Preface

Nowadays many developed countries are in recession and their consumption of natural resources like energy, minerals and other raw materials is lower than usual. At the same time the global prices of those materials stay at a high level because the BRICS-countries (short for Brazil, Russia, India, China and South Africa) have developed their economy to a higher level. Consequently, their consumption of those materials has been reaching a higher level as well. Considering the total population of the BRICS, their need will be increasing and the prices for raw materials are obviously to remain stable or go up in the future. Prices at such high levels remind us of the fact that the available resources of refinery or processing facilities and the natural reserves of those discovered materials on earth hardly cover the increasing demand.

The reasons to promote the subjects of science are extraordinarily the same as those for Materials Science and Engineering Technology, and we won't to repeat them in the foreword for MSET2014.

When we were collecting the papers for the Conference on Materials Science and Engineering Technology, the interesting things were that a number of authors were quite keen to look for the same chance to make public the theoretical works of intellectual creativity or formal results of scientific research or practice, written by those who are their former class mates, campus fellows, friends, relatives, colleagues and cooperators. It is really a chance for us to organize a chance for our smart intellectuals to expose, exchange and confidently approve each other the value of their arduous work. In six months, we have collected 758 copies of papers in the scope the mentioned subjects and their close-related subjects, and 420 copies selected after peer-view. 232 copies are in the research of materials science while 61 copies of materials properties, measuring methods and applications, 61 copies of methodology of research and analysis and modeling and 66 copies are on the subjects of close –related to materials manufacturing and processing.

Material science is one of the most important matters of our life and with us as ever we have existed, unlike computer or information technology but unfortunately we have never known all materials we have used or around us. Nevertheless, we have been working very hard to discover new sources of materials we are in need of and striving non-stop for new synthetic stuffs or man-made matters. High demand has pushed our scholars, experts and professionals to continue the mission, not only for the materials themselves but non-perilous to the life and environment as well, causing the least hazard to the world. We appreciate our authors consciously to involve into that mission.

Engineering technology appeared in the antient time in human life. All tools we found or created beside we can simply use as part of our body such as our hands and feet, eyes and teeth, are mechanics, but modern mechanical has extended its concept since steam and gasoline engine, electric motor were found. It has spread to all corners of life, without what, we can not survive in contemporary days. Consequently, there are countless subjects for our learned people to work at. As the organizer of the conference MSET2014,we have selected 232 copies of papers in materials science which are comparatively at a high level of each research.

Conference on Materials Science and Engineering Technology is scheduled to hold in Shanghai from June 28 to 29, 2014, experts and scholars, a group of the authors and other related people will attend the conference with apparent interest, we are expecting a full success of the conference.

We appreciate those who responded to our proposal and submitted their papers, especially those whose papers have been selected for the conference MSET2014, the sponsors who have provided their valuable and professional suggestions and instructions and the scholars and professors who have spent their efforts as peer reviewers. We expect the conference to be successful and we hope that our proposal

'China Made jumping to China Create' will result in many more conferences on various other scopes and subjects, nation-wide, encouraging more professionals, scholars and students to contribute their talents to improving our life.

Thank you!

Zhang Mei

Program Committee

General Chair:
Dr. R.K. Kotnala, Editorial Board Member of J. Nanoparticle Research, Indian

Technological Committees

Prof. Xiaokui Yue, Northwestern Polytechnical University, China
Prof. Zhanglian Hong, Zhejiang University, China
Dr. Yinong Wang, Dalian University of Technology, China
Prof. Qudong Wang, Shanghai Jiaotong University, China
Dr. Jianguo Lv, Zhejiang University, China
Prof. Jian Weng, Xiamen University, China
Dr. Honggang Dong, Dalian University of Technology, China
Dr. Di Zhang, Shanghai Jiaotong University, China
Dr. Xuegong Yu, Zhejiang University, China
Dr. Pingwu Du, University of Science and Technology of China, China
Dr. WeiFeng Liu, China University of Petroleum, China
Dr. Yi Cao, School of Electrical Engineering, Henan University of Technology, China
Dr. Zhijun Zhang, School of Mechanical Engineering and Automation northeastern University, China
Prof. Yongsheng Zhao, Yanshan University, China
Prof. Fuzhen Xuan, East China University of Science and Technology, China
Prof. Fushuan Wen, South China University of Technology, China
Prof. Zhaojun Yang, Jilin University, China
Prof. Lizhong Xu, Yanshan University, China
Prof. Xuemin Tian, China University of Petroleum, China
Prof. Haisheng Yu, Qingdao University, China
Prof. Yibin Song, Yantai University, China
Prof. Yong Zhang, Jinan University, China
Prof. Yuqiang Wu, Qufu Normal University, China
Prof. Yumei Wang, Weifang University, China
Prof. Yanbin Qu, Harbin Institute of Technology, China
Prof. Xiaohua Liu, Ludong University, China
Li Guo, College of Mechanical and Vehicle Engineering, Hunan University, China
Prof. Mei Su, Central South University, China
Dr. Mahmoud Ibrahim Mahmoud Moussa, Benha University, Egypt

Table of Contents

Preface and Program Committee

Chapter 1: Polymers and Composites

Mechanical and Thermal Properties of Siloxane Reinforced Biphenyldiol Formaldehyde Resin Curing Epoxy Resin Composites
S.H. Chen, J.G. Gao, H.Z. Han and C. Wang 3

Polymer Blend through Inclusion Complexation
C.Y. Liu, W.I. Lin and J.B. Wang 8

Fabrication and Properties of Composites of Linear Polyacrylamide and Functionalized Carbon Nanotubes
R.M. Yang, Y.H. Liu, G.X. Dong and D.J. Zhao 12

Thermal Degradation Behavior of Polypropylene and Ethylene Vinyl Acetate Copolymer Treated with Intumescent Flame Retardants Containing Caged Bicyclic Phosphates
X. Li and Y.X. Ou 17

Effect of Pr Modification Treatment on the Microstructure and Mechanical Properties of Cast Al-Mg_2Si Metal Matrix Composite
S. Yi 23

Curing Kinetics of Silicone Epoxy Resin Containing Fluorene
W.X. Deng, Y.W. Zhong, J. Qin, X.B. Huang and J.W. Peng 28

Synthesis of Core @ Shell Composite Particles with a Tunable Shell Containing Natural Urushiol
L.H. Zheng, B.L. Chen, H.B. Huang, Q.H. Chen and J.H. Lin 34

Preparation and Properties of Polypropylene-Graft-Cardanol by Reactive Extrusion
Q.H. Chen and J.H. Lin 39

Analysis and Experiment of Compressive Residual Strength of Composite Laminates with Holes
X.H. Kong and Z.J. Wang 43

Microstructures of Poly (9'9-Dihexylfluorene) Grown in the Non-Solvent Vapor
X.Q. Xiao, W.B. Bai and J.H. Lin 53

Synthesis and Properties of Polypropylene Carbonate Polyol-Based Waterborne Polyurethane
C.S. Xu, C.C. Tian, W.D. Zhang, J.W. Xing, Z.S. Cai, Y. Ren, W.Z. Xu and H.Y. Liu 58

Curing Process of Epoxy Resin Using Low Molecular Polyamide 651 as Curing Agent
C.H. Han, L. Wang and D.Y. Zhao 63

Synthesis of Bis(*p*-aminophenoxy)Dimethylsilane(*p*-APDS) and its Process Optimization
L.X. Chen, F. Yang and J. Yun 67

Structure and Mechanical Properties of Starch/Styrene-Butadiene Latex Composites
G. Chen, Z.J. Zhu, P. Salminen and M. Toivakka 74

Experimental Advances in Effect of Waviness on Properties of Fibre Reinforced Composite Materials
J. Zhu and J.H. Wang 82

Effect of Crosslinker Type on the Properties of Surface-Crosslinked Poly(sodium acrylate) Superabsorbents
Y. Xiong, X. Zhang and M.Z. Liu 89

Phase Separation in Thermosetting Blends of Epoxy Resin with PS-*b*-PCL and PI-Si Block Copolymers
J.D. Ding, W.Z. Li, T.Q. Jiang, Z.L. Xia and W.J. Gan 95

Chapter 2: Ceramics and Functional Materials

Effect of PZN Addition on Piezoelectric and Ferroelectric Properties of Pb ($Zr_{1/2}Ti_{1/2}$)O_3 Ceramics
T. Promjun, S. Sukprasong, L. Chumprasert and A. Ngamjarurojana 101

Effect of External Magnetic Field on Dielectric Spectroscopy of Modified PZT Ceramics
A. Ngamjarurojana, T. Promjun and A. Limpichaipanit 105

Optical Interferometric Technique for Induced Strain Ferroelectric Loop Study at Low Frequency
S. Somwan, K. Chirapatpimol, A. Limpichaipanit, K. Chokethawai and A. Ngamjarurojana 110

Effect of Dielectric Properties and Elastic Strain Behavior on x/65/35 PLZT Ceramics in Lanthanum (x) Ions Contents
L. Chumprasert, P. Larwongsa, A. Limpichaipanit and A. Ngamjarurojana 115

Dielectric and Ferroelectric Behavior in 8/40/60 PLZT Ceramics
L. Chumprasert, K. Chirapatpimol, A. Limpichaipanit, K. Chokethawai and A. Ngamjarurojana 119

Preparation and Optoelectronic Properties of In_2O_3 Microtubes
S. Chen, Y.Z. Long, H.D. Zhang, S.L. Liu, L.Z. Liu, J.C. Zhang, G.X. Liu and F.K. Shan 123

The Anti-Plane Shear Problem of Two Symmetric Cracks Originating from an Elliptical Hole in 1D Hexagonal Piezoelectric QCs
J. Yang and X. Li 127

CdS-Bentonite Sulfide Ion Sensor: pH Effect and Selectivity
K. Udomphan, A. Wongchaisuwat and L. Meesuk 136

Relationship between Annealing and Shape Memory Effect of Shape Memory Polyurethane
J. Ying, M. Nishikawa and M. Hojo 140

Preparation of Uniform α-Alumina Microspheres by Catalytic Precipitation and Calcination Process
Z. Wang, X.Q. Shen, M.X. Jing, L. Yan and Z. Luo 145

Phase Structure and Piezoelectric Properties of $(K_{0.5}Nb_{0.5})NbO_3$ - $CaZrO_3$ Ceramics
P.C. Myoung 149

A Novel Model for Predicting the Thermal Conductivity of Fiber Reinforced Ceramic Materials
R. Xu, J.K. Mao, J.Y. Zhang, D.C. Lou and W. Guo 154

Nucleation, Crystallization and Characterization of Mica-Based Glass-Ceramics with Fluorapatite
J. Bai and D. Chayasuwan 164

Preparation of C@$ZrSiO_4$ Inclusion Pigment Using Compound Colorants via Non-Hydrolytic Sol-Gel Method
X.Y. Xu, W.H. Jiang, T. Chen, J.M. Liu, L.F. Miao and X.J. Zhang 170

Fabrication and Characterization of SiC-Coated Multi-Walled Carbon Nanotubes Reinforced Reaction Bonded SiC Composite
N. Song, H. Liu, Y.T. Yuan and J.Z. Fang 176

Carbonization Effect on Phase Structures of Zirconium Oxides with 2-3 Percent Yttrium
Z.Q. Xue and Y.Q. Guo 181

Numerical Research of the Beryllia Ceramics Formation Process
U.K. Zhapbasbayev, G.I. Ramazanova and Z.K. Sattinova 187

Chapter 3: Films and Membranes

Cu(In,Ga)Se_2 Films Deposited by Sputtering with Single Cu(In,Ga)Se_2 and Cu-Ga-In_2Se_3 Targets and a Subsequent Selenization Procedure
D.H. Kuo, Y.C. Tu and W.L. Chen 197

Effect of Hydrogen Dilution Ratio and Substrate Roughness on the Microstructure of Intrinsic Microcrystalline Silicon Thin Films
B.J. Yan, S.L. Liu, X.W. Liu and T.T. Jiang 202

The Photoluminescence from (Eu, Yb) Co-Doped Silicon-Rich Si Oxides
C.L. Heng, W.Y. Su, Q.W. Zhang, X.Q. Ren, P.G. Yin, H.P. Pan, S.D. Yao and T.G. Finstad 207

Compatibility of Polyvinylidene Difluorid/Polyurethane and Preparation of Composite Tubular Membrane
D.Y. Zuo, H.J. Li, C.H. Yi and H.L. Gan 212

Preparation and Properties of Two-Dimensional Braid Heterogeneous-Reinforced Polyvinylidene Fluoride Hollow Fiber Membrane
Q. Quan, C.F. Xiao, H.L. Liu, W. Zhao, X.Y. Hu and G.L. Huan 218

Effect of Ethanol Composition in Water Coagulation Bath on Structure and Performance of Homogeneous-Reinforced Polyvinyl Chloride Hollow Fiber Membranes
H.L. Liu, C.F. Xiao, Q.L. Huang, Z.L. Fan, X.Y. Hu, W. Shu and G.L. Huan 226

Fabrication and Characterization of CuO Micro-Dimensional Structures for Superhydrophobic Surface
Y.H. Fan, Z.J. Chen, L.Y. Deng and H. Chen 233

Low Temperature Preparation of Aluminum Titanate Film via Sol-Gel Method
Y. Bao, W.H. Jiang, G. Feng, J.M. Liu and Q. Wu 238

Multilayer Film through Inclusion Complexation
C.Y. Liu and W.I. Lin 243

Preparation and Characterization of Bipolar Membranes Modified by Adding Multi-Carboxylic Metallophthalocyanine Derivatives into the Cation Layer
M. Lu, Y.Y. Hu and R.Y. Chen 248

Highly Strained Silicon Nitride Thin Film Deposited by PECVD with Double Frequencies in Strained Silicon Technologies
B. Shu, J.M. Chen, H.M. Zhang, F. Zhu, P.L. Quan, J.Y. Gu, R.X. Xuan, H.Y. Hu and J.J. Song 255

Layer Formation of SAPO-34 Zeotype Material by EPD Seeding Method Followed by Hydrothermal Secondary Growth
S.M.H. Davarani, S. Fatemi and Z. Jabbari 259

Substrate Dependence of Microcrystalline Silicon Growth with SiH_4 Diluted by Ar
H. Cheng, Y.C. Qian and J. Xue 264

Study on the Polarization Reversal Characteristics of a Ferroelectric Thin Film with Surface Transition Layers
L. Cui, Z.Y. Qiu, Z.Y. Han, R.Y. Li and J.X. Che 269

Fabrication of Diamond Films on Cu Metal Substrates with Buffers (SiC or $MoSi_2$) by Hot Filament Chemical Vapor Deposition
Q. Zhao, M.J. Dai, D. Tan, C.B. Wei, W.Q. Qiu and H.J. Hou 276

Epitaxial Pd-Doped $LaFeO_3$ Films Grown on (100) $SrTiO_3$ by Pulsed Laser Deposition
Y.W. Duan 282

The Preparation of the Highly Preferred Orientation of Wurtzite Structure Zinc Oxide Films
L.L. Lan, D. Zhou, G.R. Gu, B.J. Wu and L.H. Tian 287

Chapter 4: Nanomaterials and Applied Nanotechnologies

A Facile Method to Preparation of Amphiphilic Perylene Tetracarboxylic Diimide/ZnS Hybrid Nanocomposites and Improved Semiconducting Property
J.G. Song, H.Y. Wang, N.S. An and Y.L. Chen 295

Pt-TiO_2 Nanocomposites in Alginate for Enhancing Photocatalytic Activity
Y.R. Wang 300

Preparation of Carboxymethyl Chitosan Magnetic Nanoparticles and Separation of Chinese Medicines Components
Y.H. Xie, Y.T. Zhang, X.Z. Huang, Y.H. Ding and L.P. Huang 304

Comparison of Hydrogen Sulfide Sensing Properties between Multiple-Walled Carbon Nanotubes (MWNTs) and MWNTs-$HAuCl_4$ Materials
S.X. He, G.Z. Xie, Y.D. Jiang, G.D. Zhang and Y. Zhou 310

Effect of Cu,Cr Co-Doped on Structure and Magnetic Properties of Sm_2Co_{17} Alloy Films
C. Wang, Q.Q. Fang, D.D. Wang, J.J. Yang and J.G. Li 315

Hyaluronic Acid Functionalized Porous Silica Nanoparticles for Drug Delivery and Release
L.Y. Cui, Y.H. Li, W. Zhang, J.P. Zhang and Q. Duan 322

Preparation and Characterization of Fibrillated Nanofibrous Filter Material
T. Yu, Y.B. Jiang and J. Hu 327

The Improvement of Pd Nanoclusters Electro-Catalytic Properties for FAO by the Addition of Co Element
M. Lei, L.S. Wang, X.L. Liu, J.B. Wang, R. Xu, C.X. Lei, G.H. Yue, Y. Chen and D.L. Peng 332

Synthesis and Characterization of Emulsion Coating of Fluorinated Polymethacrylate Modified by POSS
B.J. Tian, J.G. Gao and C. Wang 337

The Performance of Gold Nanoparticles Supported on Mesoporous Zirconia for the Synthesis of Azoxybenzene
M.L. Jia, M.J. Feng, X. Li and Z.R.G.T. Bao 343

The Facile Hydrothermal Preparation of WO_3 and its Photocatalytic Performance under Visible-Light Irradiation
F.F. Li, H.T. Gao and G.J. Liu 347

Hydrothermal Synthesis and Characterization of Cerium-Based Oxides
R. Dangerfield, S. Sharp and R.G. Wang 352

Controlled Synthesis of Core-Shell Structure SiO_2 /$NaGdF_4$:Eu^{3+} Magnetic and Optical Bifunctional Composite
Y.L. Wu, M. Liao, H.X. Ding, R.C. Yang, D.D. Xiong and Q. Xiao 359

Electrochemical Properties of Graphene Nanosheet/Polyaniline Nanocomposite as Electrode for Supercapacitors
R.R. Yao, N.N. Yao, D.L. Zhao and L. Xu 364

Graphene/Sulfur Nanocomposite for High Performance Lithium-Sulfur Batteries
S.W. Ma, D.L. Zhao, N.N. Yao and L. Xu 369

Preparation and Characterization of Magnesium Oxide Aerogels
J.W. Wu, L.F. Yao, J. Shen, G.Q. Zu and F. Wang 374

Enhanced Field Emission Characteristics of ZnS Dentalation Nanostructures
J.J. Qi, Z.Q. Deng, Z. Wu and Y. Zhang 379

Enhancement of Titania Photocatalytic Properties by Fabrication of MWCNT-TiO_2 Nanocomposites
E. Soroodan Miandoab and S. Fatemi 384

Study on Tensile and Impact Performance for the MWCNTs/EP Composite
F. Yan, J.W. Fu and D.Y. Zhao 390

The Natural Rubber/Zinc Oxide Nanocomposites: Its Morphology, Mechanical and Thermal Decomposing Properties
M.Z. Lv, L. Fang, P.W. Li and C.L. Yang 394

Effect of Grain Size on the Fracture Toughness of Bimodal Nanocrystalline Materials
Y.G. Liu, X.D. Mi and S.F. Tian 400

