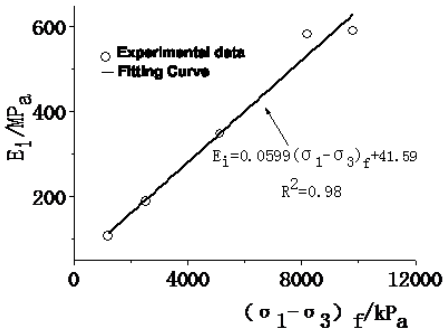

Figure 3 Relationship of $E_i \sim (\sigma_1-\sigma_3)_f$

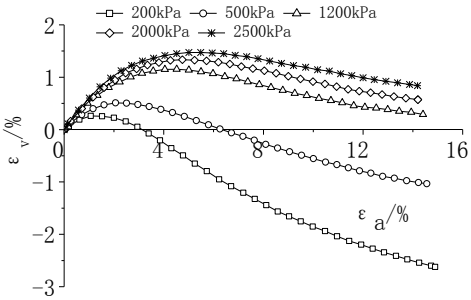

Figure 4 Curves of $\varepsilon_v \sim \varepsilon_a$ of consolidated-drained triaxial test

In order to study the characteristics of deformation of coarse-grained soil, The secant modulus E_{s1} and the tangent modulus E_{t1} under different confining pressure are sorted out and the curves of $E_{s1} \sim \sigma_3/P_a$ and $E_{t1} \sim \sigma_3/P_a$ are accumulated as the figure 5～figure 6. Which E_{s1} is the $(\sigma_1-\sigma_3)/\varepsilon_a$ ratio when ε_a is one percentage and E_{t1} is the slope of tangent when ε_a is one percentage.

figure 5 and figure 6 both show that E_{s1} and E_{t1} both increase with the increase of σ_3/P_a. they show the linear characteristics, which may be formulated by the expression

$$E_{s1} = m(\sigma_3/P_a) + n \tag{1}$$

Where m and n are both parameters of material. In this experiment, the parameters obtained by fitted is respectively 12.32 and 66.91. The relative coefficient R^2 is 0.98.

$$E_{t1} = l(\sigma_3 / P_a) + f \tag{2}$$

Where l and f are both parameters of material. In this experiment, the parameters obtained by fitted is respectively 7.66 and 41.26. The relative coefficient R^2 is 0.97.

The values of E_{s1}/E_i and E_{t1}/E_i are sorted out and listed in the table 2. The table 2 shows that the values of E_{s1}/E_i and E_{t1}/E_i are all smaller than one. That is, there is some attenuation and the attenuation gradually increase with the increase of confining pressure. This shows that particle crush increase and fine particle increase. Then, fine particles of coarse-grained soil fully fill into the pore between the large particles of coarse-grained soil. Therefor, the deformation of coarse-grained soil decrease with increase of the confining pressure

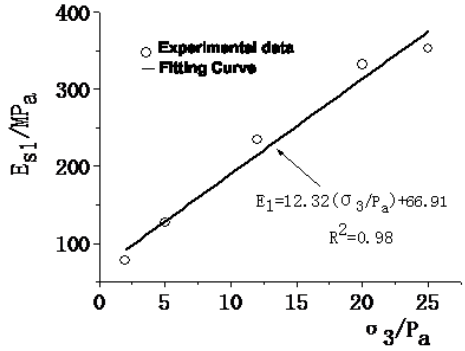

Figure 4 Relationship of $E_{s_1} \sim \sigma_3 / P_a$

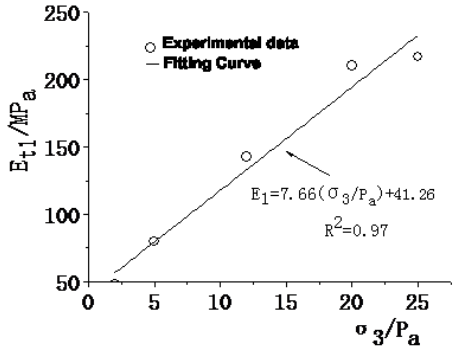

Figure 5 Relationship of $E_{t1} \sim \sigma_3 / P_a$

Table 1 Attenuation of deformation modulus

Confining pressure/kPa	secant modulus		tangent modulus	
	Es_1/E_i	attenuation	Et_1/E_i	attenuation
200	0.73	27.3	0.4465868922	55.4
500	0.685	31.5	0.423519206	58.7
1200	0.673	32.7	0.410416547	59.0
2000	0.598	40.2	0.370482302	63.0
2500	0.570	43	0.361214936	63.9

In order to comprehensively study on the characteristics of deformation of coarse-grained soil, The the failure poisson ratio v_{if} under different confining pressure are sorted out and the curves of $v_{if} \sim \sigma_3 / P_a$ is accumulated as the figure 7. The figure 7 shows that the failure poisson ratio v_{if} decrease with increase of confining pressure, and there is a relationship of power function between v_{if} and σ_3 / P_a which may be formulated by the expression

$$v_{if} = h(\sigma_3 / P_a)^g \tag{3}$$

Where h and g are both parameters of material. In this experiment, the parameters obtained by fitted is respectively 0.69 and -0.083. The relative coefficient R^2 is 0.96.

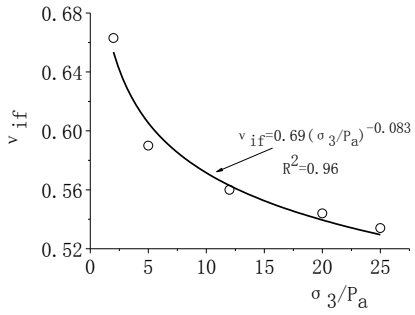

Figure 5 Relationship of $v_{if} \sim \sigma_3/P_a$

Conclusion

Isotropiclly consolidated-drained triaxial test under different confining pressures is performed for overburden material of ShuangJiangKou earth dam which relative density is 0.9 using large-scale shearing device. The engineering characteristics of coarse-grained soil such as strength and deformation is studied. Some preliminary conclusion ise obtained as follows:

(1) The peak strength of coarse-grained soil under isotropically increase with the confining pressure and there is a relationship of linear between the peak strength of coarse-grained soil and initial modulus.

(2) The volume strain value of isotropically consolidated-drained triaxial shear test increase with increase of confining pressure, and the dilatancy decrease increase with increase of confining pressure.

(3) The secant modulus E_{s1} and the tangent modulus E_{t1} obtained by the tests both increase with increase with increase of confining pressure, and the values of E_{s1}/E_i and E_{t1}/E_i are all smaller than one .

(4) The failure poisson ratio v_{if} obtained by the tests both decrease with increase with increase of confining pressure, and there is a relationship of power function between v_{if} and σ_3/P_a .

Keywords: Kinetics of polymerization, Polyethylenglycol allylether, Polycarboxylate superplasticizer

Abstract: The free radical copolymerization kinetics of polyethylenglycol allylether (APEG) with acrylic acid(AA) had been studied in aqueous solution through using ammonium persulfate(APS) and 30% hydrogen peroxide(H_2O_2) as initiators. The structure of polycarboxylate superplasticizer had been characterized by IR and ^{1}H-NMR. The rate of copolymerization was proportional to the molar ratio of monomers (AA:APEG) to the power of 0.4405, and to the amount of initiator (1.5%APS-2%H_2O_2, mass ratio to monomers) to the power of 0.7819, respectively. The overall observed activation energy of copolymerization was 45.048 kJ/mol. The kinetic relationship of copolymerization reaction of APEG with AA had been established as follow: $Rp \propto [\text{APEG/AA}]^{0.4405}[\text{APS-30\%}H_2O_2]^{0.7819}e^{-5418/T}$. The temperature and initiator were main influencing factors on polymerization reaction.

Introduction

The polycarboxylate concrete superplasticizer(PCS) has the advantages of high water reducing rate, low slump loss, good compatibility with cement and friendly to environment, which becomes the focus of concrete research[1,2]. The properties of polycarboxylate superplasticizer are obviously superior to naphthylene or melamin type superplasticizer, its application has increased in construction industry[3,4] such as preparing high-volume fly ash concrete, high-flowing concrete, high-strength concrete and high-durability concrete, etc..

Currently, there were some literatures [5,6]which had reported the synthesis of PCS, those mainly had discussed the synthesis conditions in order to improve the application performance of PCS. Some studies of binary or ternary dispersion polymerization kinetics had mainly aimed the polymerization such as biological, pharmaceutical separated materials and solid-phase supporting materials[7,8]. The study of polymerization kinetics of PCS mainly concentrated on the esterification reaction of monomers. Mehmet R. Altiokka[9] had discussed esterification reaction kinetics of acrylic acid with propylene glycol in the presence of amberlyst-15 as a heterogeneous catalyst, and developed the kinetic equations corresponding to reaction mechanism. The results of Sun[10] showed that the esterification reaction of polyethylene glycol with acrylic acid was typical two grade reaction. Xu[11] had studied the copolymerization kinetics of PCS which used the maleic anhydride, acrylic acid and sodium allylsulfonate as monomers. The relationship between the polymerization rate and the amount of initiator as well as the molar ratio of monomer had been gotten, the apparent activation energy of polymerization was 37.604 kJ/mol.

There were various types of process studies about ether-type polycarboxylate superplasticizer, however, kinetic information had not been given in those studies. Now, there are many problems in the production process of ether-type polycarboxylate superplasticizer, the water reducing effect of some industrialized products are not ideal. The polymerization kinetics study of ether type polycarboxylate superplasticizer is very important to optimizing its production process. This study had discussed the polymerization reaction kinetic of polyethylenglycol allylether with acrylic acid.

The structure of product had also been characterized. The results might provide theoretical and actual reference for production process of ether-type polycarboxylate concrete superplasticizer.

Experimental

Materials

Polyethylenglycol allylether（APEG, Hunan shida chemical engineering factory, industrial grade）. Acrylic acid（AA）, Thioglycolic acid, $(NH_4)_2S_2O_8$（APS）, H_2O_2（30%）, $KBrO_3$, KBr, $Na_2S_2O_3$, HCl, NaOH. The reagents except APEG were of analytical grade, and were of Chengdu kelong chemical reagent factory.

Experimental methods

Polymerization Reaction

A certain amount of deionized water and thioglycolic acid were first added to a 250-mL three-necked flask, then the temperature was raised to 80 °C. APEG, AA and a small amount of deionized water were mixed into a constant pressure dropping funnel. H_2O_2 (30%), APS and a small amount of deionized water were mixed to another constant pressure dropping funnel. The initiator and monomer mixture were added to the three-necked flask simultaneously. The polymerization reaction was continued for 6 hours, then cooled to room temperature. The impurities were removed by rotary distillation. Finally, the purified ether-type polycarboxylate superplasticizer(PS) was obtained.

Determination of the double bond

A certain amount of sample was taken from the three-necked flask at intervals, and placed in iodine flask, 15mL mixed reagent (357 mL of glacial acetic acid, 67 mL of carbon tetrachloride, 58 mL of methanol, 9 mL of dilute sulfuric acid and 35 mL of 100 g/L mercuric chloride-methanol solution) was added, then 20 mL $KBrO_3$-KBr solution (0.05 mol/L) and 5 mL HCl solution (2 mol/L) were added. The mixture was sealed, placed in the dark and often shaken. After 20 minutes, 10 mL of 100 g/L potassium iodide solution was added, the mixture was stood for another 10 minutes. The amount of double bonds was determined through using starch solution as indicator and 0.1 mol/L sodium thiosulfate as titrant.

Calculation of conversion rate and polymerization reaction rate

The conversion rate was calculated according with the concentration of double bond before (c_0) and after (c_i) reaction:

$$\text{Eq. 1: } \eta=(c_i-c_0)/c_0 \quad (1)$$

The linear regression between conversion rate and reaction time of constant speed phase was performed, then the slope of regression curve (dc/dt) and the correlation coefficient(R) were calculated, respectively. The polymerization reaction rate (Rp) of constant speed phase was calculated:

$$\text{Eq. 2: } Rp=(dc/dt) \ (\%/minute) \quad (2)$$

Characterization of PS

Structural characterization of the PS were done by TENSOR27 Fourier transform infrared spectrometer (Germany bruker company) and Avance 600MHz nuclear magnetic resonance spectrometer (Germany bruker company).

Results and Discussion

IR and ^{1}H-NMR spectrum analysis

IR spectrums of APEG and PS were shown in Fig.1. In addition to the common absorption peaks of APEG, such as C-H stretching vibration (2890 cm^{-1}), C-H bending vibration (1341 cm^{-1}), C-O stretching vibration (1102 cm^{-1}), C=C bending vibration (958 cm^{-1}) , PS had some characteristic peaks. The absorption band at 3380 cm^{-1} was attributed to stretching vibration of O-H. The absorption bands at 1642 cm^{-1} was ascribed to stretching vibration of C=O. The absorption bands at 1252 cm^{-1} and 947 cm^{-1} were due to stretching vibration of O=C-O and bending vibration of O-H, respectively.

Fig.2 exhibited the ^{1}H-NMR spectrums of APEG and PS. The solvent peak of deuterated chloroform was 7.26. The multiplet which the chemical shift value was about 5.90 and 3.6 were the methylene hydrogen in the side of long-chain of APEG. The chemical shift 5.2 and 2.0 were methylene and methine hydrogen in the main chain of APEG.

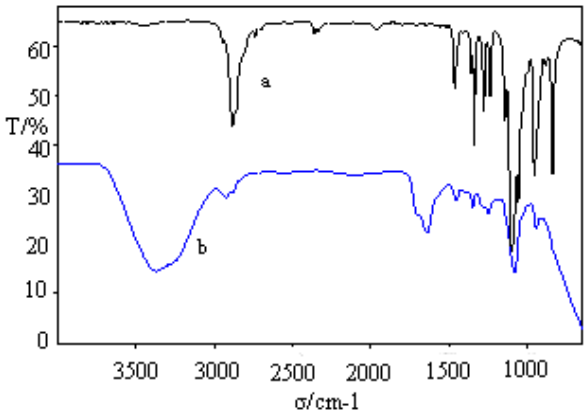

Fig. 1. IR spectrums of APEG（a）and PS(b)

The chemical shift 4.0 was the hydrogen of hydroxyl group. Compared to Fig.2a, it could be seen from Fig.2b, chemical shift at 2.7 and 1.9 were the hydrogen peak of methine and methylene which were connected to the -COOH of AA. Due to the disconnected of double bond of APEG in the polymerization reaction, the chemical shift of methine hydrogen that connected to the double bond changed, so the peaks 2.0 disappeared. The results of IR and ^{1}H-NMR showed that the copolymerization reaction had been occurred successfully.

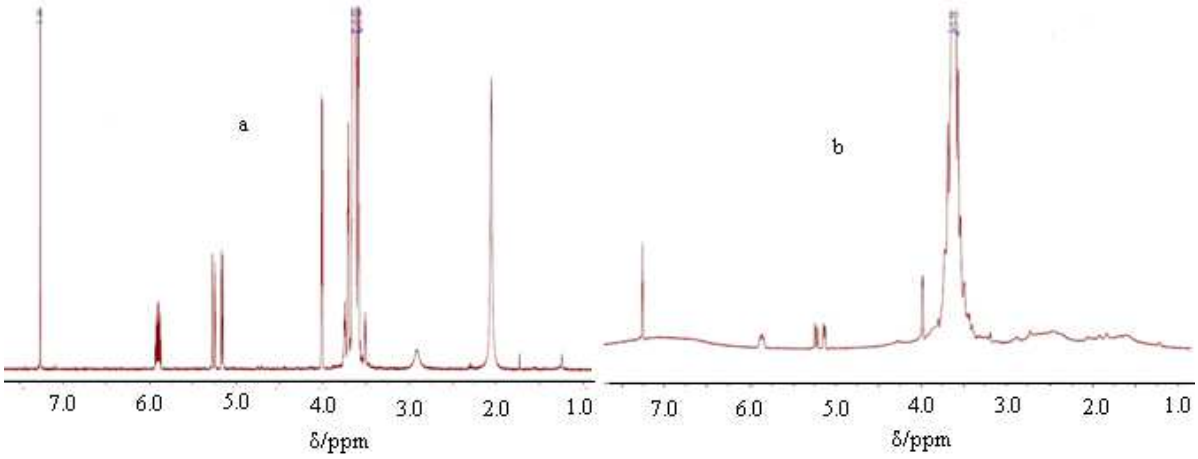

Fig. 2. ^{1}H-NMR spectrums of APEG(a) and PS(b)

The Kinetics of Polymerization Reaction

Effect of temperature on the polymerization reaction rate

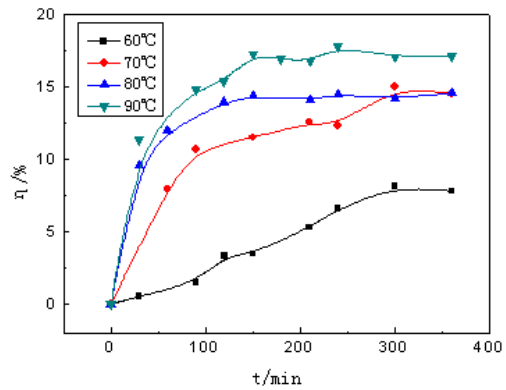

Fig. 3. Polymerization conversion rate at different temperature

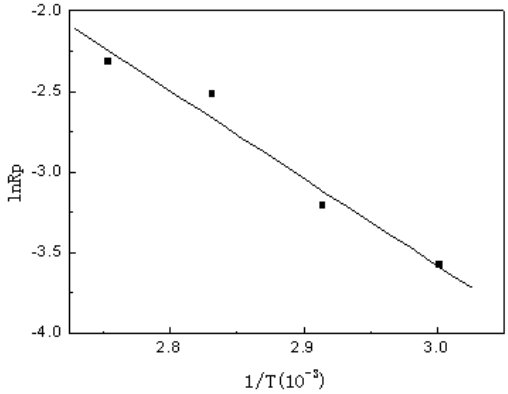

Fig. 4. Relation of lnRp and T-1(10-3)

The mixture of APS and H_2O_2 were used as initiator, the amount were 1.5% and 2.0% of the total mass of monomers, respectively. The thioglycolic acid chain was used as transfer agent, the amount was 1.6% of the total mass of monomers. The monomer molar ratio of APEG: AA was 1:4. The reaction rate curves under different temperatures were shown in Fig.3. The polymerization conversion rate increased with the time prolong, then reached balance. The polymerization conversion rate increased with the temperature increasing from 60℃ to 90℃, the equilibrium time at different temperatures were different with the shorter time under the higher temperature. The temperature raising accelerated decomposition speed of initiator, the generation rate of free radical increased, the concentration of free radical in the polymerization system increased, so the conversion rate increased. Linear regression between conversion rate and reaction time on the constant speed phase of curve was performed, and the polymerization rate（*Rp*）of constant speed phase under different temperatures were obtained, logarithm of the polymerization rate had the linear relation to T^{-1}, as shown in Fig.4. The slope（*K*）of the regression curve was -5.4183, and the correlation coefficients was -0.9824. The total apparent activation energy (*Ea*) of copolymerization was 45.048 kJ/mol calculated according to the Arrhenius equation[9]. The activation energy of polymerization was greater than 40 kJ/mol, it was a typical chemical reaction.

3.2.2 Effect of amount of initiator on the polymerization reaction rate

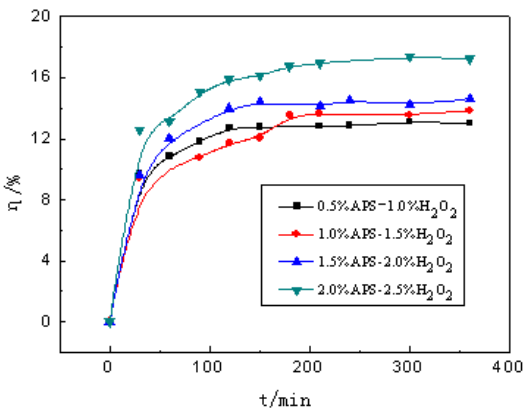

Fig. 5. Polymerization conversion rate at different concentration of initiator

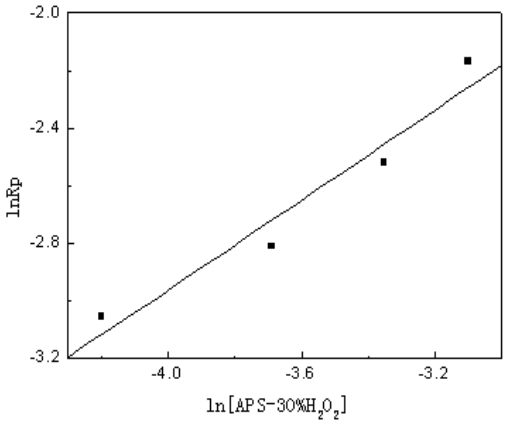

Fig. 6. Relation of lnRp and ln[APS-30%H_2O_2]

At the temperature of 80 ℃, the amount of thioglycolic acid was 1.6% of the total mass of monomers, and monomer molar ratio of APEG/AA was 1:4, the effect of initiator on the polymerization rate was measured. With the mass fraction of initiator growing from 1.5% to 4.5% (0.5%APS-1%H_2O_2,1% APS -1.5% H_2O_2,1.5% APS -2% H_2O_2, 2% APS -2.5% H_2O_2）, the concentration of free radical increased, initiator efficiency raised, and conversion rate increased gradually. In addition, the balanced time of polymerization increased with the increase of initiator amount. The polymerization reaction rate (*Rp*) could be got from the constant speed phase of conversion rate and polymerization reaction time curve under different amount of initiator by linear regression. There was good linearity between ln*Rp* and ln[APS-30% H_2O_2], as shown in Fig.6. The slope was 0.7819, the correlation coefficient was 0.9716. The relationship was showed between polymerization rate and amount of initiator: $Rp \propto [\text{APS-30\%}H_2O_2]^{0.7819}$.