Numerical Simulation of Synthetic Heat Transfer in Laminar Nanofluid in a Horizontal Pipe
M. Mirzaei, M.J. Gishin and M. Abbaspour 409

Particle Swarm Optimization Technique for DNA Sensor Model Based Nanostructured Graphene
V. Popov 415

Preparation of Ethanol-Sensing Gas Sensor Based on PECH/Multi-Wall Carbon Nanotubes Sensitive Films
W. Yao, G.Z. Xie, H.L. Tai, Y.D. Jiang and Y. Zhou 419

Preparation and Characterization of Polyacetylene/Expanded Graphite Composites
M.M. Hu, L.H. Song and B.L. Tao 424

Preparation and Mechanics Properties of the EP/SiO_2 Nanocomposites
W.F. Zeng, Y. Jiang, S.F. Bu, Y.H. Ding and J.R. Yin 429

Effects on Characteristics of the SiO_2-to-Na_2O Ratio on Nano-SiO_2 Metakaolin-Based Geopolymers
K.L. Lin, K. Gao, D.Y. Wang, K.W. Luo, W.H. Chang, D.Y. Huang, H. Cheng and R. Cui 434

Microstructures of ZnO Electrospun Nanofibers on AZO Glass
X.Z. Lu, Y.Y. Chang, M.T. Xu and B. Peng 439

Chapter 5: Materials for Energy Sources and Energy Supply

Research of Properties on Li-Ion Batteries Based on a Polypyrrole Derivative Bearing TEMPO as a Cathode Material
L.H. Xu, F. Yang, C. Su and C. Zhang 447

Nanostructured Morphology of Spinel $LiMn_2O_4$ Oxide under Microwave Heating
D. Huo 452

Effect of SnO_2 Particle Size on Properties of Ag-SnO_2 Electrical Contact Materials Prepared by the Reductive Precipitation Method
Z.J. Lin, X.D. Sun, S.H. Liu, J.L. Chen, M. Xie, J.G. Li, X.D. Li, D. Huo, M. Zhang and Q. Zhu 459

Electrochemical Investigation of $La_{0.2}Sr_{0.8}TiO_{3+\delta}$-$Ce_{0.8}Sm_{0.2}O_{2-\delta}$ Composite Cathode for the Direct High Temperature Steam Electrolysis
G.J. Wu, K. Xie and Y.C. Wu 464

Highly Hydroxylated Graphite Felts Used as Electrodes for a Vanadium Redox Flow Battery
W.W. Li, Y.Q. Chu and C.A. Ma 471

A Novel Route to Prepare Titanium Doped Mesoporous Carbon
H. Tian, Y. Zhang and Y.J. Liu 476

Enhanced Electrochemical Performances of $LiFePO_4$/C Cathode Materials by Deposited with Ge Film
Y.D. Huang, Y.B. Lin and Z.G. Huang 480

Study on Ag/SnO_2/TiO_2 Electrical Contact Materials Prepared by Liquid Phase *In Situ* Chemical Route
Y.C. Zhu, J.Q. Wang, L.Q. An and H.T. Wang 486

A Novel Synthesis of Nanometer Spherical β-$Ni(OH)_2$ Cathode Materials with High Electrochemical Performances
L. Chen, Y.M. Wang, J. Liu and X.Y. Wang 491

A High Rate, High Capacity and Long Life ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ Hybrid Battery-Supercapacitor
X.B. Hu, Z.J. Lin and Y.L. Zhang 496

Chapter 6: Chemical Physics

Modeling of Recrystallization Texture of Rolled Polycrystalline Aluminium
K. Wierzbanowski, M. Kotra, M. Wroński and K. Sztwiertnia 505

Numerical Analysis on Decay Heat Power of Weapon-Grade Uranium and Depleted Uranium
Y.L. Wang, W.L. Yu, T. Wang and S.Q. Dong 509

Hydrogen Storage Mechanism of Fe_3O_4: A First-Principles Study
H. Zhang, N.P. Cheng, Z.Q. Chen and Q. Hui 515

Phase Field Crystal Study for the Effect of Heating Rate on the Premelting of Grain Boundary
Y.L. Lu, T.T. Hu and H. Mu 523

A First-Principles Study on Electronic Properties of Ce/N Codoped Anatase TiO_2
S.Y. Yang, L.F. Yao and H. Chen 529

Effective Nuclear Field Measurement in a Single Quantum Well via Time-Resolved Kerr Rotation Technique
L.P. Yan, R. Kaji and S. Adachi 534

Theoretical Investigation on Rearrangement Mechanism of Fluoroalkylsilane
Y.F. Zhou and Q.Y. Ma 540

Assessments of Impurity Diffusion Coefficients of Selected Pure Metals in Fcc Fe
X.X. Hu, X.G. Lu and Y.L. He 545

The Properties of a Novel Green Long Afterglow Phosphor Zn_2GeO_4:$Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$
M.H. Wan, Y.H. Wang, X.S. Wang, H. Zhao, Z.F. Hu and C. Wang 552

Dy^{3+} Doping Blue-Green $Sr_4Al_{14}O_{25}$:Eu^{2+} Phosphor for Enhancing Luminescent Properties and the Mechanism Study
Z. Kong, H.B. Wang, E.P. Zhang, T. Qiu, J. Zhang and Z.G. Ji 562

Magnetic and Electrical Property in Mg^{2+} Deficient $La_{1.4}Sr_{1.6}Mn_2O_7$ Perovskite
Y. Zong, X. Zhao and W. Chen 571

The Ideal "Defects" of the Crystal Structure of GaAs
K. Iskakova, R. Akhmaltdinov and A. Amaonova 577

Cooperative Energy Transfer of Er-Gd-Tb System in Tb^{3+}, Er^{3+} Co-Doped $K_2GdZr(PO_4)_3$ as a Potential Visible Quantum Cutting Phosphor
L.F. Niu, W. Liang, C.Z. Wu and Y.H. Wang 585

First-Principles Investigations of Electronic, Dynamic and Thermodynamic Properties of α-MnO_2
A.M. Hao and N.Q. Wang 591

Chapter 7: Materials and Technologies in Microelectronics

Ultra-Multilevel-Storage Phase Change Memory
Y. Yin and S. Hosaka 599

Surface Passivation of Crystalline Silicon by a-Si:H Thin Films
Y. Wang, W. Li, A.R. Guo, F. Yu, J. He and Y.D. Jiang 603

Microwave-Assisted Synthesis of Graphene Oxide-MnO_2 Composites for Supercapacitors
Y.W. Duan, X. Sun, H.Y. Zhao and Z.B. Liu 607

Te Inclusions in CdMnTe Crystal Grown by the Traveling Heater Method and their Effects on the Electrical Properties
P. Shen, J.J. Zhang, L.J. Wang, J.H. Min, J. Huang, X.Y. Liang, K. Tang, M. Shen, L. Wang and Y.B. Xia 613

The Effect of the Cu Source on Optical Properties of Cu-Doped ZnO Films
L.C. Chen, X.Y. Zhang and K.L. Lee 618

The Model of Nano-Scale Cu-Particle Removal in CO_2-Based Micelle Solutions with Different Surfactants
Y.R. Wang 624

Failure Analysis of the Solder Joints in Flip-Chip BGA Packages under Free-Drop Test
G.Z. Yuan, X. Chen and X.F. Shu 628

The Advantages of Ga-Graded Obtained by Growth Profile Modification and Na Incorporation on Cu(In,Ga)Se_2 Solar Cells
R. Sakdanuphab, S. Chatraphorn and K. Yoodee 633

Near-Field Broadband Light Transparency via Tunneling and Cavity Effects
X.N. Zhang, G.Q. Liu, Z.Q. Liu and Y.H. Chen 639

Modification of Epoxy Resin with Silicone for Electronic Encapsulation Application
L.X. Chen, L.Y. Fan and L.S. Gao 643

Effect of Annealing Oxygen Flow Rate on the Properties of Vanadium Oxide Films Deposited by Reactive Magnetron Sputtering
H.F. Zhang, Z.M. Wu, X.F. Wu and Y.D. Jiang 651

TEM Study of AlGaN/GaN on Hexagonal SiC Substrates
A. Gkanatsiou, C.B. Lioutas, N. Frangis, N. Chandraraj, E.K. Polychroniadis, P. Prystawko and M. Leszczynski 656

Chapter 8: Biomaterials, Biotechnologies and Pharmaceutics

Protein Adsorption on Titanium Surface Functionalized with Bioactive Gelatin Methacrylate Hydrogel Coating
G.X. Tan, Y. Tan, C.Y. Ning, L. Zhang, L. Zhou and H. Wang 663

Extraction and Antifungal Activity of a Lipopeptide Biosurfactant
F.R. Fang, S. Zhong, Y. Dong and L.J. Gong 669

Immobilized Recombinant Chitinase and its Inhibition Effect on Botrytis Cinerea
N. Zhang, R.X. Yan and W.Q. Guan 674

Electrospinning Synthesis of PLA Fiber Film Containing Antimicrobial Silver Nanorods
J.Q. Bai, Y.H. Li, Q. Duan and J.J. Chang 681

Characterization of Three Calcium Phosphate Microporous Granulated Bioceramics
N.H.A. Camargo, P.F. Franczak, E. Gemelli, B.D. da Costa and A.N. de Moraes 687

Characterization of Different Nanostructured Bone Substitute Biomaterials
N. Levandowski, N.H.A. Camargo, D.F. Silva, G.M.L. Dalmônico and P.F. Franczak 695

Sintering and Characterization of Calcium Phosphate Biomaterials Elaborated from Fossilized Calcareous Shell
D.F. Silva, N.H.A. Camargo, N. Levandowski, P.F. Franczak and M.S. Schneider 701

The Content of Physiologically Active Substances in Several Medicinal Mushrooms with Various Doses of γ-Irradiation
S.J. Huang, Y.L. Liu, J.L. Mau and S.Y. Tsai 707

Synthesis and Characterization of Three Hydrated Calcium Phosphates Used as Biocement Precursors
P.F. Franczak, N.H.A. Camargo, N. Levandowski and D.F. da Silva 712

Preparation and Release Profiles of a Solid Oleoylchitosan Coated Poly(lactic-co-glycolic acid) Nanoparticles
Y.Y. Li and F.S. Liu 717

Polymer-Tethered pH-Sensitive Magnetic Nanoparticles for Targeted Delivery of Anti-Cancer Drug
Y.Q. Shen, M.L. Pu and W. Jiang 723

Preparation and Anti-Tumor Activity of Polysaccharides from *Phellinus pini* Mycelia
A.J. Liu, H.C. Sun, Y. Chen, W.H. Wang, C.H. Liu and Y.M. Wang 728

A Facile Method to Synthesize Responsive Magnetic Polymer Composite Nanoparticles with Multifunctional Groups
M.L. Pu, W. Jiang and Y.Q. Shen 734

The Effects of Immobilization Conditions and Materials on the Desulfurization Performance of Immobilized UP-3
N. Guo, Y.F. Hou, Y.Y. Gu and C.H. Li 740

The Release Characteristics of Different Model Drugs from Medicated PLGA Microspheres
T. Chen, Y.Y. Liang, Y.G. Zhao, X.Y. Zhang, T.S. Qi and Q. Shang 746

Synthesis and Performance of pH-Sensitive Hydrogel Microspheres and *In Vitro* Evaluation as Potential Drug Carriers
Y.Y. Liang, T. Chen, Y.Q. Cui, R.Q. Tian, T.S. Qi and Q. Shang 751

Study on Structure Analysis and Cell Toxicity of Okra Polysaccharide
L.J. Min 757

Resveratrol Loaded Self-Microemulsifying Drug Delivery System (SMEDDS): Development and Optimization
G.Q. Liu, H.F. Zhou, J. Zhang, Z.M. Yan, M.X. Duan, Y.F. Long and Q. Xia 763

Stress Analysis of the Hip Joint Endoprosthesis Ceramic Head for Different Values of Shape Deviations
V. Fuis and P. Janicek 770

Synthesis and Characterization of Amphiphilic Copolymer Poly[2-(dimethylamino)ethyl methacrylate-co-methyl methacrylate]
F.P. Wang, T. Yuan, W.X. Li, J.Y. Zhang and Q.Z. Wang 776

Assessment Antibacterial Activities on Essential Oil of Plant Extract
C.C. Shiao, C.M. Ma, B.Y. Chen and H.W. Chen 780

Preparation, Characterization of Cellulose Fibers Grafting by β-Cyclodextrin and their Application for Antibacterial Products
C. Dong, Y. Ye, L.Y. Qian, B.H. He and H.N. Xiao 784

Detoxification Capabilities of Adsorbents for Artificial Liver Support Devices: A Comparison
W.P. Ding, L.L. Zou, Y.Y. Pei, S.J. Sun and D.Y. Gao 789

Prediction of the Tertiary Structure and the Dimerization Interface of FNR Protein in *Klebsiella pneumoniae*
Q.R. Zhang and X. Li 795

Potassium Dichromate Surface Modification of Poly-Lactic Acid (PLA) and Poly-Lactide-Co-Glycolide (PGLA) Fibers
B.Q. Wang, P.H. Zhang and M.H. Fang 801

Chapter 9: Materials and Technologies in Environmental Engineering

Preparation and Photocatalytic Performance Study of La-WO_3 Co-Doping TiO_2
X.Z. Diao and D. Zhou 809

Preparation and Photocatalytic Performances of F-Doped TiO_2
X.Z. Diao and X.L. Zhang 814

Preparation of Doped TiO_2 Responded to Visible Light
Y.H. Zhou, X.H. Wang, J. Chen and R. Pu 819

Development and Comparative Analysis of Aluminosilicate Based Ceramic Filters for Ground Water Defluoridation
J.K. Efavi, A. Yaya, S. Adeborna and J. Fobil 822

Adsorption of Ni (II) from Aqueous Solution Based on Porous Magnetic/Chitosan Resin
H. Song, X.H. Yu, X.Q. Zhang, G.F. Yan and Y.Z. Zhen 829

Highly Efficient Adsorption of Eriochrome Black T in Wastewater on Mesoporous Alumina Sphere
H. Liu, N. Tian, Y.Y. Tian, C. Dai and Y.X. Wang 834

Construction and Application of Molecularly Imprinted Film Sensor on Determination of Chlorpyrifos in Water
G.F. Lin, Y.H. Wang, G.C. Li, W. Bai, H. Zhang and S.C. Wang 843

An Investigation of some Factors Affecting the Dispersant NNO Adsorption on Imidacloprid Particle
H. Hao, J.G. Feng, X.Y. Guo, W.J. Liu and X.M. Wu 850

Adsorption Studies of Methacrylic Acid-Styrene-Acrylic Polyethers Copolymer on Imidacloprid Particles
H. Hao, J.G. Feng, T.F. Fan, W.J. Liu and X.M. Wu 854

Adsorption Characteristics of Methacrylic Acid-Styrene Copolymer onto Azoxystrobin Particles Surfaces
H. Hao, J.G. Feng, W.T. Chen, W.J. Liu and X.M. Wu 859

Preparation of 5-Sulfosalicylic Acid Modified Silica Gel and its Adsorption Performances for Lead
X.Z. Wu, J. Meng, F.P. Li and L.L. Luo 864

Preparation and Characterization of Mesoporous Activated Carbon from Alligator Weed with H_3PO_4
H.M. Xu, G.F. He, M.T. Shi, J. Tu, W. Liu and W.N. Xiang 868

Silica Gel as an Adsorbent in the Removal of Cationic Blue X-Bl from Aqueous Solutions and its Regeneration by UV-Fenton Oxidation
Q.Y. Xiong 875

Optimization and Evaluation of Preparation Process of Activated Carbon Loaded ZrO_2 Catalyst for Oxidative Desulfurization
C. Yang, Y.F. Hou, M. Liu, N. Guo and J.H. Zhang 881

Research on the Quicklime Treatment Dewatered Sludge Technology and Mechanical
J.L. Chen, Z. Deng, R.L. Zhang, P.L. Zhu and W.W. Ding 887

Simultaneous Reduction and Immobilization of $Cr_2O_7^{2-}$ in Metakaolinite-Based Geopolymer Complexed Reductant
J.Y. Chen, X.R. Lei and S. Tao 892

Chapter 10: Materials and Technologies of Chemical Industry

Construction of a Novel 3D Indium Phosphate–Phosphite with Extra-Large 16-MRs Channels: Synthesis, Structure and Fluorescence Property
H.D. Li 901

The Effect of Polyvinyl Pyrrolidone and Nickel Acetylacetonate on the Fabrication of Polyacrylonitrile Precursor Fiber
Z.H. Wang, H.Q. Rong, A.Y. Xu, H.M. Lin and S.H. Zhao 905

Morphology and Conductivity of Self-Assembled Pyrene-Perylenetetracarboxylic Diimide Dyad
Y. Shi and X.Y. Li 911

Synthesis, Structure and Characterization of a Novel 3D Zinc Organophosphonate
H.D. Li 915

Hydrothermal Synthesis and Characterization of Hexagonal $Mg(OH)_2$ Flame Retardant with Bischofite and NH_3
X.X. Song, L.J. Li and Z.Q. Liu 919

Effect of Solvent Properties on the Swelling Assisted with Protrusion of PS@TiO_2
B.L. Chen, L.H. Zheng, J.H. He, Q.H. Chen and J.H. Lin 929

Non-Isothermal Crystallization Kinetics of Semi-Aromatic Polyamide and the Preparation of its Fiber
Y.J. Chen, P.T. Wu, H.J. Xu, D. Wang, Y.M. Wang and Y.P. Wang 933

Recycled Paper Cellulose Aerogel Synthesis and Water Absorption Properties
J.D. Feng, S.T. Nguyen and H.M. Duong 938

Preparation of P(GMA-co-EGDMA) Monolithic Columns with Adjustable Porous Properties
H.T. Zhang, Q.Y. Zhang, B.L. Zhang and C.M. Li 942

The Synthesis and Electro-Optical Properties of Perylene Dicarboximide Dimer with Electron Withdrawing Groups
H.M. Wei, N. Zhao, N. Jiang, W.F. Duan and B.X. Gao 950

Effect of Aniline Oligomer on the Electrosynthesis of Polyaniline Fibres
B.S. Li, L. Zhang, W.W. Zhang and Y. Yu 955

Preparation and Properties of Electroactive PANI by Electrodeposition
B.S. Li, Y. Yu, W.W. Zhang and L. Zhang 960

Electrocatalytic Hydrogenation of Oxalic Acid to Glyoxylic Acid on a Self-Organized TiO_2 Nanotube Electrode
Y. Qian, F.M. Zhao, Q.Q. Qiu and C.A. Ma 965

Preparation of Zircon Whiskers via Non-Hydrolytic Sol-Gel Process Combined with Molten Salt Method
H.D. Wang, W.H. Jiang, G. Feng, J.M. Liu, Q. Wu and L.F. Miao 970

Low Temperature Preparation of Mullite Whisker via Non-Hydrolytic Sol-Gel Process Combined with Molten Salt Method
K.L. Fu, W.H. Jiang, G. Feng, J.M. Liu, Q. Wu, L.F. Miao, T. Chen, Q. Zhang, H.D. Wang and J.R. Zha 975

Co-Ni Bimetallic Catalysts Coated on Cordierite Monoliths for Hydrazine Decomposition
S.G. Pakdehi, M. Salimi and M. Rasoolzadeh 981

Low-Cost Synthesis and Morphology Control of Magnesium Oxysulfate Hydrate Whiskers
C.H. Gao, L. Ding, Y.M. Wu, C.X. Wang and J. Xu 986

The Preparation of Starch Sodium Octenyl Succinate and its Application as Surface Sizing Agent
C.W. Tang, Z.L. Liu, Y.F. Cao, F.Z. Tan and Y. Li 992

Structure and Property Development of Polyacrylonitrile Fiber with Ionic Liquid as Solvent during Spinning Process
H.M. Cheng, E.J. Zhang, X.M. Yin, Y.M. Zhang and H.P. Wang 997

Plasticization of Cellulose Diacetate by Ionic Liquid
N. Liu, J.W. Zhang and H.P. Wang 1002

Studies of Vapor-Liquid Equilibrium of Meta-Xylylenediamine-Aniline System
X.H. Wang 1007

Experimental Studies of Catalytic Hydrogenation of Isophthalonitrile for Meta-Xylenediamine Preparation
Y.G. Li 1012

Orthogonal Investigation of Influencing Factors on the Modification of Montmorillonite by THPC in Acid Conditions
P. Chen and J.C. Wang 1017

Chapter 11: Corrosion and Surface of Materials, Technologies of Coatings

The Effects of PTFE Content on Microstructures and Properties of Composite Brushing Plating Coating
Y. Wang, X.F. Cui, G. Jin, H.P. Li, W. Zheng and X.M. Zhang 1025

Novel Infrared Stealth Properties of Cotton Fabric with ZnO: (Al, In) Coating
X.L. Yu, L.P. Zhang, Y. Zhong, H. Xu and Z.P. Mao 1031

Research on Influencing Factors of Adiabatic Coating Performance
G.Y. Cao, H.J. Guo, L. Li, Y.Q. Li and J. Peng 1035

One-Step Processing to Fabricate Highly Transparent Superhydrophobic Surface via Granuliform Silica Aerogels
B. Xu, J.J. Ge and Z.S. Cai 1042

Deep Cryogenic Treatment and CrN Coating Effects on Micro-Scale Abrasion of Aluminum Alloy AA 6101-T4
E.S. Ashiuchi, V.F. Steier, C.R.M. Silva, T.D. Barbosa, T.F.O. Melo and J.A. Araújo 1047

Wear Resistance of Ti-40Zr Alloy with TiN and ZrN Multilayer Coatings
F.C. Dias, C.R.M. Silva, P.V. Muterlle, V.A.R. Henriques and J.A. Araújo 1056

Preparation and Tribological Property of Novel Self-Assembled Composite Films on Silicon
S.H. Teng and H. Pan 1066

Study on the BTSPS Silane Film Prepared on the Surface of the 2A12 Aluminum Alloy
L.J. Peng, S.H. Chen, Y.N. Feng and T.Y. Li 1071

Hydrophobicity of Beeswax-Chitosan Latex Coated Paper
W.W. Zhang, L.Y. Qian and H.N. Xiao 1077

Research on Cerium Conversion Coating on ZM5 Magnesium Alloy
R.X. Zhu, G.M. Gao and Z. Miao 1082

Microstructure and Properties of Laser Surface Carburized Titanium and Titanium Alloys
J.J. Dai, C.Z. Chen, S.Y. Li and L. Zhuang 1086

The Application Research of Ship Metal Corrosion in Marine Environment
C.Y. Hu, S.W. Kou and J.J. Guo 1091

Corrosion Resistance of Three 316 Stainless Steels
J.S. Lu, Q.S. Lu and J. Xue 1097

The Corrosion Behavior of Cu-Ni-Si Alloy in Sea Water with Deep-Sea Bacteria
Y.Y. Shen, L. Zhang, L.H. Dong, T. Liu, Q. Lei and Z. Li 1102

Corrosion Performance of Medical Titanium Alloy with Different Surface Morphology
J. Zhang, S.Y. Zhang, B. Liu, M.X. Li, Q.Q. Lin and J.Q. Wang 1106

Analyzing the Corrosion of "Hai Yang Shi You 931" Jack-Up Drilling Unit
W. Hong and X. Zhi 1112

Effects of Soil Type of Shanghai and Electrode Potential on Near-Neutral pH Stress Corrosion Cracking of Pipeline Steel X60
G.F. Li and D.F. Yan 1116

The Effects of Hydrogen on Properties of Surface Films Formed on Iron in Sulfate Solutions
A. Ejaz, Z.P. Lu, J.J. Chen, X.F. Xia, Q. Xiao and B. Lu 1120

Corrosion Inhibition of Gemini Surfactant for Copper in 3.5% NaCl
K. Cao, H.Y. Sun and B.R. Hou 1125

A Study of the Corrosion Resistance of M50NiL Bearing Steel by Ion Implantation
J. Jin, Y.B. Chen, K.W. Gao and X.l. Huang 1132

Chapter 12: Alloys and Steels, Metallurgical Technologies

Microstructure Evolution Characterization of Multi-Pass Hot Rolling Simulation of Nb-Ti Microalloyed Steel
B. Shen, S.H. Zhu and H.H. Zhang 1141

Grade E550 Heavy Steel Plate by TMCP for Offshore Energy Exploration
W.H. Sun and Z.C. Bi 1146

Preparation of Crystalline Hematite from Bauxite
J. Liu, Q.Q. Jiang, J. Wang, L. Chen and X.Y. Wang 1153

The Effect of Heat Treatment of Gray and Nodular Cast Iron with Ferrite Matrix on Mechanical Properties and Corrosion Rate Compared with Medium Carbon Steel
M.A. Gebril, M.S. Aldlemey and F.I. Haider 1158

Microstructure and Tensile Behavior of Ti-Rich Ti-Ni-Cu Melt-Spun Ribbon
W.J. He, G.H. Min and O. Tolochko 1163

The Oxide Defect of C70250 Alloy
Z.P. Chen, C.J. Xiang and H.Q. Li 1168

A Study on Austenite Catalytic Cryogenic Treatment of Cr-W-Mo-V High Alloy Medium-Upper Carbon Steel
Y.Q. Ma, X.J. Zhang, Y.F. Liang and G.F. Liu 1173

Effect of Forging Process on V-Nb-Ti Microalloyed Non-Quenched and Tempered Steels
T.H. Man, P. Gao, Y.G. He, Z.L. Zhan, L. Tan and Y.Z. Bao 1179

Experimental Study and Calculation of the Precipitation Behavior of Carbides in Fe-5.78Cr-0.35C Alloy during High-Temperature Aging
M.Y. Wang, J.J. Wang, Y.L. He, X.G. Lu and L. Li 1184

Effect of Temperature on the Ti-Fe Alloy Prepared by Molten Salt Electrolysis
R.M. Shi, L.F. Bao and B. Zhang 1189

Preparation of Ti-Fe Alloy from Titanium Concentrate by Electro-Deoxidization in $CaCl_2$
R.M. Shi, L.F. Bao and B. Zhang 1195

Study on Atomic Mobility and Molar Volume for FCC Fe-Co Phase
X.M. Gong, X.G. Lu and Y.L. He 1201

Molar Volume of Fcc Phase in the Ni-Cr-Mo System
J.C. Li, X.G. Lu and Y.L. He 1209

Effect of Aging Treatment on Phase Transformation of a Pseudoelastic NiTi Alloy
P.V. Muterlle, E.B. Villamarin, P. Herrera and E.P. da Silva 1216

Improvement of Paint Hardening Response of a Novel Al-Mg-Si Alloy for Automotive Panel by Adding Zn and Pre-Ageing Matching
Z.H. Li, L.Z. Yan, Y.A. Zhang, X.W. Li, F. Wang, H.W. Liu, S.H. Huang and B.Q. Xiong 1224

Effect of Mn and Si on the Microstructure and Mechanical Properties of Bearing Steel
M. Wang, G. Xu, Z.L. Xue, T. Xiong and M.X. Zhou 1229

Influence of Nitrogen Atmosphere Annealing on Structural and Transport Properties of $Fe_{1.125}Te$
Y.J. Li, Z.P. Wu, Y.H. An, G.F. Wang, C.L. Sun, Y.T. Huang, P.G. Li, L.H. Li and W.H. Tang 1234

Interface Reaction Thermodynamics of AgCuTi Brazing Filler Metal and Alumina Ceramic
H.L. Ning, L.F. Lan, L. Wang, J.B. Peng, Z.J. Peng and J.S. Ma 1239

Influence of Deformation on Aging Precipitation Behavior of an Al-Cu-Mg-Si Alloy
X.W. Li, B.Q. Xiong, Y.A. Zhang, Y.Q. Zeng, F. Wang, Z.H. Li, H.W. Liu and S.H. Huang 1247

Workpiece Surface Integrity of GH4169 Nickel-Based Superalloy when Employing Abrasive Belt Grinding Method
G.J. Xiao, Y. Huang, Y.H. Yang and H. Yi 1252

Studies on Refining Effect and Process Optimization about LF
S.L. Cheng, X.X. Qi and Q. Jia 1258

Influence of RE Addition on Ferro-Matrix Friction Material by *In Situ* Carbothermal Reduction from Vanadium-Bearing Titanomagnetite
Y. Li, K.Q. Feng, W.L. Deng, G.M. Zhang and Y. Zhou 1262

Influence of the Mo and V Contents on Microstructure and Secondary Hardening of 6Cr6W2MoV Steel
X.J. Zhang, Y.Q. Ma, Y.F. Liang and G.F. Liu 1267

Study on Wear Behaviors of Ni_3Al/Cr-Carbides Cladding Layer on High Strength Steel Substrate
K.R. Gong, T.B. An, Z.F. Zhou, Z.L. Tian and C.H. Li 1273

Study on the Mechanical Stability of Retained Austenite in Cold-Rolled Medium-Mn Steel
J. Hu, W.Q. Cao, J. Shi and H. Dong 1283

Influence of Heat Treatment on Fatigue Resistance of Sintered Ti 35Nb 7Zr 5Ta β Alloy
A.H. Franco, C.R.M. Silva, P.V. Muterlle, J.L.A. Ferreira and J.A. Araújo 1290

Effect of Hydrogen on the Micro- and Macro-Strain near the Surface of Austenitic Stainless Steel
O. Takakuwa, Y. Mano and H. Soyama 1298

Thermographic and Microstructural Analysis of Martensitic Stainless Steel ASTM A743 CA6NM Arising out of Layered GMA Welding Process Using AWS 410 NiMo Welding Wire
M.T. Santos, P.V. Muterlle and G.C. de Carvalho 1303

Two High Strength Low Alloy Steels for Offshore Application
T.C. Yang, C.Y. Huang, T.C. Cheng, C. Yu and R.K. Shiue 1312

Numerical Simulation on Influence of Water-Cooled Stool in the Process of Unidirectional Solidification
X.D. Li, M.G. Shen and C. Wu 1317

Application of Calcium Treatment to Sulfur Gear Steel 20CrMo
X.D. Wu, D.X. Zhang and R.L. Chen 1323

Chapter 13: Building Materials and Technologies in Construction

Nonlinear Dynamic Finite Analysis of BFRP-Strengthened Masonry Structure Based on ABAQUS
Z. Lei, Y. Wang and J.T. Qu 1331

Crystal Structure and Hydration Characteristics of Tricalcium Silicate Doped with Magnesium Oxide
L. Chen, X. Wang, X.D. Shen, S.H. Ma and W.Q. Zhou 1336

Mechanical Damage Model of Concrete Subject to Freeze-Thaw Cycles Coupled with Bending Stress and Chloride Attack
P. Du, Y. Yao, L. Wang and Y. Cao 1342

Numerical Investigation on Fatigue Problem of Cable Net Structure of Five-Hundred-Meter Aperture Spherical Radio Telescope
P. Jiang 1351

Study on Compressive Performances of Fiber Reinforced Mortar with the Application of Jute and PP
J.F. Yin, Y. Zhang, T.T. Yan and H. Qiu 1356

Study on Low-Cycle Fatigue Life of Base Metal of the Shock Absorber
A.L. Li, R. Gao, M.D. Sun and X. Meng 1361

Corrosion Behavior of F30S30 Concrete under Wet-Dry Cycles in Simulated Seawater with Magnesium Salt and Sulfate
G.G. Liu, A.B. Ma, C.M. Pang, P. Zhang, H.G. Qin and L. Wang 1366

Different Salt Solution on the Deterioration of Marine Engineering Concrete under the Action of Chemical-Mechanical Coupling
H.G. Qin, J.J. Deng, P. Zhang, C.M. Pang and Y.K. Hou 1373

Polymer Modified Cementitious Waterproofing Coatings: Application and Problems
W. Yao, Q.Q. Hu, Y. Mu, J.B. Chen and F.Q. Zhao 1378

Analysis of Curing Agent on the Strength of Lightweight Soil Using Recycled Sludge
G.C. Wang, L.C. Yu and L. Sha 1382

Study on Engineering Characteristics of Coarse-Grained Soil Based on Large-Scale Triaxial Test
F.Y. Chu 1387

Copolymerization Kinetics of Polyetyhylenglycol Allylether Type Polycarboxylate Superplasticizer
Y.F. Tian, X.P. Zhu, Y.T. Deng and K. Wang 1393

Improving the Volume Stability of Steel Slag for Construction and Building Materials
P.G. Li, F.Q. Zhao and Z. Ma 1399

Effect of Grinding Aids on the Particles Characteristics of Cement and Analysis of Action Mechanism
J.H. Zhao, D.M. Wang, X.G. Wang, S.C. Liao and H. Lin 1404

Effect of Mineral Admixtures on Rheological Properties of Cement Paste
L.C. Zhang and A.L. Zhang 1409

Theoretical Study on Seismic Behavior of LYTAG Concrete
L.C. Zhang 1414

The Frost Resistance of LYTAG Concrete
A.L. Zhang and L.C. Zhang 1419

Recombinant Materials and Contemporary Energy Efficient Architecture
M. Mahdavinejad, S. Ghanavati, N. Elmi, A.N. Larki and A. Zia 1423

Effect of the Composite of Fly Ash and Slag on Alkali-Silica Reaction
T.C. Liu, B. Xiao, G.H. Li, N.H. Luo and L.S. Zhang 1428

Analysis of the Influence of Clay Dosage and Curing Age on the Strength of Plastic Concrete
L.M. Hu, X.L. Lv, D.Y. Gao, K.B. Yan and S.Q. Song 1433

The Experimental Study on Bearing Capacity of Reinforced Concrete Structure with Different Reinforce Methods
Q.Y. Liu and X.M. Liu 1438

Mechanical Properties of Crumb Rubber Concrete
J. Cai 1442

Research on Improving Shrinkage Performance of Cement Stabilized Gravel with Waste Rubber Particles
Q.Y. Liu, M. He and J. Wang 1446

Bending Properties of Laser Welded Web-Core Steel Sandwich Plates
X.X. Jiang, L. Zhu, J.S. Qiao, Y.X. Wu, Z.G. Li and J.H. Chen 1451

Effect of Rubber Particles on Properties of Pseudo-Ductile Cementitious Composites
C.M. Pang, C.K.Y. Leung and W. Sun 1456

Back Analysis of Thermal Parameters of Mass Concrete and its Application Based on Micro-Genetic Algorithm
G.R. Chen and B. Yang 1463

A Effective Solution Method Based on Bayesian Rule for Prediction of Long-Term Tensile Strength of GFRP Bars in Concrete Beams
L. Dai, X.J. He and F. Shen 1468

Seismic Fragility Analysis of RC Isolated Continuous Girder Bridge Using Radial Basis Function Neural Network
B.L. Chen, X.H. Long and J.J. Li 1473

Robust Design of Structures with Uncertain Parameters and Frequency Constraints Using Non-Probabilistic Methods
J.Y. Chen, Y. Luo and D.H. Liu 1479

Research Based on Scanning Electron Microscopy to Determine Original Water-Cement Ratio of Hardened Concrete
Y. Li, H. Tong, J.B. Yang and W.G. Dong 1485

Numerical Simulation for the Damping Effect of Empty Holes on Blasting Vibration
K.F. Bian, H.B. Li and Y.Q. Liu 1490

Analysis on the Effect of External-Wall Insulation on Energy Consumption of Residential Building in Lanzhou
C.N. Li, G. Wang and Y.J. Wang 1496

Energy Consumption for Heating Residential Building from Implementing Deferent Energy-Saving Standard
C.N. Li, Y.J. Wang and Y. Cai 1502

The Scheme Comparison of Integral Structure after Adding Steel Storey to Concrete Frame
N. Sun, G.P. Shu and Z.M. Wang 1506

Finite Element Analysis of Rainfall Infiltration in a Compacted Loess Embankment
Q.F. Lv, P.F. Liu and Y.X. Zhao 1511

Numerical Analysis on Synergetic Behaviors of AE in Concrete Failure Process
L.H. Wei 1518

Simulation and Analysis of Energy Consumption Transformation in Office Buildings' Envelopes of Lanzhou
X.L. Han, H.M. Wang and C.N. Li 1522

Study on the Key Technology of Hot Regeneration of Plant-Mixed Asphalt Material
Q. Jin, X.Z. Cui, J.J. Lou, W.Z. Tang, W. Sui and Z.J. Gao 1527

Analyses of the Protective Effect of Polyethylene-Triethoxysilane and Triethoxysilane Emulsion Coatings on Concrete Substrate
X.Y. Zhang, S.C. Li, T.J. Zhao and Z.Q. Jin 1531

Chapter 14: Technologies and Materials in Oil Industry

Research Progress of Thickening Agents for Supercritical CO_2
W.C. Sun, B.J. Sun and Z. Fan 1541

Study on the Crosslinkers Used in Gelling Agents
Q.R. Sun and R.W. Liu 1549

Oil, Water, Slag Three Phases Separation Technology of Heavy Aging Oil
M. Zheng 1553

Research on Chemical Degradation of PAM in Oil Recovery Application
R.W. Liu 1556

The Application of Based on Case-Based Reasoning for Drilling Parameter Optimization in HaiTa Oilfield
L. Chang, T. Yan, S. Li and H.M. Fei 1560

Chapter 15: Methods and Devices of Measurements in Materials Engineering

Evaluation of Uncertainty of Hydrogen's Consistency in Transformer Oil by Gas Chromatography
H.L. Shen and H.Y. Luo 1567

Dissolution of Zirconium Power and Detection of Zirconium Powder Content by ICP-AES Method
X.L. Zhang, W.H. Zhu, X. Zheng and H.X. Liu 1571

Application of Magnetic Barkhausen Noise in the Evaluation of Heat Treatment Process
H.C. Yin, L. Zhou, Z.S. Wang and C.B. Cai 1576

Stress-Stain Response of PVC Geomembrane under Uniaxial Tension Test
H.M. Wu and Y.M. Shu 1582

Design of the EMF-PF and Error Correction
K.X. Wei 1587

TURBISCAN: History, Development, Application to Colloids and Dispersions
Z.Q. Liu, X. Yang and Q. Zhang 1592

A Progress in Development and Application of Size Exclusion Chromatograph/Multi-Angle Laser Light Scattering
X. Yang, Z.Q. Liu and Q. Zhang 1597