Effect of molar ratio of monomer on the polymerization reaction rate

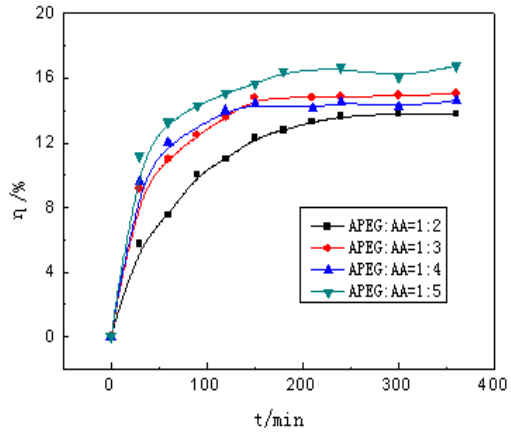

Fig. 7. Polymerization conversion rate at different molar ratio of monomers

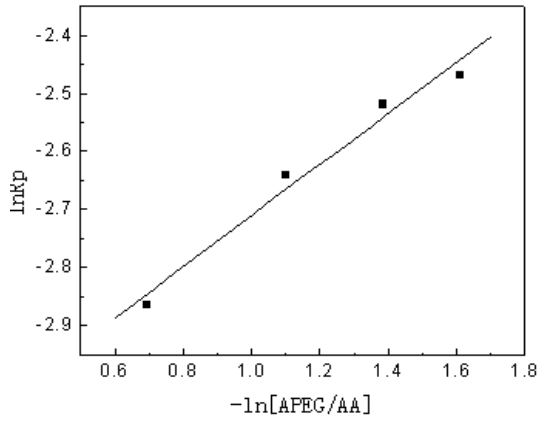

Fig. 8. Relation of lnRp and ln[APE G / AA]

The amount of initiator was 1.5% APS-2.0% H_2O_2, the thioglycolic acid was 1.6%, the kinetics curves of polymerization conversion rate under different molar ratio of monomers were measured at 80℃. The conversion rate increased with the molar ratio of APEG/AA decreasing. The activity of AA was more than that of APEG, the more content of AA, the higher activity of polymerization system and the greater of conversion rate. The molar ratio of APEG / AA had little effect to the polymerization reaction equilibrium time than temperature and initiator. It could be seen that temperature and amount and kinds of initiator could affect the polymerization equilibrium time seriously. Linear regression of conversion rate and polymerization time of the constant speed phase was performed. The polymerization reaction rate(*Rp*) of constant speed phase under different molar ratio of monomers were got. It showed good linearity between ln*Rp* and ln[APEG/AA], the slope was 0.4405, the correlation coefficient was 0.9874. So the relationship of polymerization rate and molar ratio of monomers could be expressed: $Rp \propto [\text{APEG} / \text{AA}]^{0.4405}$.

According to the dynamics results of above discussion, the kinetic relationship could be established as follow: $Rp \propto [\text{APEG/AA}]^{0.4405}[\text{APS-30\%H}_2\text{O}_2]^{0.7819} e^{-5418/T}$.

Conclusions

The overall observed activation energy of copolymerization reaction of APEG with AA was 45.048 kJ/mol. It was a typical chemical reaction. The copolymerization mechanism could be described that the self-polymerization reaction was occurred inside AA monomers firstly, and many polymeric long chain monomer was formed, then APEG opened the internal double bond under the role of initiator, copolymerization reaction with polymeric long chain monomer happened, the network polymer formed, that was the ether-type polycarboxylate superplasticizer.

Keywords: Steel slag, Volume stability, Free calcium oxide, Free magnesium oxide

Abstract. Steel slag is a solid waste produced in the process of steelmaking, and applying it to the field of building materials is the main utilization approach at present. However, steel slag contains free calcium oxide and magnesium oxide, existing serious stability problem. The purpose of this work is to discuss the approaches to solve volume stability problem of steel slag through mechanical modification, chemical modification and other methods. Two successful cases we completed recently were presented to illustrate the combined use of several modifying methods for volume stability treatment of steel slag.

Introduction

Steel slag is a solid waste produced in the process of steelmaking, which production accounted for about 11% ~ 15% of the crude steel production. The storage of a large amount of steel slag not only occupies the land, but also pollutes the surrounding environment. Due to steel slag is a kind of potentially active cementing material with the similar chemical composition to cement clinker, applying it to the field of building materials is the main way of recycling at present. But steel slag contains a great amount of free calcium oxide and magnesium oxide which may produce volume expansion in the process of hydration, existing serious stability problem which is the key factor for influencing the comprehensive utilization of steel slag.

It is necessary to modify steel slag before used for building material. The purpose of this work is to discuss various modifying method and modifiers for steel slag, hence giving the guidance and strategies for the development and application of modifying process for steel slag.

Factors for influencing the stability of steel slag

The volume stability is one of the important characteristics to measure whether it is qualified or not while steel slag was used in building materials field as a kind of cementitious materials. The volume stability problem of steel slag is mainly due to that it contains some chemical materials which produce volume expansion in the process of hydration, such as the volume of free CaO increased 1.98 times while generating $Ca(OH)_2$ in the process of hydration, the volume of free MgO increased 2.48 times while generating $Mg(OH)_2$, the volume of FeS and MnS increased 1.4 and 1.3 times respectively while generating $Fe(OH)_2$ and $Mn(OH)_2$ [1,2,3]. Among them, free CaO experiences the high temperature calcination of about 1600℃in the process of generation. As it

coating with the dense protective layer, the hydration rate is slow. It is well known that this is the main cause of resulting in the bad volume stability of steel slag. Free MgO mainly reacts with FeO and MgO and generates the RO phase of the matrix of MgO. The MgO/FeO ratio has effects on the stability of steel slag. The lower the ratio, the better the stability of RO phase. When the content of MgO contained in steel slag exceeds a certain threshold, it will seriously affect the stability of steel slag in the autoclaving conditions [4]. The content of FeS and MnS has little influence on the stability generally. Another study founds that [5], the metallic iron particles contained in the steel slag also affect the stability of autoclave test if the content is over 2.2%.

Treatment technology of stability

Aging treatment by stacking is a common method to solve the stability of steel slag and also is the most simple and effective method to eliminate the volume expansion of steel slag. It not only reduces the content of free CaO, but also makes sulfur ions oxidized which generated in the hydrating process of CaS. But this approach pollutes the environment and damages the ecological because of the long aging time and occupies the large storage area. Therefore we must study the new method to solve the stability problems of steel slag and accelerate the hydrating degradation of free CaO and MgO.

Mechanical modification

Mechanical modification of steel slag is to make ultrafine steel slag under the strong mechanical force, increase the specific surface area of steel slag, making large amounts of free CaO and MgO exposed and hydrated fast. Sun Jiaying's [6] studies showed that the finely ground power of steel slag has no stability problems using in cement mortar or concrete. This is because the dense protective layer in the surface of free CaO and MgO damaged in the grinding process, which makes more free CaO and MgO activated. As the specific surface area of steel slag increased and the hydration rate accelerated, the stability of steel slag improved effectively [7]. Xu Guangliang etc [8] pointed out that the dosage of steel slag can be improved by about 15% through increasing the grinding time of steel slag through the way of grinding respectively before mixing of steel slag and clinker. This is because some iron grain contained in the steel slag is still not clear in the process of smashing and magnetic separation, resulting in bad grindability of steel slag. Mixed grinding of steel slag and clinker fills the gaps between particles and improves the grindability. The fineness of steel slag increases gradually while the grinding time increased. Feng Chunhua etc [9] showed that using triethanolamine as grinding aid can increase the specific surface area of steel slag greatly and improve grinding efficiency. This is due to that the specific surface area of steel slag increases with the grinding time increases. The specific surface energy improves significantly and the force between particles increases gradually. The fine particles get together again. The larger particles increased gradually again and resulting in the specific surface area declined. Adding the grinding aid can make the surface active substances adsorb on the surface of particles, forming a layer of film, reduce the surface energy, decrease the attraction between material particles，preventing the fine particles reunited again. At the same time it increases the hydrophilic on the surface of particles, accelerating the hydration reaction of free CaO and MgO and thus improving the volume stability of steel slag effectively. Hou Xinkai etc [10] observed the microstructure characteristics of f-CaO and RO phase. The results showed that the most of f-CaO contained in the steel slag are strip or dendritic with bad degree of particles and low degree of aggregation. The space distribution is scattered and sparse. Therefore it is difficult to participate in the early time of hydration reaction. When f-CaO produces hydration reaction gradually later, it results in volume expansion and damages the structure of the building materials seriously. The result is accordance with the

conclusion that grinding of the steel slag, enhancing the specific surface area of particles and accelerating the hydration reaction of free CaO and MgO can solve volume stability problem.

Curing treatment

The Curing treatment is to make the free CaO and MgO contained in the steel slag further digestion with the good volume stability, ensuring the safety use of the steel slag for construction materials. Japanese steel-making company used warm water for curing treatment, the hydration expansion rate of steel slag is less than 1.5% [11]. Xu Kuijun [12] showed that using high temperature water for curing treatment can enhance the hydration process of the steel slag and fly ash mixed system obviously. This is due to some of the unsintering f-CaO participate in the hydration reaction by the excitation effect of the high temperature hydrothermal. This way can increase the alkalinity in the slurry system, stimulate the activity of fly ash and accelerate the hydration. The swelter treatment is a complex physical and chemical reaction. Firstly pour the large pieces of steel slag into the swelter tank when they cool to 300 ~ 600℃. Secondly spray the water intermittently on the hot slag through the automatic rotating sprinkler systems below the tank cover. The large amount of steam from tank makes the steel slag produce a complex physical and chemical reaction. The free CaO engenders volume expansion while generating $Ca(OH)_2$ in the process of hydration. It makes the steel slag further disintegrated. This process can improve the recovery rate of scrap steel. The separation effect of steel and slag is good, but it needs a larger area. Steam curing is to put the steel slag in the steam curing equipment and use the steam treating the steel slag. The free CaO and MgO contained in the steel slag digested before use. Japanese Kawasaki steel company cured the steel slag for 2h with 500℃ steam. It is clearly that the high temperature steam can accelerate the hydration reaction of f-CaO significantly and shorten the treating time greatly [13].