Chapter 16: Technologies and Equipment for Manufacturing and Processing of Materials

Application of Polycarboxylic Acid Anti-Crease Finishing Agent for Silk
L. Xu 1605

A Same Area Method Used to Calculate the Strain in Forming for an Axisymmetric Workpiece
Z.R. Han, Q. Xu and Z.B. Yuan 1609

Applying BP Neural Network Model to Forecast the Largest Coiling Torque of down Coilers
K. Zhao, Z.G. Wang and C.M. Liu 1614

Brazing Incoloy 800 Using the MBF-51 Filler Foil
W.S. Chen and R.K. Shiue 1620

Activating of Nickel Slag and Preparing of Cementitious Materials for Backfilling
K.Q. Li, Y.Y. Zhang, P. Zhao and L. Feng 1624

Preparation and Characterization of Plasma Treated Melt-Blown Polypropylene Nonwovens Grafted with Acrylic Acid
D. Wang, Q.Y. Xu, Y.J. Chen, H.J. Xu, Y.M. Wang and Y.P. Wang 1630

Microstructure and Mechanical Properties of High-Entropy Alloys CoCrFeNiAl by Welding
L. Cui, B. Ma, S.Q. Feng and X.L. Wang 1635

Microstructure Refinement and Crack Initiation in the Forging Process
W.L. Zhao and Q.X. Ma 1641

Effect of Aging on Microstructure and Performance after Superplastic Deformation of Fine Grained 1420 Al-Li Alloy
Y.L. Zhang, H.L. Hou and Y.Q. Wang 1647

Numerical Simulation of One Pulse Power Laser Shock Peening
L. Chen 1653

Analysis of Hydraulic Prop High Frequency Induction Cladding Temperature Field
F.D. Zhu, B.Y. Zhu and B. Liu 1657

CFD Simulation on Hydrodynamics of Liquid-Liquid Slug Flow in Microchannel
Y. Wang 1662

Characterization of Local Cavity Pressures in Squeeze Casting of Magnesium Alloy AM50
X.Z. Zhang, A. Yu and H. Hu 1666

Microstructure and Mechanical Properties of Brazed Joints Used in Electronic Devices
X.R. Wu, W.Q. Qu and H.T. Li 1671

Structure and Performance of Chemical Duplex Plating Ti Metal Layer on Diamond Surface by Hydrothermal Method
D. Xiang, L.Q. Jia and K.G. Liu 1676

Numerical Simulation and Optimization Technology of Lost Foam Casting
H.Z. Chen, H.Z. Dong and Z.D. Shan 1681

A Research on Optimization of Cutting Parameters Based on NSGA-II
X.Z. Liang, G.R. Yan and H.Z. Chu 1687

Behavior of Microwave Heating of 316 Stainless Steel Green Body
Z.W. Li, K.Y. Jiang, F. Wang and J.L. Zhang 1694

Effects of Environment Temperatures on the Microstructures and Mechanical Properties for Welding Joints of A5083-H111 Alloy
C.G. Wang, Y. Liu, X.M. Wang, G.Q. Gou and H. Chen 1701

Experimental Research on Grinding Surface Layer Behavior and Process Parameter Optimization of Spiral Bevel Gears
X.Z. Ming, Z.G. Li, X.W. Xiong and J. Zhou 1707

Development of Permanent Magnet Generator Used for Magnetic Field Assisted Micro Electroforming Technology
H.J. Li, P.M. Ming, X.H. Bao, X.D. Zhang and X.Y. Bi 1716

Spray Cooling Unit for Heat Treatment of Stainless Steel Sheets
M. Hnizdil, M. Chabicovsky, M. Raudensky, E. Magadoux and F. Code 1720

Research on Forming Accuracy of Two Point Incremental Forming for Aluminum 1060
Q.C. Wang, H.H. Hu, J.H. Wu and J. Cao 1725

Keywords: biphenyldiol; epoxy resin; siloxane; mechanical property; thermal degradation

Abstract. In order to modify the properties of the epoxy composites, an alkali catalyzed biphenyldiol formaldehyde resin (BPFR) was synthesized and used to cure epoxy resin (ER). γ-Glycidoxypropyl trimethoxysilane (KH-560) was used as a reinforcer of the composites. Laminates of the BPFR/ER fiberglass reinforced composites with different (KH-560) contents were prepared. The influence of the KH-560 content on the glass transition temperature (T_g) and thermal degradation properties of the composites was researched by dynamic mechanical analyzer (DMA) and thermogravimetric analysis (TG). The mechanical, electrical properties of the composites were determined. The results showed that the interfacial bonding strength between resin matrix and fiberglass can be efficiently improved with the presence of KH-560. When the ratio of BPFR and ER is 3 : 7, the content of KH-560 is 5 ~7 wt%, the impact resistance of the fiberglass reinforced composites is 61.35~78.59 kJ/m^2, the tensile resistance is 150.37~162.54 MPa, which are all 30 % higher than that of no added; The dielectric constant ε and dielectric loss tanδ of the composites is between 0.50~0.68 and between 0.008~0.01, respectively.

Introduction

Phenol-formaldehyde resin (PFR) is an excellent thermosetting resin, having good mechanical, flame retardancy and heat resistance properties; it has been used in preparing fiberglass-reinforced laminate, molding compounds, insulation materials and adhesives, especially in the high-technology fields, such as spaceflight, rocketry, etc [1]. PFR can also be used as curing agent of epoxy resin, which has better thermal properties than the phthalic anhydride-cured epoxy, with a higher glass transition temperature (T_g) and a higher thermal decomposition temperature [2]. Because of the more intensive aromatic ring in biphenyldiol, the biphenyldiol formaldehyde resin (BPFR) will have higher heat resistance and residual rate at high temperature. Epoxy resins (ER) are high-performance thermosetting polymers, which has excellent adhesion, corrosion resistance, insulation, high mechanical strength, good electrical insulation and compatibility with a great number of materials. It is widely used in adhesives, coatings, electrical insulating materials and composites, and is an indispensable basis for industrial materials. But epoxy resin after curing is usually more brittle, and its fatigue resistance, heat resistance, impact strength are relatively poor, and it is also difficult to meet the requirements of the development of modern engineering technology and application. In this work, a novel biphenyldiol formadehyde resin (BPFR) was synthesized. The BPFR was used to cure epoxy resin, KH-560 was used as modified reagent, and the fiberglass reinforced composites were prepared. The dynamic mechanical properties, thermal degradation behavior, mechanical and electrical properties were determined.

Experimental Section

Materials. Formaldehyde, ethanol, toluene, sodium hydroxide, N, N'-dimethylformamide (DMF), analytical reagents and supplied by Tianjin Kermel Chemical Reagent Co., Ltd; bisphenol A epoxy resin, 0.44 mol epoxy group/100g, Wuxi Resin Factory, China; N, N-dimethyl benzylamine, chemical reagent, Shanghai yuanfan additives factory, China; biphenyldiol, chemical reagent, recrystallization at 70 ^{o}C in 30 % aqueous solution of DMF, T_m 284 ^{o}C; γ-glycidoxypropyl trimethoxysilane (KH-560), chemical reagent, Shengda fine chemical Co. China.

Biphenyldiol formaldehyde resin was prepared by the condensation of biphenyldiol and formaldehyde in a molar ratio of 1 : 2.5, and with the slow addition of sodium hydroxide (2.5% of the total mass of the system), the reaction system was heated to 85 ^{o}C and held about 120 min, followed by dehydration under vacuum, finally a transparent viscous liquid was obtained. Then synthesized resin was dissolved by ethanol and obtained 60 % content of ethanol solution.

Sample Preparation and Characterization. Samples were prepared as follows: for samples of pure BPFR/ER, with the mass ratio of BPFR/ER and glass fiber all 1 : 1, and BPFR : ER = 3 : 7, 4 : 6, 5 : 5 , 6 : 4, 7 : 3, 10 : 0, labeled as 1, 2, 3, 4, 5, 6 respectively. For samples of BPFR/ER/KH-560, the mass ratio of BPFR/ER/KH-560 and glass fiber cloth were all 1 : 1, and with the mass ratio of BPFR : ER =3 : 7, the KH-560 content for resin was 0, 3, 5, 7, 9, 11 wt% and labeled as No. 0, No. 3, No. 5, No. 7, No. 9, No. 11, respectively. The resin which contains 1 wt% N,N'-dimethyl benzylamine was dissolved by small amount of acetone and coated onto the heat-cleaned glass cloth, after that the solvent were removed and pre-cured at 120 ^{o}C for 20min.. Laminated strips of 20×5×1 mm were prepared by hot pressing and curing at 180 ^{o}C for 30 min. The dynamic mechanical behavior of the materials was characterized by a dynamic mechanical analyzer (DMA, Q8000, Perkin-Elmer Co. USA) at a heating rate of 2 ^{o}C/min, under the frequency of 2 Hz.

The 3 mm thickness laminates of fiberglass reinforced composites with different KH-560 content were prepared with the same method and conditions. The tensile strength, impact strength and electrical properties were determined according to ASTM D638 and D256, Tensile strength test was performed using an electronic tensile tester (WSM-20kN, Changchun Equipment Co., Ltd. China). The notch impact test was carried out on an XCJ-40 impact tester (Hebei Chengde pilot plant, China). The electronic properties were determined with high impedance meter (ZC36 type) and high-frequency Q, (QBG-3D type, Shanghai Ai Yi Electronic Equipment Co., Ltd.).The thermogravimetric analysis (TG, Pyris-6, Perkin-Elmer Co. USA) was performed at a heating rate of 10 ^{o}C/min from 25 to 800 ^{o}C in static air.

Results and Discussions

DMA analysis of the Curing Samples. The DMA spectra of BPFR/ER composites are shown in Fig. 1. As seen in Fig. 1, the mechanical loss (tanδ) α peak temperature T_p increases with the increasing epoxy resin content correspondingly, and the peak width increases gradually. Normally, there is a corresponding relationship between the glass transition temperature (T_g) and the mechanical loss α peak temperature (T_p) of the material, and the T_p is often designated as T_g [3]. It can be seen that the addition of ER can increase the crosslingking density of the system, which preventing the relaxtion of chain segments and with a result of higher T_g as well as a wider peak, relevantly. This reflects the dispersion of the chain segments motion, and the high crosslinking density leads to a long process for the relaxation movement of molecular segments, thus the corresponding temperature T_p increases [4]. The mechanical loss peaks of the pure BPFR system tend to reduce with the increase of temperature, indicating a high crosslinking density and no

apparent molecular chain segments motion. Comprehensively, the performance of the composites is appropriate with the BPFR/ER mass ratio 3 : 7.

The properties of composites not only depend on the reinforcing agents, property of resin matrix and content, it also depends on the interfacial bonding strength between fiber glass and resin matrix. Generally, it is necessary to process the fiber glass in order to enhance the interfacial bonding strength. A significant way is using siloxane as a coupling agent [5]. The siloxane coupling agent on the surface of glass fiber may ensure the effective stress transfer, and substantially raise the comprehensive performance of composites. In this work, KH-560 was used to improve the interfacial bonding strength. Meanwhile, the reaction between epoxy group in the siloxane and biphenoldiol formaldehyde resin may promote the performance of the BPFR/ER composites further. The influence of different contents of KH-560 on the dynamic mechanical property of the BPFR/ER composite is shown in Fig. 2.

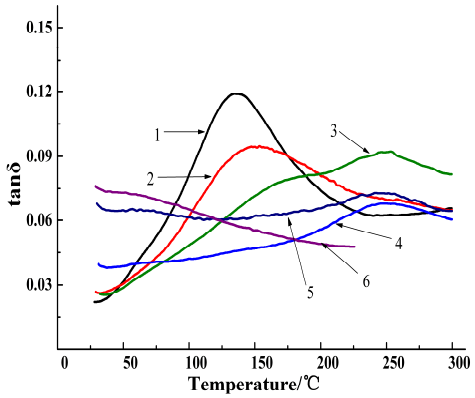

Fig.1 DMA spectra of BPFR/ER with different proportions

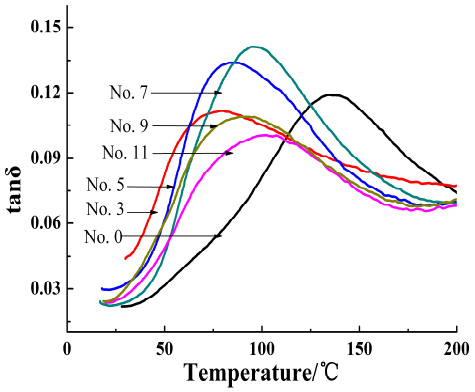

Fig. 2 DMA spectra of BPFR-ER composites with different KH-560 contents

Mechanical and Electrical Properties of Composites. The mechanical properties of the composites with different contents of KH-560 are listed in Table 1, all data are average values of 5 samples. It can be seen from Table 1, the tensile and impact strength is enhanced with increasing KH-560 content, when the content of KH-560 is 5, 7 wt%, the tensile strength can be 150 ~162 MPa, the impact strength 61~78 kJ·m^{-2}, which are all increased by over 30 % than that of no added(No.0). However, the mechanical properties decrease when more KH-560 is added in the composites. When the content of KH-560 is 11 wt%, the tensile strength and impact strength decrease to 52.98 MPa and 32.73 kJ/m^2, respectively. This indicates the mechanical properties of the material can be improved with an appropriate proportion of KH-560. It is consistent to the previous analysis both of the influence on resin matrix, glass fiber and danymic mechanical property. The reason is proper amount KH-560 siloxane can not only improve the compatibility but also form chemical bonds with hydroxyl both on the surface of glass fiber and resin matrix. It promotes to the interfacial strength between glass fiber and resin, and changes the stress of fiber glass transfer from resin. Consequently, when external force is act on to the materials, it plays an effective function of stress dispersion.

Table 2 shows the change of electrical properties of the composites along with the addition of KH-560. These data show that after adding KH-560, the volume resistivity ρ_v and surface resistivity ρ_s of materials display an increasing trend, while the dielectric loss tanδ and dielectric constant ε decrease. The increase of ρ_v and ρ_s arouse from high polarity of coupler. It is provble that the addition of silane coupler optimize the electrical properties of the composites.

Thermal Degradation Behavior. Thermogravimetric analysis of the BPFR/ER with different content of KH-560 was determined at a heating rate of 10 °C/min. Figure 3 is thermogravimetric curves of the 6 samples. As seen from Fig. 3, under the same weight loss rate of pyrolysis, the corresponding temperatures of samples increase with the adding KH-560 amount at same heating rate, it suggests that the thermal properties of the BPFR/ER composites has been effected by siloxane. Because of the increased content of inorganic –Si-O-, and the limitation to small molecule from diffusing caused by increasing crosslinking center, the weight loss rate decrease gradually. It should be noted that, when the content of KH-560 is 11 wt%, the pyrolysis temperature of the composites decline contrarily. This is because excess coupling agent cannot participate crosslinking reaction and small molecule has a low thermal stability.

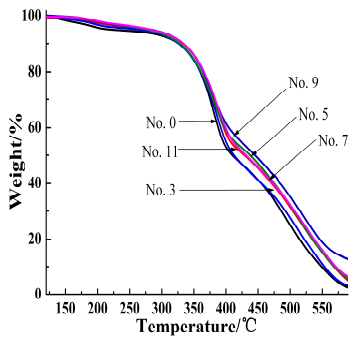

Fig. 3 TG curves of BPFR/ER with different KH-560 contents

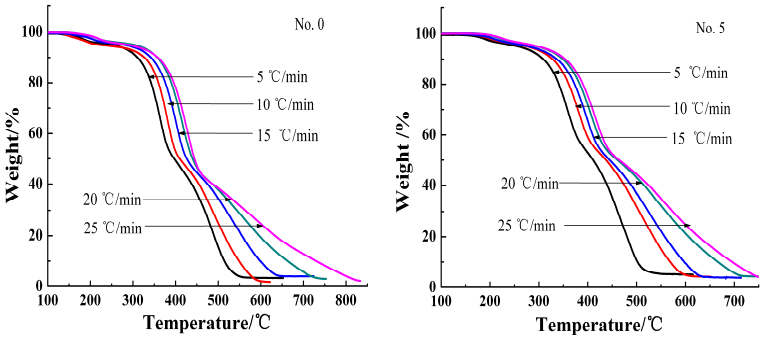

Fig. 4 TG curves for No.0 and No.5 at different heating rates

In order to investigate the activation energy and reaction order of thermal degradation process, samples No. 0 and No.5 were taken as examples for analysis. Thermal degradation was determined at different heating rates 5, 10, 15, 20 and 25 °C/min, respectively. The TG curves for No. 0 and No. 5 are shown in Figure 4.

As the figures displayed above, it shows that the thermal degradation process of the composites can be roughly divided into three stages: the first stage is between 150~300 °C, weight loss for

about 5 wt%, which is the volatilization of moisture and other small molecule. The second stage is between 300 ~ 450 ^{o}C, weight loss in this stage is mainly caused by oxidative cleavage of ether bond, carbonyl group and C-H. In this stage, the weight loss of the resin is nearly 60 wt%, which shows thermal degradation in the second stage is substantially dominated. The third stage is between 465 ~ 650 ^{o}C, which is the degradation and oxidation of metheylene, aromatic ring and the carbonization of the resin [6].

In this work, the thermal degradation kinetics of the two stages are all investigated by the Friedman method with dynamic treatment [7], respectively.

$$\ln(\frac{\mathrm{d}\alpha}{\mathrm{d}t}) = \ln(\beta\frac{\mathrm{d}\alpha}{\mathrm{d}T}) = \ln A + n\ln(1-\alpha) - \frac{E_a}{RT} \quad (1)$$

According Eq. 1, the average activation energy E_a at the different heating rates and α for each sample can be calculated from the using plot of the $\ln(\mathrm{d}\alpha/\mathrm{d}t)$ ~ $1/T$, the reaction order n can be obtained from plot of the $\ln(1-\alpha)$ ~ $1/T$, respectively. The average E_a and n for No.0 and No.5 are listed in Table 3, the linear relative coefficients of E_a and n are all between 0.9816 and 0.9957.

Tab. 3 Thermal degradation kinetic parameters calculated by Friedman method

Samples	β (^{o}C·min^{-1})	E_a/kJ·mol	r_1	n	r_2
No.0	Mean	59.287	0.9911	1.67	0.9895
No.5	Mean	54.547	0.9932	2.01	0.9942

Summary

Biphenyldiol formaldehyde resin (BPFR) can be synthesized from biphenoldiol and formaldehyde in the presence of sodium hydroxide. The interfacial bonding strength between resin matrix and glass fiber can be efficiently improved by siloxane KH-560. When the mass ratio of BPFR/ER is 3 : 7, and with a 5~7 wt% KH-560, the impact strength and tensile strength can be 61.35~78.59 kJ/m^2 and 150.37~162.54 MPa, respectively, which are all increased by over 30 %. The dielectrical properties also can be improved. The addition of siloxane coupling agent can enhance the thermal properties of BPFR/ER composites.