Chemical modification

Chemical modification of the steel slag is to solve the volume expansion problems in the process of hydration by adding a small amount of chemical aids. It can destroy the vitreum on the surface of the particles and react with the active components of steel slag. Wang yue [14] showed that adding the blast furnace slag more than 7% or the quartz sand greater than 5% into molten steel slag can solve the stability of steel slag effectively. This is due to the blast furnace slag and quartz sand contains SiO_2 which can react with the f-CaO contained in the steel slag generating silicates. At the same time it lowers the volume expansion of steel slag. Zhang Zuoshun etc [15] showed that the high temperature modification of steel slag using iron tailings as modifier can reduce the content of f-CaO significantly and improve the stability of steel slag. The mass fraction of f-CaO contained in the steel slag reduced from 4.84% to 1.82% while adding the mass fraction of iron tailings 20% at 1250℃. This is due to iron tailings contains a large amount of SiO_2 which can react with the f-CaO contained in the steel slag generating dicalcium silicates and tricalcium silicates. At the same time it promoted the RO phase's decomposition in the process. Part of them changes into $MgFe_2O_4$ and further into Fe_3O_4 under higher temperature. It solves the volume expansion problem of the f-CaO and RO phase in the process of hydration effectively. Wu Fuzhong etc [16] studied the fly ash dosage containing high silicon and temperature effects on the content of f-CaO. The results showed that fly ash can reduce the content of f-CaO. The more the dosages of fly ash, the higher the temperature is, and the lower the content of f-CaO. The turning point for f-CaO absorption is 1100℃. The absorption rate of modifier for the f-CaO increases sharply at this temperature. This is also due to the SiO_2 contained in the fly ash of high silicon react with the f-CaO contained in the steel slag generating the calcium silicate salt. At the same time fly ash begins to melt at 1300℃. It produces the liquid - solid reaction with the steel slag promoting the reaction further.

Typical cases

In 2013, we proposed two methods to improve volume stability of steel slag for construction and building materials: one is the combined use of chemical modification and physical modification, the other is the combined of three method of chemical modification, physical modification and thermal modification.

The combination of chemical modification and physical modification[17]

Firstly get the crude steel slag powder by grinding the steel slag and magnetic separation. Secondly add the digestive agent, dispersing agent and water into the steel slag powder, stir evenly then maintain the mix for 48 ~ 72 hours at 50 ~ 60℃. The highest dosage of slag can reach 50%. The cement products have good stability and the strength fits Chinese national standards. This invention combining the characteristics of steel slag strengthen the process of hydration of the free CaO and MgO through fine grinding, adding the digestive agent and dispersing agent, controlling the temperature and humidity. At the same time, controlling the processing time to form the calcium carbonate as little as possible can solve the stability problem of steel slag and maintain high gelling activity in uses.

The combination of chemical modification, physical modification and thermal modification [18]

Also in 2013, we proposed a method which can prepare the autoclaved aerated concrete block by iron tailings and steel slag. Firstly prepare the wet mixture by grinding the iron tailings, steel slag, water and water reducing agent. Secondly pour the wet mixture into the digestion tank through eliminating the iron after flotation, then add the activator and inflow the waste heat steam keeping 3 ~ 5h at 45 ~ 60℃. Lastly add the crude lime, cement and aluminum powder into the slurry of digestion. The slurry became embryonic body by casting, foaming, aging and cutting. The autoclaved aerated concrete block is produced through autoclave curing the for 8h at 1.2 MPa. This technology solves the stability problem of steel slag and improves the activity of steel slag. .

Conclusion

The stability problem of steel slag is the main obstacle of its utilization in construction and building materials. It is imperative to solve the stability problems of steel slag in the process of application. It can improve the stability of steel slag effectively and expand the safety use through mechanical modification, curing treatment and chemical modification. The combined use of the three methods can improve the stability of steel slag more effectively because each of them exists its own advantages and of course, the corresponding disadvantages. More important, there exist synergistic effects among these methods.

Keywords: cement particles; grinding aids; grinding; particle size distribution; adsorption; dispersion; action mechanism

Abstract. Effects of triethanolamine grinding aids on the angle of repose, fineness, particle morphology and particle size distribution of cement are studied, and the action mechanism of grinding aids is discussed by surface tension and Zeta potential. The results show that the powder fluidity and particle circularity of cement are improved and the particle size and grinding time of cement are effectively reduced by grinding aids. And Grinding aids improve the particles content in the range of 3-32μm particle size by 6.63% and promote destruction of the chemical bonds and lattice distortion of cement mineral during the grinding process. The dispersion grinding mechanism of grinding aids is that they can reduce the surface free energy of powder to prevent fine particles from closing each other and shield or neutralize the particles surface partial charge to prevent facture surface from healing and promoting the cracks to extend easily.

Introduction

Grinding process of cement is a dry grinding process with air as medium. When grinding to certain fineness, cement fine particles have a strong tendency to agglomerate. Thus the fine particles easily mutual adhesion, and particle fracture surface easy to heal, so that the small particles will re-combine to form larger particles [1-3], which can seriously affect the grinding efficiency of cement and miniaturization of particles and particles can not be further ground. In recent years, trace grinding aids are used in the cement grinding can improve the characteristics of cement particles and play a role in the dispersion grinding, then grinding aids have become an important means to improve cement grinding efficiency [4,5]. Currently, the chemicals used as cement grinding aids include triethanolamine, triisopropanolamine, ethylene glycol, glycerol and other organic matter, and triethanolamine is most widely used, so the effect of triethanolamine on cement particles is very important. In this paper, the effect of organic grinding aids on the characteristics of cement particle group is discussed from the angle of repose, fineness, particle morphology, particle size distribution, uniformity coefficient, etc. And the action mechanism of grinding aids in the miniaturization process of cement is analyzed by infrared spectroscopy and adsorption characteristics of ground fine particles.

Materials and Methods

Raw Materials: (1) Cement clinker, slag and limestone are provided from a cement plant in Chongqing city of China, and their chemical compositions are shown in Table 1; (2) Organic grinding aid is triethanolamine (abbreviated TEA) which is diluted with water to the concentration of 48wt%.

Table 1 Chemical composition of raw materials / wt %

Sample	CaO	SiO_2	Al_2O_3	Fe_2O_3	MgO	K_2O	Na_2O	SO_3	Loss
Clinker	66.05	22.28	4.79	2.87	1.84	0.97	0.25	0.63	0.40
Slag	36.12	30.30	13.82	0.66	8.31	0.51	0.28	0.12	9.75
Limestone	50.35	3.29	1.05	0.30	1.51	0.29	0.07	0.21	

Grinding Experiment Methods: Mixing ratio of cement in the grinding experiment is shown in Table 2. The grinding aids are uniformly dropped on the surface of materials which are to be grinding, and the dosage of grinding aids is 0.06wt% of the total mass of materials. The weight of materials for each grinding experiment is 3kg and the grinding time is 15min, 20min and 25min respectively. And cement is sieved by 0.9mm square mesh sieve after grinding, and then the characteristics of cement particles group are tested.

Table 2 Mixing ratio of cement / wt%

Clinker	Slag	Limestone	Gypsum
80	10	5	5

Testing Methods: ① The angle of repose is tested according to GB/T11986-1989, and cement powders is poured into funnel by the injection method, and then samples fall within the disc below the funnel, so the angle of repose for powders is obtained according to the formula ($\tan\theta=h/R$) by measuring the height of powder layer and the radius of the disc; ② The fineness, specific surface are and particle size distribution of cement are tested respectively according to GB/T1345-2005, GB/T8074-2008 and JC/T721-2006; ③ The particles morphology of ground fine cement is observed by Hitachi S-3400 scanning electron microscope and IR is analyzed by Nicoletis 10 Fourier transform infrared spectrometer; ④ The testing method of surface tension is as follows: cement and water are mixed according to 1:200 and the mixture is filtered by suction flask, and then the surface tension of cement filtrate is tested by JK99B type full-automatic tensiometer; ⑤ Zeta potential is tested by electrophoresis, and cement and water is prepared into suspension, then Zeta potential of suspension is tested by Zeta potential meter after stirring suspension 1-3min.

Results and Discussion

Effect of Grinding Aids on the Fluidity of Cement Powder

In this paper, the fluidity of cement powder is characterized by the angle of repose which reflects the friction characteristics between the particles of powder in loose accumulation condition. The relationship of the angel of repose and the fluidity of powder is that the angle of repose is bigger, the fluidity of powder worse, and the repeatability of testing is poor. It can be seen from Table 3 that the angle of repose for cement with grinding aids is smaller than that of blank cement without grinding aids at the same time of grinding, which the angle of repose for cement decrease respectively 9°, 6° and 7° at the grinding time for 15min, 20min and 25min respectively. It is due to the molecules of grinding aids adsorbed on the surface of cement particles form mono-molecular adsorption layer or thin firm, which reducing the contact area, friction and attractive force between particles, and then cement powder are easy to slip between particles, so the fluidity of cement is increased and the grinding efficiency of cement is improved.

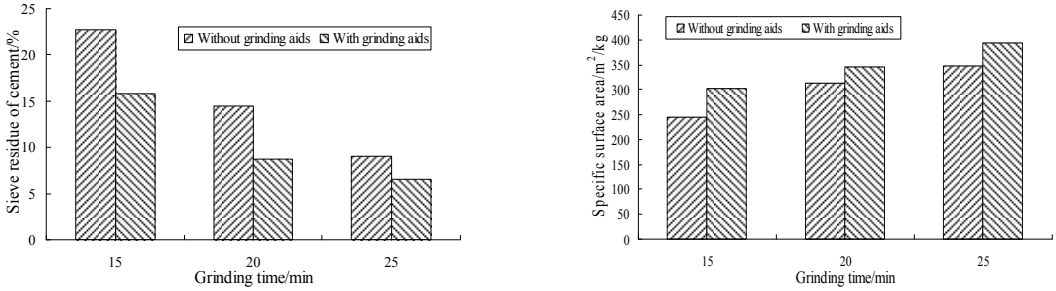
Table 3 Repose angle of cement powder

Grinding time / min		15	20	25
Repose angle / °	Blank	65	53	43
	With grinding aids	56	47	36

Effect of Grinding Aids on the Fineness and Particle Morphology of Cement

It can be seen from Fig.1 that both the sieve margin of cement with grinding aids is smaller than that of blank cement sample at the same time of grinding, while both the specific surface area of sample with grinding aids is larger than blank sample. It shows that the content of coarse particles is increased and the content of fine particles is reduced after adding the grinding aids into cement in the grinding process of cement, so the cement particles are effectively refined. In addition, it can be found from Fig.1 that the sieve margin and specific surface area of the cement with grinding aids at the grinding time for 15min and the blank cement without grinding aids are respectively close at the grinding time for 20min, and the sieve margin and specific surface area of the cement with grinding aids at the grinding time for 20min also respectively reach to the level of blank cement. It also shows

that the grinding aids added in the grinding process of cement can reduce the grinding time and power consumption for grinding and improve efficiency of grinding.



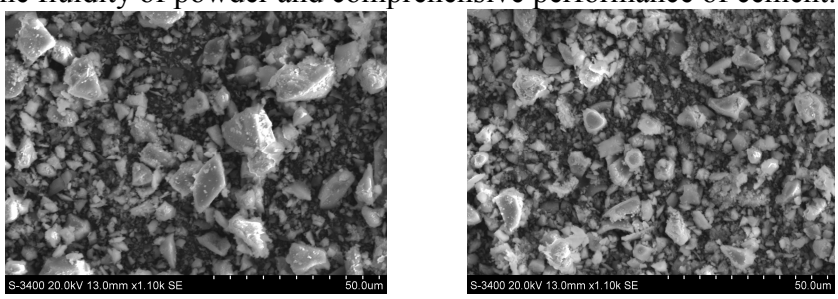


Fig.1 Effect of grinding aids on sieve margin and specific surface area of cement

The morphology of cement particles is shown in Fig.2 which shows that the particles of cement with grinding aids are more uniform and dispersion and the shape of particle more tend to sophericity. Thus it indicates that the circularity of cement particle is increased, which is conducive to improvement of the fluidity of powder and comprehensive performance of cement.

(a) Cement without grinding aids (b) Cement with grinding aids

Fig.2 Effect of grinding aids on the morphology of cement particles

(Note: grinding times of the cement particles is 25min, below)

Effect of Grinding Aids on the Particle Size Distribution of Cement Particles

It can be seen from Fig.3 that the particle size distribution of cement with grinding aids is more narrow than blank cement. And it can be seen from Table 4 that the content of less than 3μm and more than 65μm particles of cement with grinding aids is less by 1.04% and 1.92% respectively than the blank cement, while the content of 3-32μm particles of cement with grinding aids is more by 6.63% than the blank cement, and the 3-32μm particles play a major role on the strength of cement. And the median diameter of cement particles is less than the blank. So the results show that cement particles are effectively refined after adding grinding aids in the grinding process, and the particle size distribution become narrow by reducing over-grinding of cement and the content of large-size particles of cement, especially the particles concentrate in the range of 3-32μm, So grinding aids play a optimal role on particle size distribution.

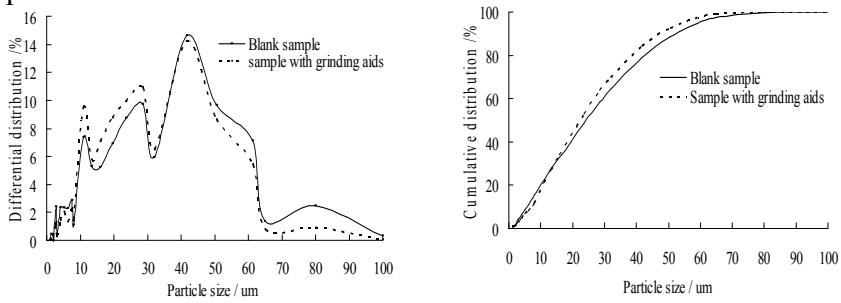

Fig.3 The particle size distribution of cement

Table 4 Particle size distribution of cement powder

Sample	Particles size distribution of cement / %				D50 (Median diameter)/ μm
	≤3μm	3-32μm	32-65μm	≥65μm	
Blank	4.17	60.23	32.82	2.78	24.23
With grinding aids	3.03	66.86	29.05	1.06	22.48

IR Analysis of the Ground Fine Cement

The changes of the order degree and chemical bond of crystal structure for the composition of solid materials in the process of grinding can be investigated by IR [6,7]. It can be seen from Fig.4 that the bands shape of characteristic absorption peaks in the IR chart of cement with grinding aids tends to blunt compare with the blank cement. It shows that grinding aids can reduce the symmetry of crystal structure of cement minerals and promote it to no qualitative of cement surface. The absorption peak [8] of [AlO_6], [SiO_4] in C_3S, [SO_4] in gypsum and [CO_3] respectively appear at about 551cm^{-1}, 925cm^{-1}, 1115cm^{-1} and 1425cm^{-1}, and the absorption peak of [H_2O] in gypsum appear at about 1625 cm^{-1}, 3400 cm^{-1}and 3542cm^{-1}. By comparing the IR of cement with grinding aids with the IR of the blank cement, it can be seen that the wave number of [AlO_6] band is reduced from 551.0 cm^{-1} of blank sample to 550.8 cm^{-1} of sample with grinding aids, and the waves numbers of [SiO_4] band, [SiO_4] band and [CO_3] band are respectively reduced from 926.5 cm^{-1} of blank sample to 925.1 cm^{-1}, from 1115.4 cm^{-1} to 1114.3 cm^{-1} and from 1425.3 cm^{-1} to 1424.5 cm^{-1}. The decrease of wave number for absorption peak of these groups indicates that the damage of crystal structure and chemical bond of cement minerals are accelerated in the process of grinding by adding grinding aids, which increasing lattice distortion of cement minerals.

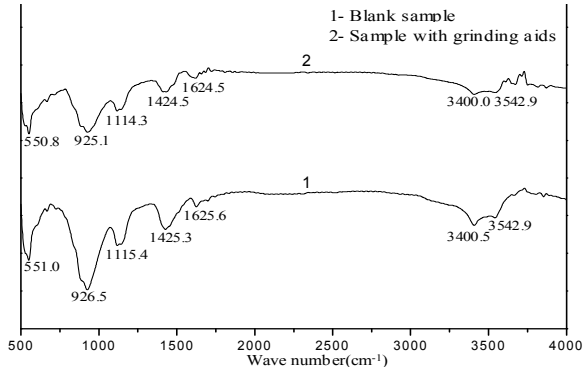

Fig.4 IR of the ground fine cement

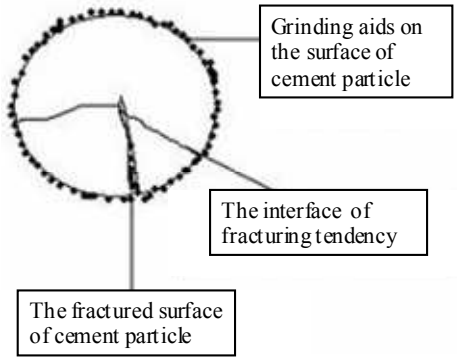

Fig.5 Adsorption of grinding aids in cement particle

Mechanism Analysis of Grinding Aids

It can be seen form the Table 5 that the surface tension of cement with grinding aids is less than the blank, it shows that triethanolamine grinding aids has good surface activity and can reduce the surface free energy of cement particles. In addition, it can be seen from Table 5 that the absolute value of Zeta potentials of cement with grinding aids is less than the blank, this may be due to grinding aids adsorbed in the surface of cement shield or neutralization the partial charge of particles, thus the negative charges of cement particles is reduced, And it shows that grinding aids can change the surface charge distribution of cement particles.

Table 5 Surface tension and Zeta potential of cement

Sample	Surface tension / mN/m^2	Zeta potential / mV
Blank	82	-10.34
With grinding aids	63	-6.02

Triethanolamine is a kind of polar organic compound with amino, hydroxyl and other groups, which has a strong adsorption. In the grinding miniaturization process of cement, the functional groups of grinding aids adsorbed in the surface, fracture surface and cracks of cement particle (as shown in Fig.5), thus play the role of dispersion and grinding. The possible mechanism of grinding aids is as follow: 1) Grinding aids adsorb between micro-crakes of particles and provide the foreign ions or molecules to balance out or shield unsaturated charges of crack section, which preventing facture surface to healing, thus the cracks become easier to extend; 2) grinding aids molecules adsorb in the surface of cement particles and form adsorption film, thus the free energy and interfacial tension of powder surface are reduced and particles to close each other are prevented, and then it plays the role of dispersion and prevents the fine particles agglomeration, so the dispersion of powder and grinding efficiency are improved. Furthermore, the more compact grinding aids form the adsorption film in the particle, the better grinding aids play dispersion action.

Conclusions

(1) In the process of grinding, grinding aids can effectively reduce the sieve margin of particles and grinding time of cement. And the fluidity of powder, specific surface area and sophericity of particle are also improved. Grinding aids play an optimal role on cement particles size distribution by improving the particles content in the range of 3-32μm particle size.

(2) Destruction of the crystal structure and chemical bond of cement minerals are accelerated in the grinding process by adding grinding aids, which increasing lattice distortion.

(3) Grinding aids can reduce the surface free energy of powder and prevent fine particles from closing each other. And they change the surface charge distribution by shielding or neutralizing the particles surface partial charge and prevent facture surface from healing and promoting the cracks to extend easily.

Effect of Mineral Admixtures on Rheological Properties of Cement Paste

Linchun Zhang, Ailian Zhang

School of Civil Engineering, Sichuan College of Architectural Technology, Deyang 618000, China

zhanglinchun1980@126.com

Keywords: rheological properties; mineral admixtures; cement paste; Marsh cone method; rotary viscosimeter

Abstract: The Marsh cone method and rotary viscosimeter are used to study the effect of mineral admixtures such as ultra-fine fly ash, ultra-fine slag, zeolite powder and silica fume on rheological properties of cement paste. Test results show that the optimal ratio of ultra-fine fly ash, ultra-fine slag, zeolite powder and silica fume are respectively 20%, 20%, 10% and 8%. And the optimized mix proportion is the composition of 8% silica fume and 12% slag. By using water reducing agent and mineral admixtures we could get the cement paste which has good liquidity and no bleeding.

Introduction

Today concrete is one of the most widely used building materials in the world [1], and it is increasingly used in civil engineering. It is especially important when producing the concrete we must consider its use performance [2]. Rheological property is one of major factors influence on concrete working performance [3, 4]. So it is obviously that it is very important to prepare the concrete which has good liquidity and no bleeding.

Most research so far had focused on controlling superplasticizer, thickener and the dosage of mineral admixtures to achieve great success in improving the rheological properties of concrete [5-10]. The industrial waste residue such as ultra-fine fly ash, ultra-fine slag, zeolite powder and silica fume is the main raw material sources of mineral admixtures [11]. Studying the effect of the single and compound mineral admixtures on the rheological properties of concrete has the vital significance regarding the modern civil engineering construction. The Marsh cone method and rotary viscosimeter are used to study the effect of mineral admixtures such as ultra-fine fly ash, ultra-fine slag, zeolite powder and silica fume on rheological properties of cement paste.

General Situation of Test Area

Raw Material

Cement

P·O 42.5 ordinary portland cement is produced in Harbin cement plant and ordinary medium sand whose fineness modulus is 2.3. Its physical properties and chemical component is respectively shown in Table 1 and Table 2.