Keywords： polymer blend , inclusion chemistry

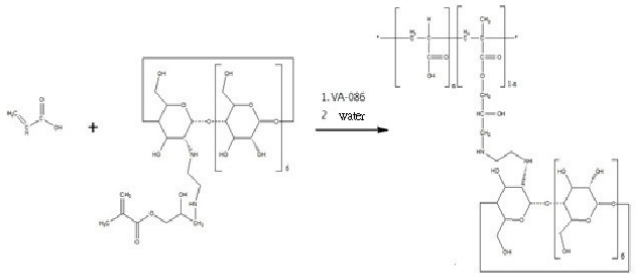
Abstract: A new method is proposed to improve blend compatability through inclusion complexation. The host polymer and the guest polymer are synthesized respectively and blended to form a film. The transparency of blend film increases and, at some composition, a third T_g is obsereved, indicating the inclusion complex between these two polymers

Introduction

Nowadays, there is no denying the fact that polymer blends[1-3] are ubiquitous among all high performance polymer materials. A lot ot research work is intensely motivated for tailored properties, reduced product cost, and processability. Compared with small molecules, most polymers are not compatible to each other in that the entropy gain of mixing is too small to form a homogeneous mixture. To improve the blend compatibility, introduction of some interacting groups onto polymer chains is very effective methods. Among them, hydrogen-bonding[4,-6] and Coulombic forces[7] between cation and anion are most popular techniques.

In addition to these two methods above, here, we present another alternative, inclusion complex(IC), to improve blend compatibility. Forming inclusion complexes with guest molecules selectively, Cyclodextrins(CD's)[8-12], the macrocyclic and water-soluble oligosaccharides, are widely used in many areas, particularly in drug research and biochemistry. CD's have a hydrophobic cavity where various guest molecules can be inserted to form IC's, while the hydrophilic nature of their outer surfaces render CD's somewhat water soluble. It is said that CD's are all purpose molecular containers for organic, inorganic, organometallic compounds which may be neutral, ionic or even radical. The host polymer, poly(acrylic acid) containing ß–Cyclodextrin(ß–CD), and the guest polymer, poly(methacrylic acid) containing adamantane groups, were synthesized respectively. Even a small contents of IC groups would improve significantly the blend compatibility.

Experimental



Synthesis of monomer containing ß –CD

In dry pyridine ß –CD was reacted p-TsCl overnight and after evaporation to dryness, the residue was dissolved in water and precipitated in acetone. The white crystal(ß–CD-6-O-TsCl) from twice recrystallization, was reacted with excess amount of ethylene diamine(EDA) for 4 hr at 60°C to

obtain a white solid(EDA-6-ß–CD). Then, the ß–CD containing monomer was synthesized by reaction between EDA-6-ß–CD and glycidyl methacrylate with a small amount of 1, 4 dihydroxyl benzene as inhibitor in DMF for 8 hr. After reaction, the monomer((GMA-EDA-6-ß–CD) was obtained by precipitation the solution into acetone and vacuum drying.

Preparation of host polymers:

PAA-based host polymers(PAA-co-GMA-EDA-EDA-6-ß-CD) were prepared by free radical copolymerization of acrylic acid and GMA-EDA-6-ß–CD , as showm in Scheme 1. Preparation of host polymer

Preparation of guest polymers

As shown in Scheme 2 , PMA-based guest polymers(PMA-g-3AD) were prepared by labelling adamantane group onto of PMA chain. The guest polymer obtained was purified by reprecipitation and dialysis.

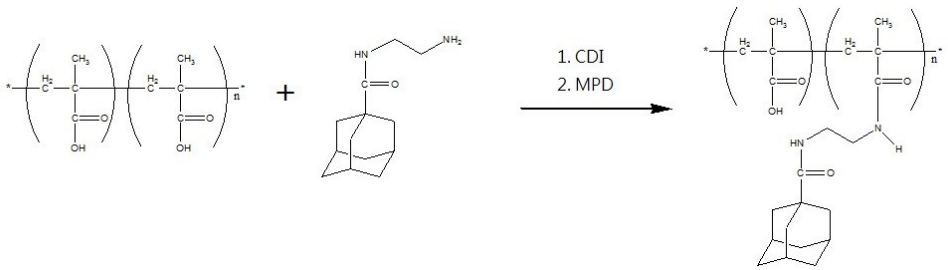


Fig 2. Preparation of guest polymer

Preparation of blend film:

PAA-based host polymer and PMA-based guest polymer were dissolved in water, which were then casted on Teflon plate for one week and vacuum dried until no decrease in weight before DSC measurement.

Results and discussion:

The characterization of polymers is listed in Table 1., where the molecular weights were measured by GPC and contents of ß-CD and adamantane moiety were obtained from **^{1}H** NMR.

Table 1. Characterization of host and guest polymers

Polymers M.W. (x10^5)		β-CD content (mole %)	adamantane content (mole %)
PAA-co- GMA-EDA-6-β-CD	3.8	3.9	0
PMA-g-3AD	3.7	0	9.8

As shown in Table 2., the T_g of host polymer(PAA-co- GMA-EDA-6-β-CD) is higher than that of PAA by ca. 12 ^oC, while the T_g's of guest polymer(PMA-g-3AD) and PMA are almost the same. Compared with PAA/PMA blend, the transparency of host polymer/guest polymer blend increases and, at some compositions, a third T_g appears, ranging from 128.4 to 137.8 ^oC, indicating the inclusion complex between the host polymer and the guest polymer. It is strongly suggested that a various of blend compatibility can be obtained by changing the contents of inclusion groups.

Table 2. Compositions and DSC results of blend films

Sample	Weight ratio	molar ratio of β-CD/adamantane	Tg_1 (^oC)	Tg_2 (^oC)	Tg_3 (^oC)
1. A	--	--	98.5	--	--
2. A / B blend	1/1	--	97.2	--	210.2
3. C	--	--	110.5	--	--
4. D	--	--	--	--	210.5
5. C / D blend	1/1	1/1.97	--	137.3	208.3
6. C / D blend	1.71/1	1/1.16	--	131.0	207.5
7. C / D blend	2.40/1	1/0.82	113.5	137.8	203.8
8. C / D blend	2.71/1	1/0.73	112.5	128.4	--
9. C / D blend	0.91/1	1/2.17	--	--	207.1
10. C / D blend	0.78/1	1/2.53	--	--	204.1

A： PAA (MW=3.8×10^5) ， B： PMA(MW=3.7×10^5)

C： PAA-co-GMA-EDA-6-β-CD (β-CD content: 3.9 mole%，MW=3.8×10^5)

D： PMA-g-adamantane (adamantane content: 9.8 mole%， MW=3.7×10^5)

Summary

A new method is proposed and demonstrated to improve blend compatibility through inclusion complexation. PAA-based host polymer and PMA-based guest polymer are synthesized and blended to form a film. The transparency of blend film increases and, at some composition, a third T_g is obsereved, indicating the inclusion complex between these two polymers

Keywords: atom transfer radical polymerization, carbon nanotubes, graft, transmission electron microscopy

Abstract: Polyacrylamide (PAM) was chemically anchored to the surface of multi-walled carbon nanotubes (MWCNTs) by atom transfer radical polymerization (ATRP) of acrylamide (AM). It started from the functional groups such as –COOH on the sidewall of MWCNTs, which derived from the oxidation of carbon nanotubes. FT-IR and ^{1}H NMR results shown that the multi-walled carbon nanotubes grafted PAM (MWCNT-g-PAM) have been successfully carried out. The MWCNT-g-PAM showed different relative weight loss kinetics with PAM determined by thermal gravimetric analysis (TGA). The transmission electron microscopy (TEM) shown that the PAM grafted polymer was wrapped on the surface of carbon nanotubes.

Introduction

Carbon nanotubes (CNTs) have emerged as a miracle material that will have significant impact on the 21st century due to their unique structure. However, since the crude multi-walled carbon nanotubes (MWCNTs) are large molecules with thousands of carbon atoms in an aromatic delocalized system, they are practically insoluble in most solvents and incompatible with chemical and biological systems [1-4]. Several papers about the application of acid treated MWCNTs (MWCNT-COOH) in LPA have been reported, but the solubility and compatibility of MWCNT-COOH are still not so good [5]. In order to make polymer/CNT composites, chemical modification of carbon nanotubes is necessary. Several approaches including side-wall functionalization, polymer encapsulation, and polymer grafting have been tried to overcome these problems [6-7]. At present, the strategies for grafting appropriate polymers onto the surface of the CNTs include "grafting from" method, "grafting to" method, via efficient radical coupling reaction and γ-ray irradiation methods. Among these approaches, living radical polymerization, especially atom transfer radical polymerization (ATRP) "grafting from" technique, is the method used most to graft polymer chains with controlled MW from substrates [8-9]. In general, there are two obvious benefits to the chemical treatment of nanotube surfaces: (1) improved compatibility of the filler with the polymer and/or (2) further reaction with the matrix to accomplish covalent bonding between the nanocomposite components. In both cases, the final functionality of the nanotube surface should, in principle, match the chemistry of the matrix [10].

In this work, surface-modified MWCNTs (MWCNT-g-PAM) were synthesized based on the hydroxyl functionalized MWCNTs through ATRP of acrylamide (AM). FT-IR and ^{1}H NMR results shown the PAM-functionalized multi-walled carbon nanotubes have been successfully carried out. The PAM-functionalized MWCNT showed unusual relative weight loss kinetics determined by TGA. The grafted MWCNTs have a better reinforcing effect on the mechanical properties of the matrices compared to the raw carbon nanotubes.

Experimental section

Materials

All water used in this experiment was deionized water. The MWCNTs (diameter 10-30 nm, Length 5-15 μm, Sun Nanotech Co Ltd in Nanchang) were used without further purification.

2-bromoisobutyryl bromide (98%) was used as received from Aldrich. CuBr (Sinopharm Chemical Reagent Co., Ltd) was purified by stirring in acetic acid, washing with ethanol, and then drying under vacuum. AM (Sinopharm Chemical Reagent Co., Ltd, 99%)was recrystallized from chloroform and stored in a refrigerator prior to use. 2-dimethylaminoprydine (DMAP), triethylamine (TEA) and $CuBr_2$ (Sinopharm Chemical Reagent Co., Ltd)were purified before used. Me_6[14]aneN_4 was synthesized according to our previous works [11]. Other organic reagents purchased from Shanghai Reagent Company were of analytical grade and were used as received.

General procedure for polymerization from MWCNT

The general strategy for preparing initiator (bromoisobutyrate group-functionalized MWCNT, MWCNT-Br) used for ATRP of AM according to literature [12], as shown in Fig. 1: the crude MWCNT was firstly oxidated by 60% HNO_3 to obtaining carboxyl-contained MWCNT (MWCNT-COOH), which was then reacted with $SOCl_2$, glycol, and α-bromoisobutyryl bromide in sequence to generating MWCNT-Br. The in situ ATRP approach to polymer-functionalization of MWCNT is described as follows: 50 mg of MWCNT-Br initiator, 15 mg of CuBr/$CuBr_2$ (10/1, molar rate) catalyst, 80 mg of Me_6[14]aneN_4 ligand, a certain amount of AM monomer and DMF solvent were placed in a dried tube and degassed by freeze-pump-thaw cycles three times. Then the tube was sealed under vacuum, immersed in a thermostated oil bath at 40 ^oC immediately and kept stirring for 24 h. After polymerization, the mixture was diluted with a large amount of H_2O and filtrated through a 0.45 μm polytetrafluoroethylene (PTFE) membrane three times to ensure that no any possible un-grafted polymer and free reagents were mixed in the product [13]. The resulting solid was then redispersed in 5 mL of DMF and precipitated in 100 mL of ether. The MWCNT-g-PAM was obtained by filtration and drying. The synthesis route is displayed in Fig. 1.

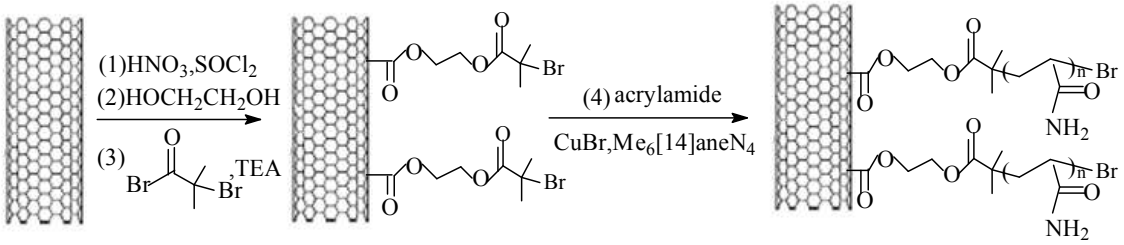

Fig. 1. Formation of MWCNT-*g*-PAM.

Characterization

^{1}H NMR spectra were performed in an AV-300 NMR spectrometer (BRUKER BIOSPIN AG, Switzerland), using D_2O as solvents. The IR spectra were recorded in solid state using KBr pellet. A MAGNA-IR 750 (Nicolet Instrument Co. U.S.A) was used to record the spectra in the range of 400–4000 cm^{-1}. The morphologies of the MWCNT-g-PAM was studied by transmission electron microscopy (TEM) performed on a JEOL – 2010 (JEOL, Japan). Thermal gravimetric analysis (TGA) was carried out on a PE TGA-7 instrument at a heating rate of 10 ^oC /min under nitrogen.

Results and Discussion

Fig. 2 reveals the representative FT-IR spectra of crude MWCNTs and the MWCNT-*g*-PAM. The crude MWCNTs reveal that the characteristic stretching vibration signal is hardly detected, but clearly observed for the MWCNT-*g*-PAM. The–NH stretching which appeared as a shoulder band around, 3200 cm^{-1} of the graft copolymer, has overlapped with a broad peak 3420 cm^{-1} of the hydroxyl group. The characteristic absorption peaks C-H at 2926 cm^{-1} can be found in FT-IR spectra of MWCNT-*g*-PAM. The band at 1656 cm^{-1} is due to the carbonyl group of amide moiety of the grafted AM chain, the presence of the above bands in the graft copolymer gives strong evidence of grafting.

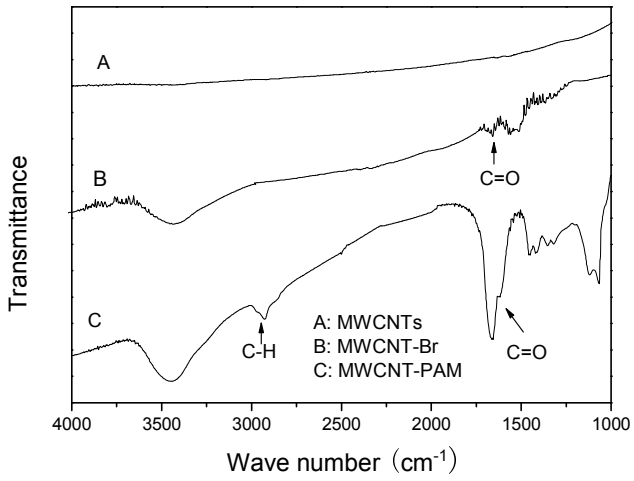

Fig. 2. FT-IR spectra of (A) MWCNTs, (B) MWCNT–Br and (C) MWCNT-*g*-PAM.

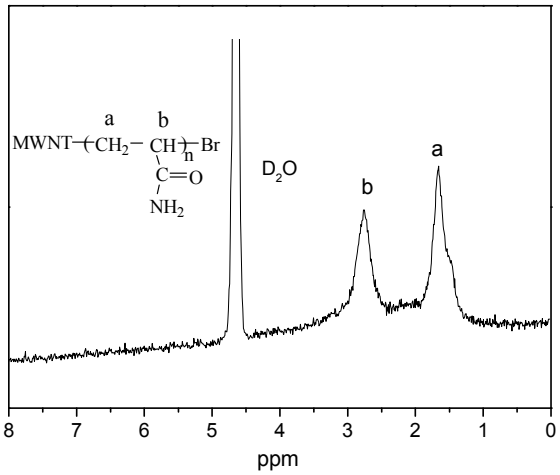

Fig. 3. ^{1}H NMR spectra of MWCNT-*g*-PAM.

The formation of MWCNT-*g*-PAM can be verified by its ^{1}H NMR spectrum shown in Fig.3. The integration ratio of peaks d=1.5–1.9 (a) and d=2.5–3.1 (b), which are the peaks of methene and methine protons in the main chain of PAM, is 2:1, indicating the formation of PAM.

The TGA results were shown in Fig. 4. For MWCNT, there is only a very slight decomposition before 450 °C and a weak thermal decomposition peak appeared nearby 110 °C, which is related to the hydroxyl part on the carbon nanotubes. After grafting, the weight loss before 450 °C increased. A thermal decomposition peak appeared between 245 and 345 °C. This peak should be attributed to the decomposition of the grafted polymer part. The loss-weight fractions (fwt) of the polymer layers for the MWCNT-*g*-PAM ranging from about 20 % to 30 % were determined from TGA data and increased with an increase in the weight ratio (Rwt) of AM monomer to MWCNT-Br initiator, indicating that the contents of the polymer side chains on the functionalized MWCNTs can be controlled by Rwt. The average Mw of grafted PAM side chains on MWNT-*g*-PAM calculated from TGA data. $Mw= fwt/[(1-fwt)\times 0.71\times 10^{-3}]$. herein, 0.71 represents the concentration of ATRP initiator sites per gram of neat MWCNTs (mmol/g). In order to compare conveniently, we assume that every ATRP initiator site participates in the polymerization reaction. so the calculated Mw of the grafted PAM is 1500. The major decomposition temperature corresponding to surface grown PAM on MWCNTs is higher and wider than that of pure PAM. All these results indicate that the PAM was covalently linked to MWCNTs.

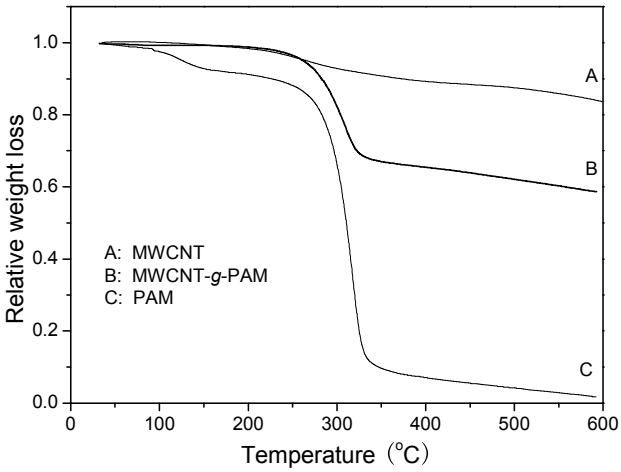

Fig. 4. TGA curves of (A) MWCNTs, (B) MWCNT-*g*-PAM, (C) PAM

MWCNTs and the MWCNT-*g*-PAM were mixed in water by sonication for 30 min at room temperature. MWCNTs were deposited to the bottom in water within seconds (Fig. 5A), a very stable solution of MWCNT-*g*-PAM in wate was observed (Fig. 5B)

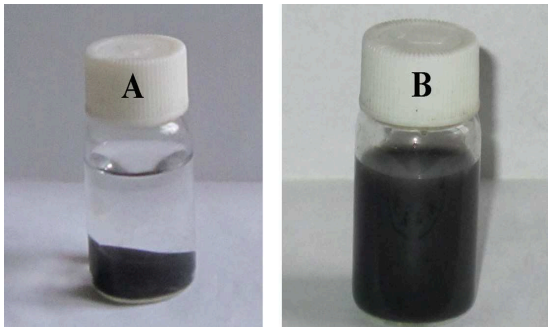

Fig. 5. Solubility of the (A)MWCNTs and (B)MWCNT-g-PAM in water.

A few drops of MWCNT-*g*-PAM composites dispersion in water was deposited onto carbon-coated grids, TEM images were observed after the solvent was evaporated. Fig.6 shows the TEM images of the pristine MWCNTs and the MWCNT-*g*-PAM composites. Very well separated MWCNTs are observed in Fig 6B, while the pristine MWCNTs are densely entangled as shown in Fig. 6A. After coated with PAM, a thin layer and several protuberances of the polymers were accreted on the surface of the MWCNTs. This reveals that the PAM chains grafted onto the surface of MWCNTs.

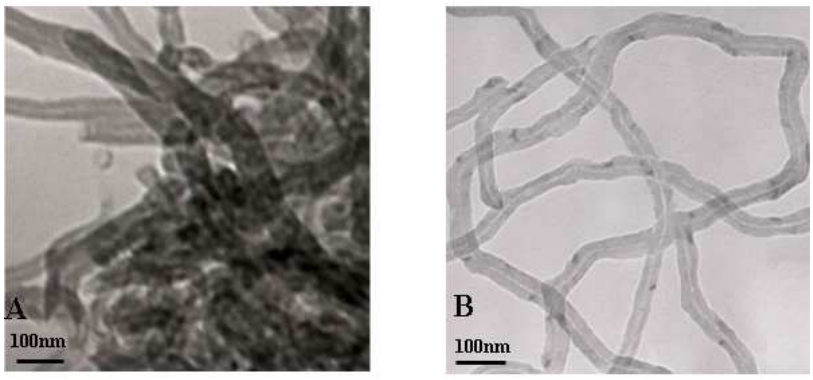

Fig. 6. TEM micrograph of (A) MWCNTs and (B) MWCNT-*g*-PAM in water.

Summary

A novel approach to the functionalization of pristine MWCNTs has been successfully carried out. FT-IR and NMR were used to verify the success of the graft polymer formation. Both debundling of MWCNT ropes and polymer attachment are achieved in a single step. Detailed research by TGA and TEM demonstrates that PAM were probably strongly anchored on the side walls of the nanotubes. This convenient noncovalent method can be employed to graft other functional polymer chains onto MWCNTs, and may be useful for the preparation of MWCNT- polymer hybrid nanomaterials without risking the destruction of the intrinsic graphitic structure of the pristine MWCNTs.

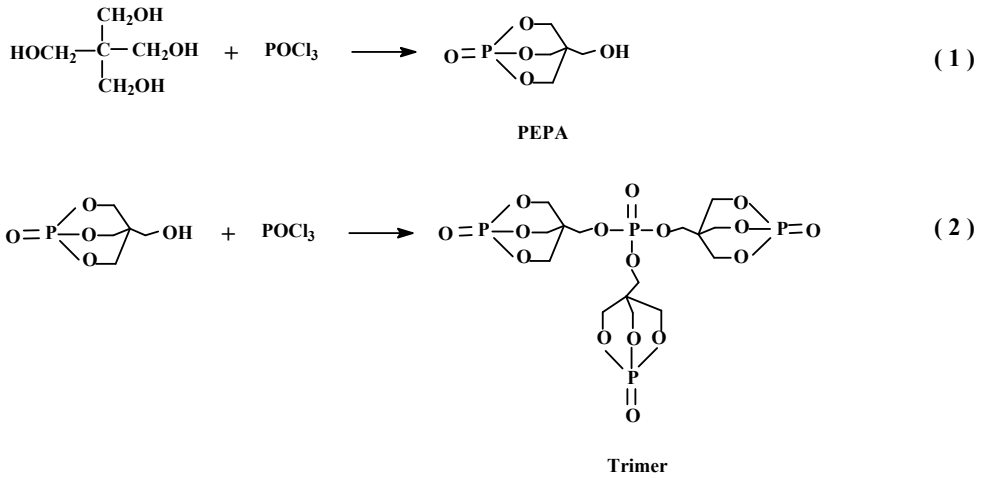
Keywords: PP; EVA; Intumescent flame retardant; Caged bicyclic phosphate; Thermal degradation

Abstract: Polypropylene (PP) and ethylene vinyl acetate copolymer (EVA) were treated with intumescent flame retardants containing caged bicyclic phosphates. The behavior of thermal degradation of the flame-retarded PP and EVA were studied by TG, DSC, and the FTIR spectra of PP's residues at different temperature were recorded. In addition, the possible thermal degradation and char formation mechanisms were analyzed and discussed.

Introduction

Polyolefinic polymers and copolymers are widely used in many industrial and agriculture fields. Due to their chemical constitution, these polymers are easily flammable, and so flame retarding is required for a great number of applications of polyolefins. There exist several ways to impart them flame retardancy. One of the solutions is to corporate additives into the base polymers. Up to now, the most effective flame retardant additives in polyolefines are halogen-antimony systems. But the corrosiveness, the toxicity of their combustion products and the smoke production have limited the applications of these systems. At the present time, certain sections of industry, notably those concerned with aerospace, electronics, cable and wire manufacture, are particularly interested in halogen-free flame retardants, such as phosphorus-nitrogen systems which are known as intumescent flame retardants. They do not present serious corrosive and toxic gases problems and produce much less smoke in comparison with halogen-antimony formulations [1].



In this work, we have studied the thermal degradation behaviour of PP and EVA treated with halogen-free intumescent flame retardants containing caged bicyclic phosphate. The aim of our work is to study the effects of the intumescent flame retardants based on caged bicyclic phosphate on the thermal degradation process and mechanism of flame-retarded PP and EVA. In addition, the authors want to examine the char formation performance of the flame retardants studied.

Experimental

Materials. PP(J300, MFI 1.5), EVA(EVA18-3, MFI 2~3; EVA45,MFI 40~60) and APP(A.R. grade) were kindly supplied by Beijing Yanshan Petrochemical Works and Beijing Organic Chemical Works respectively. Both ammonium polyphosphate (APP, Beijing Haotian Additive Works, n~20, N≥12%, P_2O_5≥65%) and melamine(MA) is commercial sample. Both 1-oxo-4-hydeoxymethyl -2,6,7-trioxa-1-phosphabicyclo [2.2.2] octane (PEPA) and tri(1-oxo-2,6,7-trioxa-1-phosphabicyclo [2.2.2] octane-methyl) phosphate (Trimer) are synthesized at the authors' laboratory via the following reactions [2] (Fig.1). All of the reagents and solvents are of analytical grade and were purchased from Beijing Reagent Corporation.

The used flame retardants are two ternary mixtures which are composed of a phosphate, MA and APP. The phosphate Trimer is for the first mixture(IFR-T), and PEPA for the second mixture(IFR-P).

The composition of the two mixtures is as follows: Trimer:APP:MA=100:32:49 (mass ratio) for IFR-T, and PEPA:APP:MA=100:54:54 (mass ratio) for IFR-P.

(1)

(2)

Fig.1. Reaction routes for PEPA and Trimer

Sample Preparation. Ternary mixed flame retardants(IFR-T and IFR-P) were prepared by manual mixing in a mortor and by grinding at room temperature for 3h in a ball crusher.

The flame-retarded PP and EVA samples for testing were prepared by mixing PP(EVA) and IFR-T(IFR-P) in a double roller mixer at 170~175℃, and then pressed on a flat vulcanizer at 160~165℃ for 3~5 min. All of the raw materials were dried at 60℃ under pressure until weight constant before use.

The formulation of tested samples are shown in Table 1.

Table 1. The formulations (wt%) of the tested samples

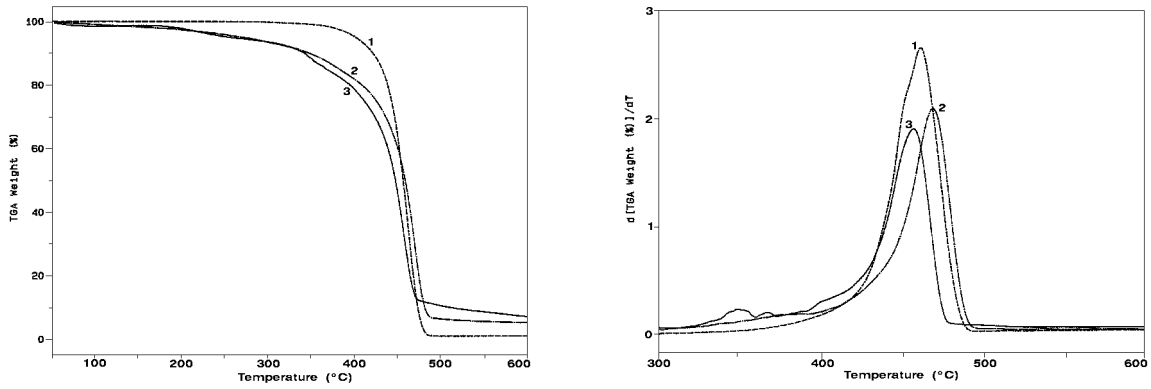
Samples	PP/IFR-T	PP/IFR-P	EVA18/IFR-T	EVA18/IFR-P	EVA45/IFR-T	EVA45/IFR-P
PP	80	80				
EVA18			80	80		
EVA45					80	80
IFR-T	20		20		20	
IFR-P		20		20		20

Measurement and Testing. The TG measurement was done using a Du Pont TGA-2950 thermogravimetric analyzer at a heating rate of 10℃/min in nitrogen with a flow rate of 40mL/min, heating from 50℃ to 600℃.

Powder polymers were thermal degraded at 200℃, 300℃, 350℃, 400℃ and 500℃ respectively for 5 min in a muffle furnace. The obtained residues in KBr discs were recorded on A MAGNA 560 FTIR spectrophotometer.

Results and Discussion

TG Analysis of PP Series. The thermal analysis results of the samples are summarized in Table 2. Fig.2 shows their TG and DTG curves.



It can be seen from Table 2 and Fig.2 that the weight loss of flame-retarded PP occurs at much lower temperature in comparison with pure PP, for example about 130℃ lower for $T_{5\%}$ and 25℃ lower for $T_{10\%}$. This is mainly due to the release of NH_3 and H_2O from MA at relative lower temperature [3]. Among the three samples listed in Table 2, the pure PP has the largest R_{max} and the highest rate of thermal degradation, and PP/IFR-P in the next place, PP/IFR-T the third. Three of them have the weight loss peak on their TG curves in the range of 450~470℃. When vigorous thermal-oxidation takes place to pure PP, it losses its weight rapidly, and the carbon sketch of PP is

destroyed quickly. In the mean time, water vapor, CO, CO_2, hydeocarbons with low molecular mass and aldehydes are produced [4]. The thermal-oxidation reaction proceeds rather thoroughly for pure PP, and it is completely oxidized without any residue left at about 500℃. On the other hand, the intumescent flame retardants (IFR) based on Trimer or PEPA can decrease the weight loss rate, and R_{max} of flame-retarded PP is 0.7%·min^{-1} lower than that of pure PP on the average. When IFR decomposes at high temperature, viscous phosphoramides are formed. The surface of the base polymer is covered by these compounds. As a result, the pyrolysis rate of carbon skeleton of base polymer and the volatility of the pyrolytic products with lower molecular mass can be retarded. Besides, the carbon skeleton can be catalyzed to produce stable network char layer by cross-linking due to the formation of the additional covalent carbon chains. It has been demonstrated that P-O-C bond could provide a link between pyrolytic polymer and alkyl group, and promote the formation of char containing phosphorus. Moreover, P-N bond is also helpful to the formation of corss-linking network structure [5,6]. As was stated above, it can be seen that both IFR-T and IFR-P have the ability to stabilize the carbon skeleton structure of base polymers and to increase the char yield due to cross-linking. IFR-T shows better char formation than IFR-P for PP.

Table 2. TG data of PP series

samples	T5% a / ℃	T10%a / ℃	R maxb / %·min-1	T maxc / ℃	CHRd / %
PP	404.4	422.3	2.688	462.1	0
PP/IFR-T	268.5	344.3	1.903	458.7	10.1
PP/IFR-P	272.6	350.0	2.086	469.5	7.7

[a] $T_{5\%}$ and $T_{10\%}$ represent the temperatures at which the weight loss corresponds 5% or 10% respectively.
[b] T_{max} is the temperature at which the peak of weight loss on the TG curves appears.
[c] R_{max} represents the maximum rate of weight loss.
[d] CHR represents the char yield at 600℃.

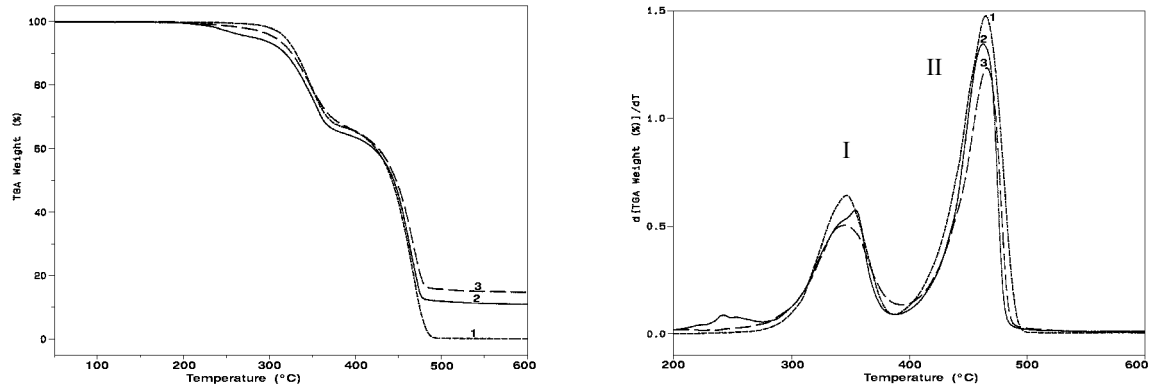
Fig.2. TG(a) and DTG (b) curves of PP system
1: PP; 2: PP/IFR-P; 3: PP/IFR-T



TG Analysis of EVA Series. EVA shows two weight loss peaks on the TG curves within pyrolysis process (see Fig. 3, Fig. 4 and Table 3). The first peak appears at the range of 300~380℃ due to the release of acetic acid from EVA. The height of the first peak increases with the increase of VA, but smaller than that of the second peak which occurs at the range of 410~490℃ corresponding the thermal degradation of EVA's carbon skeleton. There exist short chains in EVA which is formed by the linking of polar acetate group into the ethylene branch chain. Therefore, the thermal degradation of EVA is characterized by the cleavage of side chains and the release of acetic acid, and belongs to the type of chain-stripping degradation. During the pyrolysis of EVA, many reactive centres in the molecular chains are formed, and so char layer will be produced because of the cross-linking between molecular chains. The char formation can be promoted with the increase of VA in EVA [7]. In comparison with flame-retarded PP, IFR retards the degradation of EVA in the second weight loss stage more effectively. Consequently, the char yield of flame-retarded EVA is enhanced. Besides, the

char formation of IFR for EVA45 is better than for the EVA18. In contrary with PP, the char yield of IFR-P is quite higher than that of IFR-T for EVA systems. This indicates that PEPA based IFR is more effective for EVA's char formation from the cross-linking reaction than Trimer based IFR. This is probably due to the fact that PEPA possesses hydroxyl group which reacts with oxygen containing polymers and catalyzes the char formation.

EVA45/IFR-T	276.0	318.0	0.576（353.4℃）	1.348（462.7℃）	15.4
EVA45/IFR-P	304.3	326.0	0.510（344.7℃）	1.243（465.9℃）	18.7

[a] R_I and R_{II} represent the first and the second weight loss peak respectively, and the figures in the parenthesis are the corresponding temperatures.

FTIR spectra of PP series. In order to study the chemical reaction taken place in the process of thermal oxidation-degradation and the resulting char's composition, the FTIR spectra of the residues of flame-retarded PP were recorded. These residues were obtained by the heating PP at different temperature(200~500℃) for 5 min. The FTIR spectra are shown in Fig.5.

(a) PP/IFR-T (b) PP/IFR-P

Fig.5. FTIR spectra of residues of PP series

The FTIR spectra of residues obtained by heating both PP/IFR-T and PP/IFR-P at 500℃ have the similar patterns. This demonstrates that the compositions of these two residues might be nearly the same. In these two spectra, there exist absorption peaks due to P-O-C bonds (at 1000cm^{-1}) [5], polyaromatics (at 1628cm^{-1}), C=N bonds (at 2370cm^{-1}), carbon skeleton of PP (at 2930~2950cm^{-1}) and OH group from phosphoric acid and polyphosphoric acid (at 3400cm^{-1}). The last two peaks from PP/IFR-T are broader than those from PP/IFR-P. It may be considered that the residues formed by heating flame-retarded PP contain polyaromactics, incompletely burned carbon-carbon chains, phosphoric acid or polyphosphoric acid and species containing C=N bonds [8]. The absorption peak due to polyaromatic appears in the FTIR spectrum of residue obtained from heating flame-retarded PP at 350℃ for PP/IFR-T system, while at 300℃ for PP/IFR-P system. In addition, the FTIR spectrum at PP/IFR-P system at 300℃ has already got much changes. This proves that the carbon-carbon skeleton of PP/IFR-P thermally degrades at lower temperature than that of PP/IFR-T. For both systems, the absorption peak due to P-N bond [9] at 1406cm^{-1} appears at 350℃, and this peak has strengthened significantly at 400℃ but disappeared at 500℃. It is thought that P-N bond is formed at relatively low temperature, and involved in the cross-linking reactions. At higher temperature, P-N bond is not likely to form. Therefore, it is probably impossible to find $(PN)_x$ structure in the residue formed at high temperature.

It is evident from the FTIR spectra and TG curves of the flame retardant systems that the heat resistance of PP/IFR-T is better than that of PP/IFR-P in air. The carbon skeleton of the former has not been completely destroyed at 400℃ in air. But in nitrogen, PP/IFR-T has lost 5% of its weight at 268.5℃, and 10% at 344.3℃, while the corresponding temperatures of PP/IFR-P are 272.6℃ and 350.0℃ respectively, about 5~6℃ higher than those of PP/IFR-T. The possible explanation for this might be the difference of pyrolysis model and pyrolytic rate for these two flame retardant systems.

Summary

1. In comparison with pure PP, the initial weight loss temperature and the 5% weight loss temperature of PP/IFR-T and PP/IFR-P are lowered about 130℃ and about 75℃ respectively. The

rate of thermal pyrolysis and weight loss rate have been notably decreased, and the char yield and the stability of char layer increased for the flame-retarded PP.

2. The pyrolysis of flame-retarded EVA with IFR-T or IFR-P proceeds in two stages. The weight loss of the first stage is smaller than that of the second stage. The intumescent flame retardants used can effectively retard EVA's pyrolysis in the second stage, and can promote the char formation via cross-linking reactions. PEPA is better than Trimer for EVA's char formation because of the existence of hydroxyl group in PEPA's molecule.