TABLE 1 ELEMENTARY PHYSICAL AND MECHANICAL PROPERTIES OF CEMENT

Density (g/cm^3)	BET (m^2/k g)	Setting time (min)		Setting time (min)		compressive strength (MPa)	
		Initial set	Initial set	3d	28d	3d	28d
3.06	334	163	315	5.8	9.5	29.2	52.0

TABLE 2 CHEMICAL COMPOSITIONS OF CEMENT

(wt %)

SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	R_2O	LOI
21.08	5.47	3.96	62.28	1.73	2.63	0.50	1.61

Other Raw Materials

The test uses mineral admixtures are as follows, ultra-fine fly ash which is produced in Harbin cement plant, ultra-fine slag which is produced in Anshan Iron and Steel Factory, zeolite powder which is produced in Neijiang, and silica fume which is produced in Elkem Company. And the additives are as follows, Mighter 100 naphthalene superplasticizer produced by Japan Kao whose quantity is 1% of the cement and whose water reducing ratio is 20%, MICRO-AIR202 concrete air-entraining agent produced by Master Builder Technoloy in Shanghai, and the running water in Harbin.

Mix Proportion

The sum of the quality of cement and mineral admixtures is respectively identically equal to 1000g and 1400g. The water-binder ratio is 0.4. And the cementitious system respectively contains 1% and 0.1‰ of naphthalene superplasticizer and air-entraining agent in accord with weight.

The effects of ultra-fine fly ash, ultra-fine slag, zeolite powder and silica fume composite admixture of them on the rheological properties of cement paste is also studied in this paper. The mix proportion is influenced by the result of every single mineral admixture. So it will be taken on later in this article.

Experimental Programme

First, weigh the raw material according to the above mix proportion. Then, pour the mixture of mineral admixture, water reducer and cement into beaker and mix for one minute. Add the prepared air-entraining agent water into the beaker, and stir for five minutes. After this, pour the new paste into recogizer of NDJ-79 type cylinder rotational viscometer, read the data after stirring for ten seconds. In this way, plastic viscosity and shear stress of new paste could be respectively got by the big rotor and the small rotor.

Measure the time how long it would take for 1725 milliliters pure cement paste five milliliters, plus or minus have all come out the Marsh cone. Then pour the cement paste into the small cone which is used to measure the fluidity of cement paste. Take away the small cone. Five seconds later, measure the diameter using vernier caliper.

Conclusions and Prozspects

Single Mineral Admixture

Slag

Influence of replacement of slag on rheology is shown in Table 3.

TAB. 3 INFLUENCE OF REPLACEMENT OF SLAG ON RHEOLOGY

Replacement (%)	Plastic viscosity (Pa·s)	Shear stress (Pa)	Diameter (cm)	Marsh Time (s)
10	0.02434	122.34797	23.10	24.69
20	0.02300	140.85207	26.90	22.95
30	0.02259	142.70945	28.10	20.47
40	0.01807	148.58512	37.85	17.29

Results show that plastic viscosity of new cement paste and Marsh time reduced gradually with the increase of slag dosage. As slag dosage increases, shear stress and diameter measured by the small cone becomes larger gradually.

The surface of cement particles gets high surface charge when high efficiency water reducing agent molecules are adsorbed on the surface of cement particles after cement is mixed with high efficiency water reducing agent. The same charge cause repulsion between particles. The repulsion has

important roles to play in deflocculating and dispersing the paste, so that the free water wrapped in flocculating constituent could be released. So it has a significant increase in the flow of slurry.

It is particularly gratifying that when high efficiency water reducing agent and slag are both added into the cement, the flow of slurry is further heightened. That's because the free water wrapped in flocculating constituent could be further released due to the electric double layer produced by high efficiency water reducing agent adsorbed by the surface of slag particles.

The best slag dosage is 20% only from view the influence on the rheological properties of cement paste.

Fly Ash

Influence of replacement of fly ash on rheology is shown in Table 4.

TAB. 4 INFLUENCE OF REPLACEMENT OF FLY ASH ON RHEOLOGY

Replacement (%)	Plastic viscosity (Pa·s)	Shear stress (Pa)	Diameter (cm)	Marsh Time (s)
10	0.02319	136.50222	27.75	26.94
15	0.01797	148.61964	28.00	22.40
20	0.01133	162.08344	29.15	20.19
25	0.00689	171.92238	30.05	18.00
30	0.00244	176.89362	30.40	17.60

Results show that plastic viscosity of new cement paste and Marsh time reduced gradually with the increase of fly ash dosage. As fly ash dosage increases, shear stress and diameter measured by the small cone becomes larger gradually.

The influence of fly ash on the rheological properties of cement paste was influenced by its particle morphology. Spherical Vitreous surface of the fly ash is very smooth. Fly ash is filled in cement particles which has the effect of ball bearing so that it has a significant increase in the flow of slurry. At the same time, fly ash surface potential is very big which could adsorb part of water reducing agent. So that, fly ash surface could generate rejection itself which could give rise to the increasement of the flow property.

The best fly ash dosage is 20% only from view the influence on the rheological properties of cement paste.

Silica Fume

Influence of replacement of silica fume on rheology is shown in Table 5.

TAB. 5 INFLUENCE OF REPLACEMENT OF SILICA FUME ON RHEOLOGY

Replacement (%)	Plastic viscosity (Pa·s)	Shear stress (Pa)	Diameter (cm)	Marsh Time (s)
4	0.02264	103.15343	24.95	21.59
6	0.01956	120.55280	25.00	20.06
8	0.01853	122.62415	26.70	19.66
10	0.03446	91.346710	20.30	33.94

The plastic viscosity and Marsh time of the cement paste will go down with the gain of silica fume's dosage at first, and the plastic viscosity will reach a minimum value when the dosage of the silica fume is 8%, and then it will enhance with the increment of the dosage of the silica fume again. As slag dosage increases, shear stress and diameter measured by the small cone have the opposite trend.

The influence of silica fume on the rheological properties of cement paste was influenced by its large specific surface and high water requirement. Silica fume particle surface water raised with the

increment of the dosage of the silica fume. So the plastic viscosity will increase when the silica fume dosage is too much.

The best silica fume dosage is 8% only from view the influence on the rheological properties of cement paste.

Zeolite Powder

Influence of replacement of zeolite powder on rheology is shown in Table 6.

TAB. 6 INFLUENCE OF REPLACEMENT OF ZEOLITE POWDER ON RHEOLOGY

Replacement (%)	Plastic viscosity (Pa·s)	Shear stress (Pa)	Diameter (cm)	Marsh Time (s)
5	0.01274	160.73710	29.05	17.10
10	0.01992	143.86696	28.70	21.82
15	0.02739	133.59078	27.30	22.25
20	0.02929	126.66329	24.00	29.88

Results show that plastic viscosity of new cement paste and Marsh time increased gradually with the increase of zeolite powder dosage. As zeolite powder dosage increases, shear stress and diameter measured by the small cone becomes smaller gradually. We can see that, viscosity of new cement paste increased with the increase of zeolite powder dosage.

Natural zeolite powder itself is lattice structure whose inside is full of uniform pores and channels. At the same time, there is a lot of openness for lattice structure. After being levigated, zeolite powder gets high specific surface area. It can absorb a large number of water molecules and gases with the equilibrium relative humidity in the atmosphere in its natural state.

The zeolite powder mixed with cement paste could absorb the extra mixing water of cement paste so as to overcome the cement's bleeding. Meantime it could increase the cement's viscosity and the amount of wrapped slurry of aggregate.

In the process of condensation hardening of concrete, cement hydration continue to need water. Right now the water absorbed by zeolite powder could release gradually until its inside has the effect of vacuum. That makes the gel in the cement more closely to condense into a whole. So the viscosity of new cement paste increased with the increase of zeolite powder dosage.

The best zeolite powder dosage is 10% only from view the influence on the rheological properties of cement paste.

Composite Mineral Admixtures

By the preceding content, we can conclude that the optimal ratio of fly ash, slag, zeolite powder and silica fume are respectively 20%, 20%, 10% and 8%. For comparison, composite mineral admixtures are as follows, 8% silica fume and 12% slag, 8% silica fume and 12% fly ash, 10% fly ash and 10% slag. A represents 8% silica fume, B represents 20% slag, C represents 20% fly ash, D represents 10% fly ash and 10% slag, E represents 8% silica fume and 12% fly ash, F represents 8% silica fume and 12% slag. Influence of these six groups on rheology is shown in Table 7. The results of ABC are taken from single mineral admixture.

TAB. 7 RHEOLOGY OF NEW CEMENT MORTAR

	plastic viscosity (Pa·s)	shear stress (Pa)	Diameter (cm)	Marsh Time (s)
A	0.01853	122.62415	26.7	19.66
B	0.02300	140.85207	37.9	17.29
C	0.01133	162.08344	28.0	18.00
D	0.01903	120.56842	25.8	20.28
E	0.02856	63.36952	22.7	34.57
F	0.03482	63.56925	22.7	38.63

The rank of the rheological properties of new cement paste with different mineral admixture is: F>E>D>A>C>B.

Summary

In this paper, we choose study the effect of mineral admixtures such as ultra-fine fly ash, ultra-fine slag, zeolite powder and silica fume on rheological properties of cement paste. We can draw the following conclusions:

The plastic viscosity of the cement paste will decrease with the increase of slag or fly ash, but the yield shearing strength will increase gradually with the increase of slag or fly ash. The best slag and fly ash dosage is both 20%.

The plastic viscosity of the cement paste will go down with the gain of silica fume's dosage at first, and the plastic viscosity will reach a minimum value when the dosage of the silica fume is 8%, and then it will enhance with the increment of the dosage of the silica fume again. The best silica fume dosage is 8%.

The plastic viscosity of the cement paste will go up and yield shearing strength will go down with the increase of the ratio of the zeolite powder either the zeolite powder is added as a single agent or combined with silica fume. The best zeolite powder dosage is 10%.

The rank of the rheological properties of new cement paste with different mineral admixture is: F>E>D>A>C>B. silica fume and slag> silica fume and fly ash>slag and fly ash>silica fume>fly ash>slag. The rheological properties of the double mixing mineral admixtures is superior to single doped the rheological properties of mineral admixtures.

Theoretical Study on Seismic Behavior of LYTAG Concrete

Linchun Zhang

School of Civil Engineering, Sichuan College of Architectural Technology, Deyang 618000, China

zhanglinchun1980@126.com

Keywords: LYTAG concrete; seismic; ANSYS; ductility

Abstract: In order to estimate seismic behavior of LYTAG concrete, the seismic behavior of ordinary concrete have been studied in comparison with LYTAG concrete in this article. At first it discusses the advantages of LYTAG concrete, and then it draws following conclusions through the contrast tests of LYTAG concrete and ordinary concrete and the method of finite element analysis. The seismic performance of Lytag concrete is better than that of ordinary concrete. LYTAG concrete has better social and economic benefits than ordinary concrete from the aspects of seismic fortification.

Introduction

It is generally known that the ordinary concrete itself has significant shortcomings in some respects, for example, big weight, easy to produce cracks, poor fire resistance, poor seismic performance, and poor heat insulation performance[1, 2]. These shortcomings limit the application of common concrete in some special engineering. At present, we are in the age whose building technology renew day by day. The buildings have to be more and more weight[3, 4]. Therefore, in the current big weight, how to minimize the weight while improving the seismic performance of buildings has become a pressing question. And it has become one of the important topics which the domestic and foreign scholars are concerned about. We need materials that have the characteristics of light weight and good seismic performance. Therefore, lightweight aggregate concrete rises in response to the proper time and conditions.