3. The ability of char formation of IFR-T for PP is better than that of IFR-P, and the thermal oxidation-resistance of the char layer produced from PP/IFR-T is higher than that from PP/IFR-P.

4. Both PP/IFR-T and PP/IFR-P produce P-N bond at relatively low temperature, and this bond may be involved in the cross-linking reaction. But it might be impossible to find $(PN)_x$ structure in the residues fromed at higher temperatures.

Keywords: Al/Mg_2Si composites; casting; Pr addition; microstructure; tensile properties

Abstract: The effect of different concentrations of Pr on the microstructure and tensile properties of cast Al-18 wt.%Mg_2Si in situ metal matrix composite was investigated. The results show that the addition of proper amount of Pr has significant modification effect on primary Mg_2Si in the Al-18 wt.% Mg_2Si composite. With the increase of Pr content from 0.1 to 0.7%, the morphology of primary Mg_2Si is changed from irregular or dendritic to polyhedral shape, and its average particle size is significantly decreased from 65 to 17 μm. When the Pr content exceeds 1.0%, the primary Mg_2Si become coarse again. Tensile tests reveal that the Pr addition improves the tensile strength and ductility of the material. Comparing with those of unmodified composite, the ultimate tensile strength and percentage elongation with 0.7% Pr are increased by 36.5% and 161.6%, respectively.

Introduction

Al-based composites reinforced by in-situ Mg_2Si particles have been lately introduced as a new group of particulate metal matrix composites (PMMCs) with attractive advantages such as low specific gravity, high strength at elevated temperature, excellent wear resistance, and low coefficient of thermal expansion, since the intermetallic compound Mg_2Si formed on solidification exhibits a high melting temperature, low density, high hardness, low thermal expansion coefficient and reasonably high elastic modulus [1]. Thus, the Al-Mg_2Si in-situ metal matrix composites have high potential as candidates to replace Al-Si alloys used in aerospace and automotive applications, in particular in the applications where the alloys are a substitute for cast iron when the engineering advantage of light weight and wear resistance in service are considerations such as for the production of engine blocks, air compressor cylinders and cylinder heads. However, conventional casting process usually produces coarse primary or eutectic Mg_2Si phases, and the Mg_2Si particles themselves are hard and brittle, which causes the serious disseverance to the matrix and stress concentration at the tips or edges of the Mg_2Si particles, leading to the cracking at the grain boundary or in Mg_2Si particles oneself, thereby, mechanical properties, especially elongation are significantly reduced.

Chemical modification is a simple and effective technique for improving the morphology and size of Si particles in Al-Si alloys, which was usually used in the industrial field. Recently, several investigations have been carried out for the modification of primary and eutectic Mg_2Si crystals in Al-Mg_2Si, Al-Si-Mg_2Si and Mg-Si-Mg_2Si composites by the additions of P [2], Sr [3], RE elements such as Y[4], Nd [5] and Ce [6], Li [7] and Na [8] to the melts.

Past investigation concentrated on RE modification on Mg_2Si phase, but the influence of RE on the mechanical properties of Al/Mg_2Si composites was rarely reported. The present study first investigates the modification effect of RE element Pr on the Mg_2Si phase in Al/Mg_2Si composite, and then an attempt was made to reveal the tensile properties of the composite with different amounts of Pr additions. The relationship between tensile properties and microstructures was also discussed.

Experimental procedure

Commercially pure aluminum (ingot, 99.1% purity), magnesium (ingot, 98.5 % purity), silicon (block, 98.4 % purity) and Al-10Pr master alloy were used as precursor materials to prepare Al–18

wt.% Mg_2Si composite. Aluminum ingot and silicon blocks were charged into a graphite crucible and heated in an electric resistance furnace, and then the different amounts of Pr were introduced into the melt by adding Al-10Pr master alloy at 800℃. The Pr level, ranging from 0.1 to 1.3 wt% in step of per 0.1 wt%, was added into the melt. After that, magnesium blocks were added into the melt when temperature dropped to about 720℃. Then the melt was degassed with C_2Cl_6. After gently stirred, the melt is cast into a steel mold preheated at 200℃ to produce 30 mm diameter rods.

All the specimens for microstructure characterization were cut from the same positions of the ingots at 10 mm from the bottom of the castings. The specimens were mechanically ground, and then polished through standard routines. Each cross section was etched using 0.5vol% hydrofluoric acid (HF) water solution. The microstructures of the composites were investigated by a optical microscope (OM). The average grain size was measured by linear intercept method.

Tensile properties at room temperature were conducted using a computer controlled universal tensile testing machine. For each group, four tensile test specimens were used. Each value of tensile properties was the average value of four tensile specimens.

Results

Microstructure

Fig. 1 show the optical microstructures of the composites containing different amounts of Pr. From Fig. 1, the dark particles are primary Mg_2Si, the gray matrix is (α-Al+Mg_2Si) binary eutectic, and the white phase surrounding the primary Mg_2Si or in the eutectic matrix is primary α-Al. As can is seen from Fig. 1a, the morphology of the primary Mg_2Si particles of the unmodified composite shows a mixture of coarse dendritic and polyhedral shape. The average diameter of the Mg_2Si particles reaches 64.7 μm and the size distribution is far from uniform, the maximum is near 92 μm and the minimum only is 27 μm. The addition of Pr produces modification effect on primary Mg_2Si and efficiency depends on the addition level of Pr. With 0.1 and 0.4%Pr addition, the morphology of

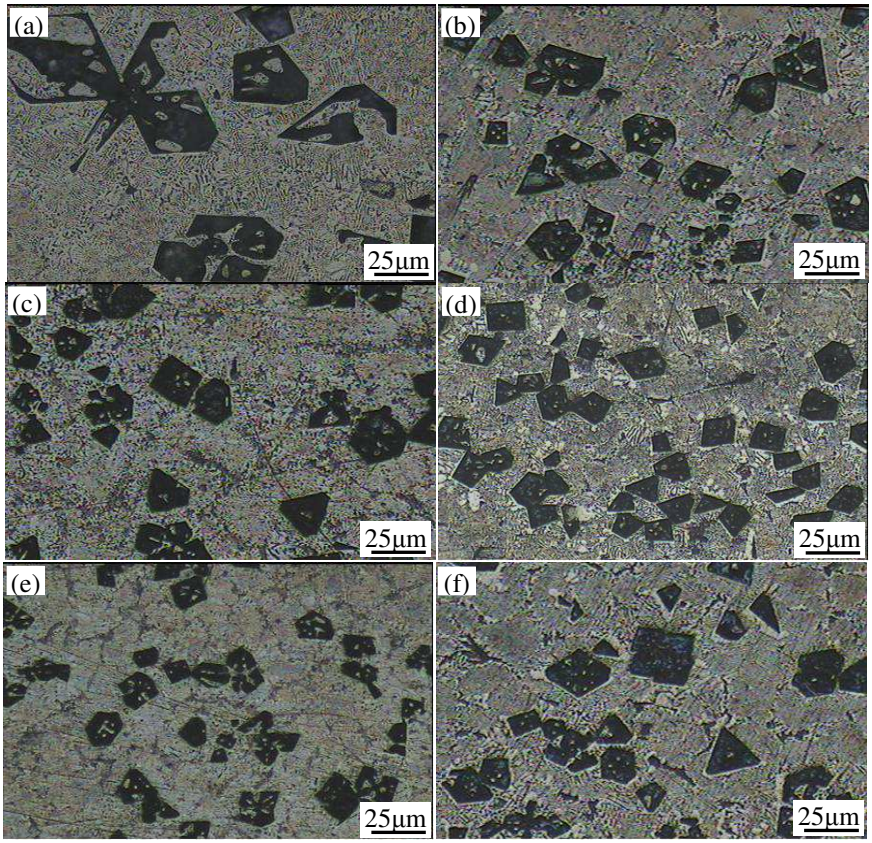

Fig. 1 Optical microstructures of the Al-18wt.%Mg_2Si composites containing different amounts of Pr (wt.%): (a) 0, (b) 0.1, (c) 0.4, (d) 0.7, (e) 1.0 and (f) 1.3.

primary Mg_2Si do not be changed significantly, but their sizes are decreased to 35.2 and 28.6 μm, respectively (Fig. 1b and 1c). As the addition level of Pr increases to 0.7%, the size of primary Mg_2Si further is reduced to 17.3 μm or less, and its morphology transforms into fully polyhedral morphology (Fig.1d). The addition of 1.0%Pr done not obviously change the morphology and size of primary Mg_2Si, and its morphology still keeps the irregular and polyhedral modified morphology (Fig. 1e). However, when the addition level of Pr is further increased to 1.3%, it is found that some coarse Mg_2Si particles are formed again, but smaller than that in the unmodified composite. As compared to those in Fig. 1(d) and 1(e), its sizes increases to about 31.4 μm, although there is no obvious change in the modified morphology of primary Mg_2Si (Fig. 1f). It should be noticed that the additions of 0.7%Pr of the particles more uniform, as shown in Fig. 1(d). Based on the experimental results, it can be concluded that minor Pr (less more 0.4 %) results in partial modification on primary Mg_2Si, while more Pr additive (0.7–1.0 wt%), produces full modification. But, excess Pr (1.3%) leads to the appearance of over-modification phenomenon. The variation of primary Mg_2Si grain size with different Pr is shown in Fig. 2.

Tensile properties

The influence of Pr addition level on the tensile properties of the composites is shown in Fig. 3. It is seen that the trend of variations in the ultimate tensile strength (UTS) and percentage elongation (EL) of the composites with Pr content was similar, i. e. the UTS and EL of the composites increased firstly with an increase in Pr content and then decreased. The unmodified composite had an UTS of 191 MPa with an elongation of 0.73%, while the UTS of 0.7%Pr-modified composite was 262 MPa with an elongation of 1.90%. The tensile strength and elongation of modified composites increased 36.5% and 161.6%, respectively. However, excess Pr (1.3%) decreases UTS and EL to 245 MPa and 1.22%, respectively.

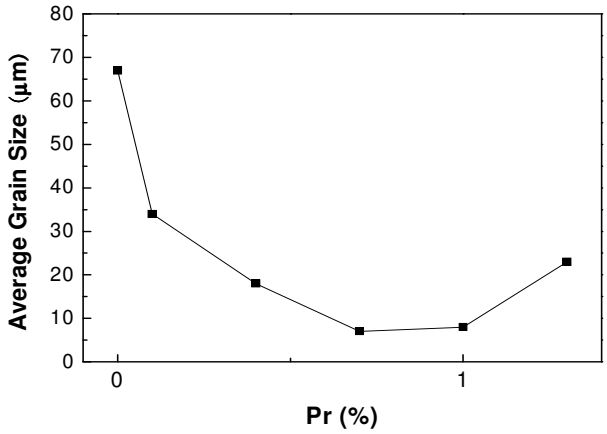

Fig. 2 The variation of primary Mg_2Si grain size with different Pr contents

The reason for the refinement of Mg_2Si crystals by the addition of Pr might be related to the composition supercooling caused by the segregation of Pr at the front of the solid/liquid interface of Mg_2Si during solidification. It can be considered that because of the extremely low solidity of Pr in the Al matrix, the Pr element is easy to congregate at the growing interface of Mg_2Si, resulting in a local composition supercooling in the alloy melt. With the concentration increase of Pr, the composition supercooling is further increased. When the concentration of Pr reaches a certain extent, the growth of Mg_2Si phase can be suppressed and thus its crystals become fine. Another refining reason might be because Pr addition may create some distortion in the Mg_2Si lattice due to a high solidity limit of Pr in Mg_2Si and the larger radius size of Pr atom, and thus change the surface energy of the Mg_2Si crystals. Therefore, Pr addition may arrest and suppress the anisotropic growth of the Mg_2Si dendritic morphology. With regards to the detailed modifying mechanism, there is still a need for further research to be carried out. Variations in the tensile properties for Al-18 wt.%Mg_2Si in situ metal matrix composites are mainly be due to the change in the average sizes of primary Mg_2Si particles. Above studies have revealed that the variation tendency of the UTS and EL with Pr content

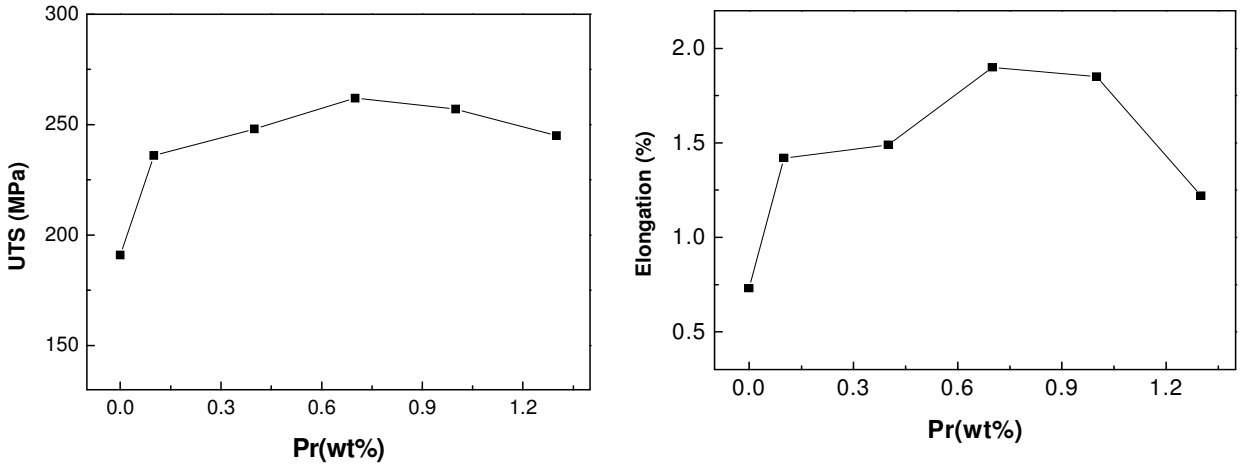

Fig. 3. The curves of tensile properties vary with the contents of Pr

for the composites basically is similar to that of primary Mg_2Si with Pr content. For particulate metal matrix composite, the matrix receiving load plastically deforms and stress transfers to the particles via interface during stretching process. The primary Mg_2Si particles in the unmodified composite are coarse and prone to crack because coarse particles permits larger defects to be presented in the particle, which cause it to have a lower fracture stress [9]. When small uniaxial tensile loading exerts on the sample of the material, the primary Mg_2Si particles first cracks. Consequently, the stress intensity in the matrix bounded on the tip of the cracks of the broken Mg_2Si crystallites increases, rapid crack propagation takes place, resulting in the premature failure and the low fracture strength of the whole composite (Fig. 3), which is similar to the embrittlement in the unmodified hypereutectic Al-Si alloy [10] and an angular particulate-reinforced 6061-Al composite containing 20 pct vol Al_2O_3. On the contrary, the modified composite has fine primary Mg_2Si particles. These particles do not crack prematurely after yielding large loading, then retard the crack formation and propagation in the matrix during stretching process, and therefore, the modified composite possessed better plasticity and strength (Fig. 3). On the other hand, the uniformity distribution of the primary Mg_2Si particles in the modified composite (Fig. 1d) could also enhance the strength and ductibility, which has also been demonstrated in many PMMCs such as aluminum 6092/B4C composite.

The decrease of tensile properties for 1.0 and 1.3%Pr-modified composite might be attributed to the existence of Pr-containing brittle intermetallic compounds. And as the Pr additive increases, the relative amount of Pr-containing intermetallic compounds increases. So, the tensile properties in the Pr-modified composite are influenced. It was also confirmed that the formation of MM-containing intermetallic compounds decreases the tensile properties of A356 alloy [13]. In the present study, the addition of Pr increases UTS and EL until the amount of Pr reaches 1.0%. This probable is because the temperature of melting Al-MM master alloy is low (725℃), MM-containing intermetallic compounds such as Al_4La, AlCe, Al_2Ce, $A_{11}Ce_3$ and $A_{11}La_3$ existing in Al-MM master alloy are not melted and remained in the microstructure of materials, which deteriorates tensile properties. While the temperature of melting Al-Pr master alloy in our experiment reaches 800 ℃, so Pr-containing intermetallic compounds are melted and then Pr solubilizes in Al matrix when amount of Pr is small, and Pr-containing intermetallic compounds precipitate when amount of Pr is large in subsequent solidification process. Only the latter lowers tensile properties of the composite.

Conclusions

The influences of different Pr contents on the microstructures and tensile properties of in situ Al-18 wt,% Mg_2Si composites were investigated. The following conclusions can be drawn:

(1) The addition of proper amount of Pr is found to be modifying the primary Mg_2Si in the composites.

(2) With the increase of Pr content, primary Mg_2Si particle morphology is changed from dendritic to polygonal, and its size decreases from 65 to 17 μm. When the Pr exceeds 1.0 wt.%, the size of the primary Si becomes larger furthe.

(3) The tensile properties of the modified composite are improved by adding suitable amount of Pr. After modification with 0.7 % Pr, the ultimate tensile strength (UTS) increased about 36.5% from 191 to 262 MPa and percentage elongation (EL) increased about 161.6% from 0.73 to 1.90%. The refined primary Mg_2Si particles have a higher fracture stress and resistance of crack, which leads to the enhancement of tensile properties.

Keywords: 9,9-bis(4-hydroxyphenyl)fluorene; organic silicon-modified epoxy resin; curing kinetics

Abstract: A new epoxy resin based on dichlorosilane and 9,9-bis(4-hydroxyphenyl)fluorene was synthesized to produce a highly heat-resistant network. The chemical structure was characterized with FTIR spectroscopy and 1H-NMR. 4-4′-Diaminodiphenylsulfone (DDS) was used as the curing agent. The curing kinetics of different epoxy/DDS systems were investigated using non-isothermal differential scanning calorimetry (DSC). The results showed that the values of activation energy (E) were affected by the chemical structure of epoxy resin, and BPEBF exhibited lower curing reactivity towards DDS compared to E-51.

Introduction

Epoxy resins have been widely applied in polymer industry fields as structural adhesives, coatings, encapsulation material, insulating materials and composite matrices due to their superior electrical and mechanical properties, low shrinkage, good cohesiveness, excellent moisture and chemical resistance in comparison with many materials[1-5]. However, the conventional epoxy resins do not posses adequate thermal and mechanical properties to meet the requirements of high performance structural products [3, 6, 7]. Thus, designing novel high-performance epoxy resins have been the trends of recent studies [8-10].

Introducing siloxane (Si-O bond) into the epoxy skeleton is considered to be an effective way to improve thermal properties of epoxy resins, owing to its superior thermo-oxidative stability. In the past few years, many researchers have synthesized various kinds of siloxane-modified epoxy resins. It has been confirmed that the incorporation of siloxane into epoxy can noticeably enhance the thermal stability of siloxane-modified epoxy resins [11-16].

In this work, a novel organic silicone epoxy resin containing fluorene (BPEBF) was synthesized and characterized with FTIR spectroscopy and ^{1}H-NMR. The epoxy resin was cured with 4-4′-Diaminodiphenylsulfone (DDS). The curing kinetics were studied with dynamic differential scanning calorimetry (DSC) and simulated with both Kissinger and Ozawa methods.