There are many pores which can meet the characteristics of light weight in lightweight aggregate concrete. But we don't know how its seismic performance is. Because of our country in the implementation of the strategy of sustainable development, and rich fly ash haydite resources, production of low energy consumption, so it can be recycled and returning in line with the basic national policy of our country. Therefore, this paper focuses on the study of the seismic performance of LYTAG concrete.

Advantage of LYTAG Concrete

Light weight and high strength

There are lots of pores in LYTAG concrete, who can reduce the weight of the lightweight concrete, so as to realize the characteristics of light. LYTAG concrete unit weight is generally 800~1950kg/m^3. But when it is used for structure, its density is generally 1400~1950kg/m^3. And LYTAG concrete used for structure weighed about from 20 percent to 30 percent less than normal concrete, while its intensity can reach of ordinary concrete strength grade (C15~C50). When it is used for wall thermal insulation structure, its density is generally 800~1200kg/m3, while its intensity can reach CL5~CL15. And it weighed about from 30 percent to 50 percent less than normal concrete.

Good temperature preservation and heat insulation performance

There are many voids in the fly ash haydite. These pores not only reduce the weight, but also reduce its coefficient of thermal conductivity to a certain extent, and improve its thermal insulation performance. The data makes clear, coefficient of thermal conductivity of LYTAG concrete can reduce the thermal conductivity of about 50%~60% than ordinary concrete. Especially as wall

materials, the advantage is more prominent. Data show that, as the wall materials, the ratio of coefficient thermal conductivity of LYTAG concrete to ordinary concrete is only about 1/6~ 2/3.

Good fireproof performance

Lytag is made from being baked at the centigrade of 1200~1300. Its main chemical composition is SiO_2, $A1_2O_3$ and so on. Its coefficient of thermal conductivity is low, that is to say, under high temperature, the heat flow from the inside of the LYTAG concrete to the outside is slow compared to the speed of common concrete. So its fire resistant performance is good.

Others

In addition to the above advantages, LYTAG concrete also has other advantages such as good impermeability, good frost resistance, strong corrosion resistance, good anti shock proof performance and low elastic modulus. In addition, its production process is simple, and its strong adaptability, so it is a new building material with good economic and social benefits. There are also data indicate that Lytag concrete seismic performance is good, so this article focuses on its seismic performance. Analysis on seismic performance will be introduced next.

General Situation of Test Area

Raw material

The test uses P·O 42.5 ordinary portland cement produced in Harbin cement plant and ordinary medium sand whose fineness modulus is 2.3, LYTAG produced in Daqing, ultra-fine slag which is produced in Anshan Iron and Steel Factory and silica fume which is produced in Elkem Company.. The chemical component is shown in Table 1.And the additives are as follows, Mighter 100 naphthalene superplasticizer produced by Japan Kao whose quantity is 1% of the cement and whose water reducing ratio is 20%, MICRO-AIR202 concrete air-entraining agent produced by Master Builder Technoloy in Shanghai, and the running water in Harbin.

Tab. 1 Chemical compositions of main raw materails

(wt %)

	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	R_2O
cement	21.08	5.47	3.96	62.28	1.73	2.63	0.50
slag	38.61	7.27	0.4	42.49	6.71	0.9	0.70
Silica fume	93.7	0.3	0.8	0.2	0.2	0.5	0.30

Mix proportion

According to the relevant requirements of concrete workability, cohesiveness, high strength and large liquidity, the optimum mixture ratio, as shown in table 2 is based on large numbers of experiments. The optimum mixture ratio is to comply with the design and construction requirements. In table 2, NC stands for normal concrete, and LC stands for LYTAG concrete. Water in table 2 is the sum of pure water and the water absorbed by the LYTAG. The water reducer dose used is 5.3kg, and air-entraining agent dose used is 0.053kg in one cubic meter of concrete. And the material dose in Table 2 is in one cubic meter of concrete.

Tab. 2 Mix proportion of LYTAG concrete and normal concrete

	cement	slag	Silica fume	water	sand	LYTAG	stone
NC	330.0	0	0	181.5	765	0	1016
LC	424.0	63.6	42.4	244.0	556	568	0

Table 2 demonstrates that aggregate in Lytag concrete is much lighter than in ordinary concrete. The ratio of aggregate in Lytag concrete to in ordinary concrete is about 0.5.Therefore, the LYTAG concrete can greatly reduce the bulk density of concrete.

Conclusions and Prospects

Strength

The cubic specimens size of cube compressive strength was 150mm×150mm×150mm. The compressive strength was tested by hydraulic universal testing machine. The LYTAG concrete were vibrated forming according to the best ratio shown in Table 3. And the forms are removed after 24 hours. Then put the concrete into the standard curing room to cure 3d, 7d and 28d respectively. Take out the specimens from the standard curing room. And test the compressive strength of each specimen at 3d, 7d and 28d respectively. Each group adopts the average of three pieces as the final result, as shown in table 3.

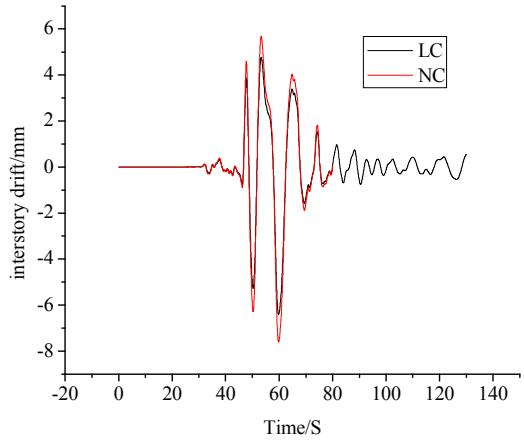
Tab. 3 Performance of LYTAG concrete and normal concrete

	density/ kg·m^{-3}	Slumps /mm	Compressive strength/MPa		
			3d	7d	28d
NC	2389	195	35.8	57.9	65.7
LC	1835	180	25.9	41.2	52.8

From table 3 we can learn that, slump had little difference between LYTAG concrete and ordinary concrete that can be able to meet the liquidity requirements. It has reached the requirement of concrete structure, although compressive strength of LYTAG concrete of 3d, 7d and 28d is small than ordinary concrete. And the late strength of Lytag concrete growth momentum was sound.

Anti-seismic property

After the 1976 Tangshan earthquake researchers have found that the earthquake-stricken brick structure houses collapsed or were almost completely destroyed in the earthquake area, but dozens of buildings built by the use of lightweight aggregate concrete building is almost intact. This fact proves that the earthquake resistance of lightweight aggregate concrete building is very good. As followed, research the seismic performance of LYTAG concrete.

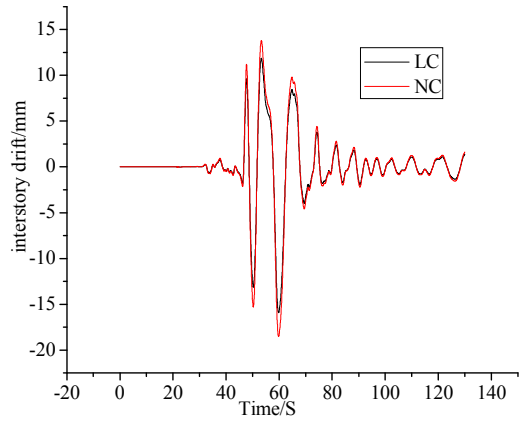


In this paper, the seismic performance of the two buildings of architectural models which were built by the mix proportion shown in Table 2 were compared and analyzed, adopt the Chi-Chi earthquake in Taiwan tcu052 waves recorded. The two buildings are the frame structure model which is located at the earthquake zone of intensity 7. Then, a time history analysis method for the two building model is proposed. To be specific, the seismic performance of the interstory drift and acceleration of the first floor, the third floor, the fifth floor and the seventh floor of the two buildings were analyzed as shown in Table 4 and figure 1.

Tab. 4 The seismic performance of LYTAG concrete and normal concrete

		interstory drift/mm	acceleration/gal
NC	**1**	7.6	192
	3	12.8	273
	5	15.9	362
	7	18.5	469
LC	**1**	6.4(18.8%)	175(9.7%)
	3	10.2(25.5%)	261(5.0%)
	5	13.8(15.2%)	351(3.0%)
	7	15.9(16.4%)	492(-4.9%)

Notes: Figures in brackets denote Damping ratio.



We can learn from Table 3 and Figure 1 that seismic acceleration of Lytag concrete and ordinary concrete frame structure model under the action of waves tcu052 Taiwan Chi-Chi earthquake records is not much difference. But the displacement decreased significantly. Reducing layer displacement has a powerful effect on the seismic performance of buildings. Reducing layer displacement has a powerful effect on the seismic performance of buildings.Therefore, the seismic performance of the seismic performance of Lytag concrete is much better than that of ordinary concrete.

Fig. 1 Reaction curve of LYTAG concrete and normal concrete

Summary

When an earthquake occurs, light weight, low elastic modulus of LYTAG concrete and good deformation performance make the seismic wave velocity performance slow, and it can quickly absorb the impact energy of earthquake. Therefore, the damage of LYTAG concrete with long auto-oscillation period is light under the same load of earthquake. Damping effect is significant when the aggregate is LYTAG. Damping effect will be more significant if both of the bearing structure and maintenance structure adopt LYTAG concrete.

The Frost Resistance of LYTAG Concrete

Ailian Zhang, Linchun Zhang

School of Civil Engineering, Sichuan College of Architectural Technology, Deyang 618000, China

zhangailian1980@163.com

Keywords: frost resistance; LYTAG concrete; mineral admixture

Abstract: This article studies the frost resistance of LYTAG concrete and ordinary concrete respectively used the RILEM recommended test method (CIF) about frost resistance of concrete. The results indicate that the single surface's frost resistance of Lytag concrete with mineral admixture is much better than normal density concrete's. And the rank of the single surface's frost resistance at 56 cycles of Lytag concrete with different mineral admixture is: silica fume and slag> silica fume and fly ash>slag and fly ash>silica fume>fly ash>slag. The important reasons why LYTAG concrete has good frost resistance is that the scope of blending interfacial transition zone of LYTAG concrete between aggregate ceramsite and cement stone was significantly smaller than ordinary concrete.

Introduction

The lower density and higher insulating capacity and better durability are the most obvious characteristics of Lytag-based lightweight aggregate concrete (Lytag concrete) by which it distinguishes itself from ordinary normal density concrete [1, 2]. But how the frost resistance of LYTAG concrete is. This article studies the frost resistance of LYTAG concrete and ordinary concrete respectively used the RILEM recommended test method (CIF) about frost resistance of concrete.

There are problems in engineering concrete freeze-thaw damage at the area of cold and hot alternate. In general, freeze-thaw conditions including freezing and thawing medium, freezing and thawing temperature and annual cycles of freezing and thawing [3] . By comparison of domestic and foreign specifications, we can find that it is more concise for foreign environment division. It is divided into non freezing, frost damage but no salt freezing, frost damage and salts contact (deicing salt and seawater) three categories.

CIF is one of the RILEM recommended test methods about frost resistance of concrete[4, 5]. CIF has the following advantages: single side test and cooling rate is closer to the actual cold region climate on concrete spalling. CIF adopts the weight and internal damage at the same time as the evaluation index about frost damage[6, 7]. Its test cycle is short. The test results are with high accuracy, repeatability, reproducibility. But its disadvantages are high cost experimental equipment.

General Situation of Test Area

Raw Material

LYTAG

The test uses Lytag with density grade of 800 produced in Daqing whose main raw material is fly ash. Lytag is a special material which is achieved through fining, balling, sintering at high temperature. Its basic properties and particle size distribution are respectively supported for specification compliance. The index is all accorded with the technical requirements of Lytag whose diameters are between 5 and 16 mm in Lightweight aggregates and its test methods.

Other Raw Materials

P·O 42.5 ordinary portland cement is produced in Harbin cement plant and ordinary medium sand whose fineness modulus is 2.81.The test uses mineral admixtures are as follows, ultra-fine fly ash which is produced in Harbin cement plant, ultra-fine slag which is produced in Anshan Iron and Steel Factory, zeolite powder which is produced in Neijiang, and silica fume which is produced in Elkem Company. And the additives are as follows, Mighter 100 naphthalene superplasticizer produced by Japan Kao whose quantity is 1% of the cement and whose water reducing ratio is 20%, MICRO-AIR202 concrete air-entraining agent produced by Master Builder Technoloy in Shanghai, and the running water in Harbin.

Mix Proportion

In this test, Standard cube specimens of 100mm× 100mm× 100mm is used to determine the cubic compressive strength. And 150mm× 150mm× 55mm is used to determine the frost resistance of concrete. The mix proportion is shown in Table 1. And the material dose (in kg) in Table 1 is in one cubic meter of concrete. The slumps (in mm) and 28d compressive strength (in MPa) represented by σ_{28} is measured value in Table 1. O represents ordinary concrte. A represents 8% silica fume, B represents 20% slag, C represents 20% fly ash, D represents 10% fly ash and 10% slag, E represents 8% silica fume and 12% fly ash, F represents 8% silica fume and 12% slag.

TAB. 1 THE MIX PROPORTION AND COMPRESSIVE STRENGTH OF LYTAG CONCRETE

	cement	slag	Fly ash	Silica fume	water	sand	LYTAG	Slumps	compressive strength
O	530.0	0	0	0	244.0	565	568	175	39.0
A	487.6	0	0	42.4	271.0	565	568	175	42.2
B	424	106.0	0	0	244.0	565	568	165	38.1
C	424	0	106.0	0	244.0	565	568	170	37.8
D	424	53.0	53.0	0	244.0	565	568	165	39.1
E	424	0	63.6	42.4	244.0	565	568	170	39.8
F	424	63.6	0	42.4	244.0	565	568	165	41.2

Experimental Programme

Concrete specimens are treated by pre-saturated processing by the way of capillary suction in 3% NaCl solution in the CIF method. At first, determine the initial quality and dynamic modulus of elasticity. Then, the experiment is conducted in the freeze-thaw cycle test machine with the 3% NaCl solution as the freezing and thawing medium. The 12h freeze-thaw cycle is used in the CIF method. The highest temperature for each freeze-thaw cycle test is 20 degree Centigrade and holding one hour at 20 degree Centigrade. While the lowest temperature for each freeze-thaw cycle test is minus 20 degree Centigrade and holding three hours at minus 20 degree Centigrade. It lasts for four hours from 20 degree Centigrade to minus 20 degree Centigrade, so does the time from minus 20 degree Centigrade to 20 degree Centigrade. Temperature cycle of monitoring will be subject to the temperature of the reference point. Reference point for measuring temperature deviation in the low temperature should not exceed 0.5 degree Centigrade, and 1 degree Centigrade for other degrees. The constant time drift between test containers is acceptable. In the CIF method, it takes advantage of the relative dynamic modulus of elasticity under different times of freeze-thaw changes and the mass loss per unit area to evaluate the salt scaling resistance of concrete.

Conclusions and Prospects

There are three blocks for each mix proportion. Specimens are cured in the standard curing room for 28 days. Then put the blocks into 3% salt solution for six days. Freezing and thawing test is conducted. There are two freezing and thawing cycles every day. Test the coming off amount of concretes and sound respectively after 14, 28, 42 and 56 times, and at the same time watch out the surface of scaling of concretes. Coming off amount of concretes is shown in Fig. 1. Loss percentage of

dynamic elastic modulus is shown in Fig. 2. Surface of scaling of concretes is shown in Fig. 3. As shown in Fig. 1, the least of coming off amount of concretes is F, which is about less than 75% than the most B.

According to Fig. 3, the surface of the crack expanding quickly after 56 cycles of freezing and thawing, and at last it leads to faster damage. With the further damage, the aggregate of concrete is exposed, and the exposed aggregate develop step by step. The formation of porous layer makes the surface uneven. The uneven surface creates a good opportunity for NaCl entering into the internal part of concrete. When concrete is in damp environment, NaCl will dissolve and enter into the internal part of concrete. When concrete is in dry environment, NaCl will recrystallize. Recrystallization pressure is larger than interface bond of aggregate and cement paste. Under the action of wet-dry cycling, the concrete bear freezing and thawing is destroyed step by step.

The same result can be gained in surface of scaling of concretes, coming off amount of concretes and loss percentage of dynamic elastic modulus. The rank of frost resistance of LYTAG concrete with single-doped mineral admixture after 56 cycles is silica fume>fly ash>slag. The rank of frost resistance of LYTAG concrete with multiple-doped mineral admixture after 56 cycles is silica fume and slag> silica fume and fly ash>slag and fly ash. The frost resistance of LYTAG concrete with multiple-doped mineral admixture is much better than that of LYTAG concrete with single-doped mineral admixture.

Fig.3 Surface of Scaling of Concretes

Mechanism Analysis

Lightweight aggregate contains many closed pores, and the pore is not easy to be saturated with water. Frozen concrete, lightweight aggregate within the closed pores can play a buffer role on ice pressure water freezes, thereby reducing the expansion pressure and the internal stress of concrete. Therefore, the lightweight aggregate concrete can be obtained a good frost resistance.

Mineral admixtures have differences in particle size distribution, particle morphology and reactivity. When mineral admixtures are mixed with cement particles, the strength of hardened cement paste could sustainably develop because the reaction of cement particles composition and mineral admixtures is based on a certain hydration speed and sequence. The hydration of cement clinker is the fastest, and the hydration of slag powder comes second. The hydration of fly ash is the slowest in the calcium hydroxide excitation conditions. They can be used together to ensure concrete hydration carrying on in order. That is, cement hydration carries on first, and then the secondary hydration of slag powder followed. Finally, the secondary hydration of fly ash carries on. Cement structure becomes denser and the strength is continuous development along with the ongoing hydration. Such as cement composite functional superposition effect of fly ash and silica fume, effectively regulate the hydration process of cement, cement stone structure is optimized. Therefore, single frost resistance of concrete incorporated with mineral admixtures single freeze-thaw resistance is better than the single doped mineral admixture concrete.

Summary

The single surface's frost resistance of LYTAG concrete with mineral admixture is much better than normal density concrete's. The frost resistance of LYTAG concrete with multiple-doped mineral admixture is much better than that of LYTAG concrete with single-doped mineral admixture. And the rank of the single surface's frost resistance at 56 cycles of Lytag concrete with different mineral admixture is: silica fume and slag> silica fume and fly ash>slag and fly ash>silica fume>fly ash>slag.

Keywords: energy efficient building, material science, net-zero building, recombinant material

Abstract: Nowadays, reducing energy consumption, using clean resources and the aim of creating net-zero building are going to be more and more important. It seems that use of recombinant materials may be a way to reach a more energy efficient architecture. There are considerable advances in development of new material, while the use of these materials is limited in architecture. Regarding to hypothesis of the research, identification of new materials, their performance and their properties, which cause decrease in energy consumption may be helpful for development a more energy efficient architecture. The results of the paper show that architects may incorporate recombinant material to reach energy efficient buildings, however they can play a crucial role in saving natural energy resources through adoption of recombinant materials in architecture and planning

Introduction

The relationship between architecture and materials had been fairly straightforward until the Industrial Revolution. Interaction of building and architecture determined the material choice, and as such, we can consider the pre-19th century use of materials in design to have been subordinate to issues in function and form. The role of materials changed dramatically with the advent industrial revolution. Rather than depending on an intuitive and empirical understanding of material properties and performance, architects began to be confronted with engineered materials. [1] This study is to find material properties, functions and how they reduce energy consumption to recognize when their implementation is appropriate. Renewable energy such as wind energy, and solar source, are known as valuable resources to replace with convention sources, because of the large impact in reducing energy crisis.

Literature Review

Materials play important roles in building stability and construction [2] therefore those are very important in architectural design [3] especially when interaction of tradition and contemporary architecture is needed. [4] Usage of indigenous architectural patterns [5] and modeling traditional achievements [6] are suitable ways to fulfill helpful strategies and tactics [7] for contemporary architecture [8] which roots in traditional architecture of hot and dry climate. [9] Theoretical framework of the paper focuses on challenges regarding old parts of historic cities of developing countries especially Iran. Interaction of energy and materials for sustainability in architecture and planning [8] and focus on social issues [9] is to guarantee comprehensive approach toward environmental sustainability [10] and meet eco-friendly design and planning [11]. Developing countries such as Iran are in need of this comprehensive approach [12, 13] more than other parts of the world. [14, 15] It seems that redevelopment plans in formal documents are more eco-friendly than it is in real perspectives. [16, 17] This article is to present how to reduce the usage of energy

through materials and investigate that recombinant materials are capable of producing desirable behavior to achieve energy efficient architecture. [18, 19] Recent materials can play a crucial role in optimization of energy consumption, and using renewable energy in order to deal with global warming and energy crisis. Hence, utilization of recombinant materials like smart materials and nanostructured materials can help to generate and store energy. Smart material [9, 20] can be categorized in following branches: 1- Immediacy – they respond in real-time. 2- Transiency – they respond to more than one environmental state. 3- Self-actuation – intelligence is internal to rather than external to the material. 4- Selectivity – their response is discrete and predictable. And 5- Directness – the response is local to the 'activating' event.

Discussion

The results of the paper show that [21, 22] there are lots of new adoption of recombinant materials and nanotechnology in contemporary architecture of developed countries as well as developing societies. [23, 24] It is so important to clarify that usage of ultra-fine grains and nano structured materials may result in more energy efficient architecture as adoption process follows proposed method. (Table 1)