Experimental

Materials

9,9-Bis(4-hydroxyphenyl)fluorene, Dichlorodiphenylsilane, Tetrabutyl ammonium bromide (TBAB) and Epichlorohydrin were obtained from Sigma-Aldrich. 4,4'-Diaminodiphenylsulfone (DDS) and bisphenol A epoxy resin E51 were provided by Sinopharm Chemical Reagent Co., Ltd. All chemical agents were used without further purification.

Synthesis of BPEBF

9,9-Bis-(4-hydroxyphenyl)-fluorene and anhydrous 1,4-dioxane were added into a round bottom flask and heated to 40 °C. Dichlorodiphenylsilane was added dropwisely to the solution. Hydrogen chloride was expelled by bubbling dry nitrogen. The reaction was stirred at 40 °C for 4 hours and heated to 70 °C followed by addition of ECH, TBAB and aqueous NaOH solution (50 wt %). The reaction was stirred for another 4 hours and cooled to room temperature. Excess ECH and solvent were removed and the residue was washed with water and ethanol leading to a white precipitation. Pure silicone epoxy resin containing fluorene was obtained by recrystallization from acetone/ethanol (5:1, v/v) in 65% yield.

Result and discussion

Synthesis and characterization

Scheme 1 presents the chemical structure and the procedure for the synthesis of silicone epoxy resin containing fluorene, which is denoted as BPEBF. Pure BPEBF was obtained by recrystallization from acetone/ethanol as white podwer. The melt point of BPEBF is 180 °C determined by DSC.

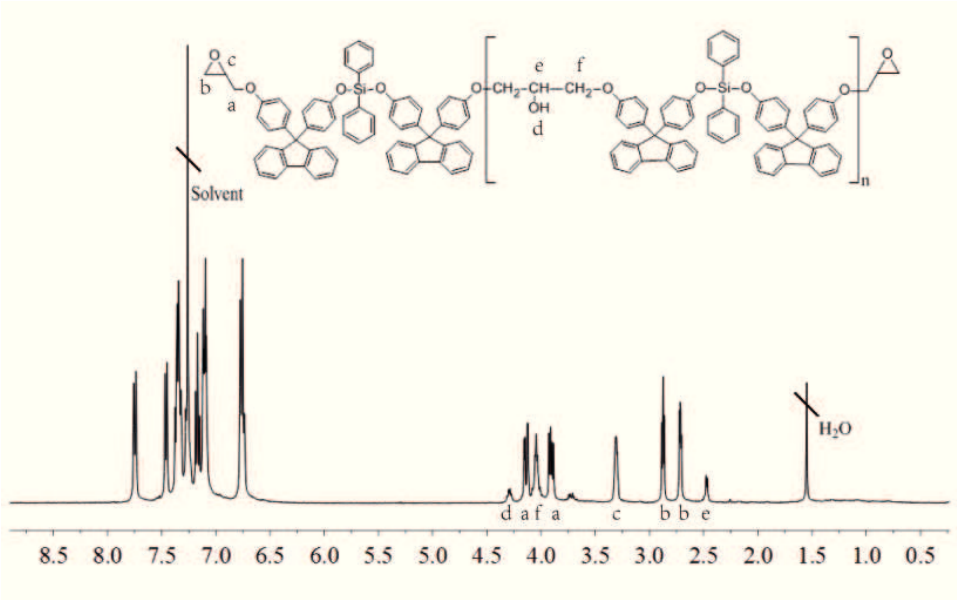

Fig. 1. 1H NMR spectrum of silicone epoxy containing fluorene (BPEBF) in CDCl3.

Fig. 1 shows the ^{1}H NMR spectrum of BPEBF in $CDCl_3$. The chemical shifts at 7.34 – 7.76 are attributed to the protons on fluorene and peaks at 6.75-7.19 are attributed to the protons on phenyl groups. The characteristic chemical shifts of oxirane can be clearly read at 4.12, 3.91, 3.30 2.87 and 2.71. FTIR was also used to characterize the structure of BPEBF. The characteristic absorption peaks of phenyl-oxide-silicone at 1245 cm^{-1} and absorption peak of oxirane at 913 cm^{-1}, 1243 and 1034 cm^{-1} are attributed to the stretching vibrations of C-O-C, 1119 and 1111 cm^{-1} indicate the phenyl-silicone-phenyl stretching vibration. Epoxy equivalent weight titration results showed the EEW of BPEBF is 500 g / eq.

Curing kinetics of epoxy resin-DDS systems

The curing behavior and kinetics of a novel silicon-modified epoxy resin containing fluorene (BPEBF) was studied by DSC technique together with E-51 epoxy. Figure 2 shows the DSC thermograms of different epoxy/diamine systems at heating rates of 5, 10,15 and 25 °C/min. From Figure 2, information about the nature of the curing reaction such as initial curing temperature (T_i), peak temperature (T_p), final curing temperature (T_f) and the curing range at different heating rates

could be derived. The peak temperatures of different systems obtained are summarized in Table 1. Meanwhile, as can be seen from the thermograms that the exothermic peak shifts to a higher temperature with higher heating rate.

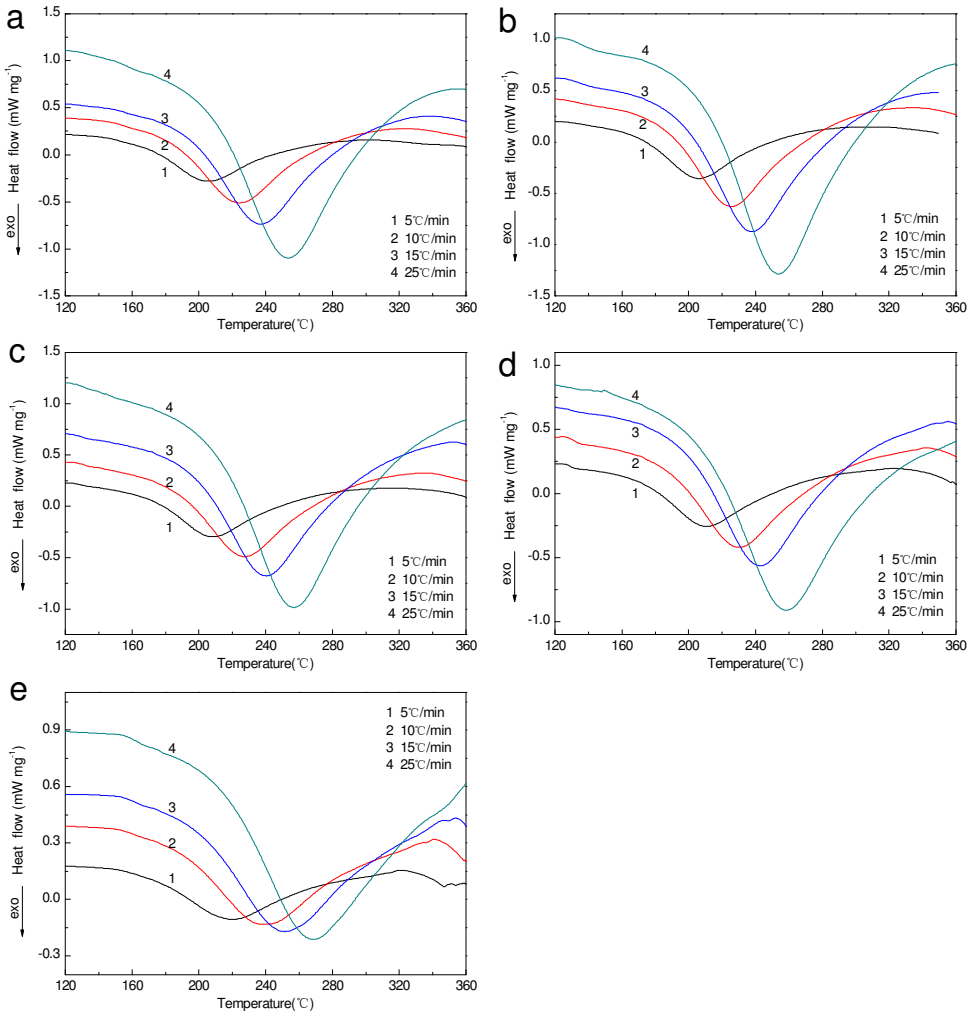

Figure 2 Dynamic DSC thermograms for different epoxy/DDS systems at heating rates of 5, 10, 15 and 20 oC/min under nitrogen atmosphere. (a) E-51/DDS; (b) B0.1E0.9/DDS; (c) B0.2E0.8/DDS; (d) B0.3E0.7/DDS ; (e) BPEBF/DDS.

To evaluate the kinetic parameters of the epoxy/diamine systems, the well-known Kissinger and Ozawa methods were applied to calculated the activation energy (E) and the pre-exponential factor (A) because of their simple ways to deal with the dynamic curing process. Kissinger method is based on the fact that T_p varies with the heating rates, and it assumes that the maximum reaction rate occurs at the peak temperature. The Kissinger's equation can be expressed as Eq. (1):

$$\ln\frac{\beta}{T_p^2} = \ln\left(\frac{AR}{E_k}\right) - \frac{E_k}{RT_p} \tag{1}$$

where β is the heating rate and R is the ideal gas constant. The E_k values of curing can be derived from the slope of $\ln(\beta/T_p^2)$ versus $1/T_p$ plot. Figure 3 shows the plots of $\ln(\beta/T_p^2)$ versus $1/T_p$ for

different cured systems. For Ozawa's method, it's on the assumption that the degree of conversion at peak temperature for different heating rates is constant. Ozawa's equation can be expressed as follows:

$$\ln \beta = -5.331 - 1.052\left(\frac{E_o}{RT_p}\right) + \ln\left(\frac{AE_o}{R}\right) - \ln f(\alpha) \tag{2}$$

Thus, E_o could be obtained by plotting lnβ versus $1/T_p$, as shown in Figure 4. According to the Kissinger method, the pre-exponential factor A can be calculated with Eq.(3):

$$A \approx \frac{\beta E \exp\left[E / RT_p\right]}{RT_p} \tag{3}$$

In addition, when the value of E_k was introduced into the Crane's equation[17], as shown in Eq.(4), the curing reaction order (n) could be obtained from the slope of lnβ versus $1/T_p$ plot when E_k/nR is much higher than $2T_p$. All the results obtained are summarized in Table 2.

$$\frac{d(\ln \beta)}{d(1/T_p)} = -\left[\frac{E_k}{nR} + 2T_p\right] \tag{4}$$

As can be seen from Table 2, the E values calculated from Ozawa method were slightly higher than that of the Kissinger method. The differences may be caused by their different assumptions, but the trend of E values determined by both of methods was consistent with each other. Table 1 and Table 2 showed that the T_p and E values of BPEBF/DDS system were higher than that of E-51/DDS system, respectively. And they increased with increasing the content of BPEBF in mixture resins. This results mean that BPEBF exhibited lower curing reactivity compared to E-51 and would require a higher curing temperature. The decreased reactivity of BPEBF can be obviously attributed to the steric hindrance based on the fluorene structure, which may reduce the molecular mobility and depress the reactivity of reactive group. In addition, the reaction orders of these five epoxy/diamine cured systems were very close to each other and all less than 1, which mean that the reaction type of these systems was all the same but the cure reaction may proceed complicatedly.

TABLE 1 PEAK TEMPERATURE (TP, OC) OF CURE EXOTHERMS FORTHE EPOXY/ DDS systems at different DSC heating rates (β)

samples	β (°C/min)

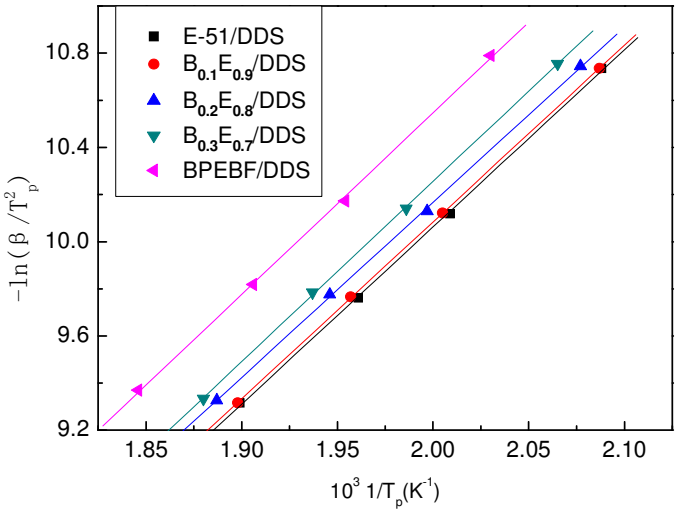

Figure 3 Plots for determination of the E and A by Kissinger method of different epoxy/DDS systems

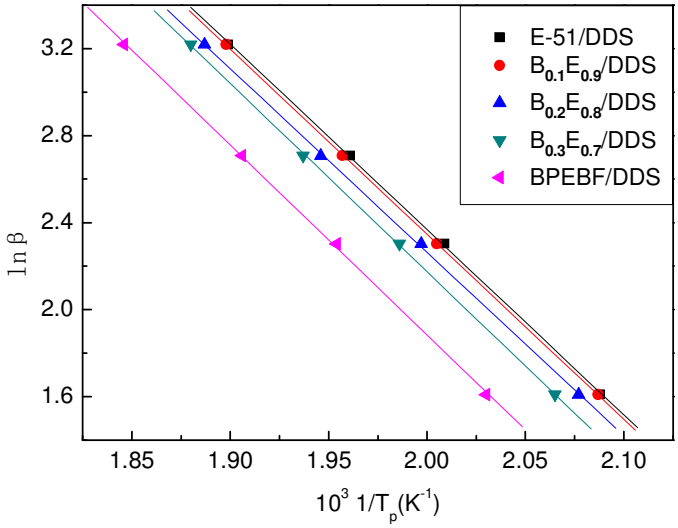

Figure 4 Plots for determination of the E and A by Ozawa method of different epoxy/DDS systems

Conclusions

A novel organic silicon-modified epoxy resin containing fluorene (BPEBF) was successfully synthesized and characterized. The DSC analysis indicated that BPEBF exhibited lower curing reactivity towards DDS compared to E-51 and would require a higher curing temperature. BPEBF might become an attractive candidate for electronic encapsulation materials, laminate materials and high performance composite materials.

Keywords: urushiol; polystyrene; renewable resources; core @ shell composite particles

Abstract: The core @ shell composite particles of polystyrene @ urushiol-titanium chelate polymer (PS @ UTi) was prepared through in-situ reaction between sulfonated polystyrene microspheres coated tetrabutyl titanate and urushiol. The resultant PS @ UTi was characterized by scanning electron microscope and transmission electron microscope. Results indicated that the PS @ UTi with the excellent properties of raw lacquer was synthesized. The shell thickness of UTi coated on PS was tunable by changing the sulfonation time.

Introduction

The core @ shell composite particles has increasingly attracted interest because of their unique electronic, optical and catalytic properties [1,2]. They show broad potential applications in photovoltaic [3] and biological [4] applications, catalysis [5], Janus materials [6,7], etc. There are various core @ shell types, including inorganic/inorganic, inorganic/organic, organic/inorganic, and organic/organic materials. Some synthesis approaches have been proposed including lithographic techniques, laser-beam processing, laser-induced assembly and colloidal aggregation, etc [8]. In core @ shell composite particles, however, existing core and shell parts of them mainly come from synthetic material. Urushiol (

) is a natural resource, which can be extracted from raw lacquer, thus becomes more and more important in the situation of resource scarcity. Urushiol is the main component of raw lacquer, for their excellent performance, outstanding characteristic and widespread application prospect, receiving a widespread attention of research workers [9-11]. Thus, it is very interesting to introduce the urushiol-metal polymers into core @ shell composite particles.

Two adjacent phenolic hydroxyls of urushiol can react easily with metal compounds and generated urushiol-metal chelate polymer [12,13]. Herein, we report a simple approach to synthesize the core @ shell composite particles of polystyrene @ urushiol-titanium chelate polymer (PS @ UTi) by using sulfonated polystyrene particles as templates. Then, tetrabutyl titanate is absorbed on the surface of sulfonated polystyrene sufficiently and reacts with urushiol.

Experimental

Materials

Chinese lacquer purchased from the Institute of Lacquer, Xi'an, China. Urushiol was obtained after extraction with ethanol from Chinese lacquer. Styrene (St), tetrabutyl titanate and ethanol were purchased from Sinopharm Medicine Holding Co., Ltd. Sulfuric acid was purchased from Tianjin Fuchen Chemical Reagent Factory. St was used after purification by alkaline Al_2O_3 to remove the inhibitor.

Characterization

The morphology and the composition of the samples were characterized by a JSM-7500F scanning electron microscope (SEM) with operation voltage of 5 kV. Transmission electron microscope (TEM) images were obtained with a JEM-2010 electron microscope.

Synthesis of the core @ shell composite particles of PS @ UTi

The sulfonated polystyrene (SPS) microspheres with different sulfonation time were synthesized according to the literature of [14,15]. 1 g of SPS particles were dispersed in 100 mL of ethanol, and then 100 mL of tetrabutyl titanate (TBT) was added into the ethanol dispersion under stirring for 8 h to allow a complete adsorption. The mixture was centrifugated and washed with ethanol to remove redundant tetrabutyl titanate. And then, 5 g of urushiol in ethanol was added into the mixture. The reaction was maintained for 4 h under stirring. The core @ shell composite particles of PS @ UTi were purified by centrifugation and washed with ethanol for several times.

Results and Discussion

After sulfonation of polystyrene particles with concentrated sulfuric acid, sulfone groups were simultaneously derived in the gel shell. When tetrabutyl titanate was adsorbed in the gel shell, two adjacent phenolic hydroxyls of urushiol reacted easily with tetrabutyl titanate and generated core @ shell composite particles of PS @ UTi [13].

The images of Fig.1 exhibited the TEM image of PS @ UTi. It was clearly that the particles were divided into two parts, including inner core and outer shell. Fig.2 was SEM images of PS @ UTi with different sulfonation time. As shown in Fig.2, the as-synthesized sample was well dispersed. While increasing the sulfonation time from 1 h to 6 h, the average diameter of PS @ UTi became larger and larger from 256 nm (Fig. 2a, at the sulfonation time of 1 h) to 295 nm (Fig. 2g, at the sulfonation time of 6 h). The sulfonated layer was thicker and thicker and the amount of butyl titanate adsorbed on sulfonated polystyrene increased with extension of sulfonation time. Thus, the shell thickness was larger and larger. In addition, the particles of PS @ UTi with a rougher surface could be obtained after reacting to urushiol. In order to explore the thickness of the shell further, the particles of PS @ UTi were calcined to remove the polystyrene core in 450 ^{o}C for 1 h at the atmosphere of nitrogen. It was found that the sulfonation time was a key role to affect the shell layer of PS @ UTi (Fig.3). When the sulfonation time of PS @ UTi was less than 2 h, the particles collapsed completely (Fig.3a and Fig.3b). When the sulfonation time of PS @ UTi was 4 h, the particles collapsed partly (Fig.3c). With prolonging sulfonation time to 6 h, the particles became intact (Fig.3d). It demonstrated that we can obtain monodisperse core @ shell particles with tunable shell thickness by varying the sulfonation time.

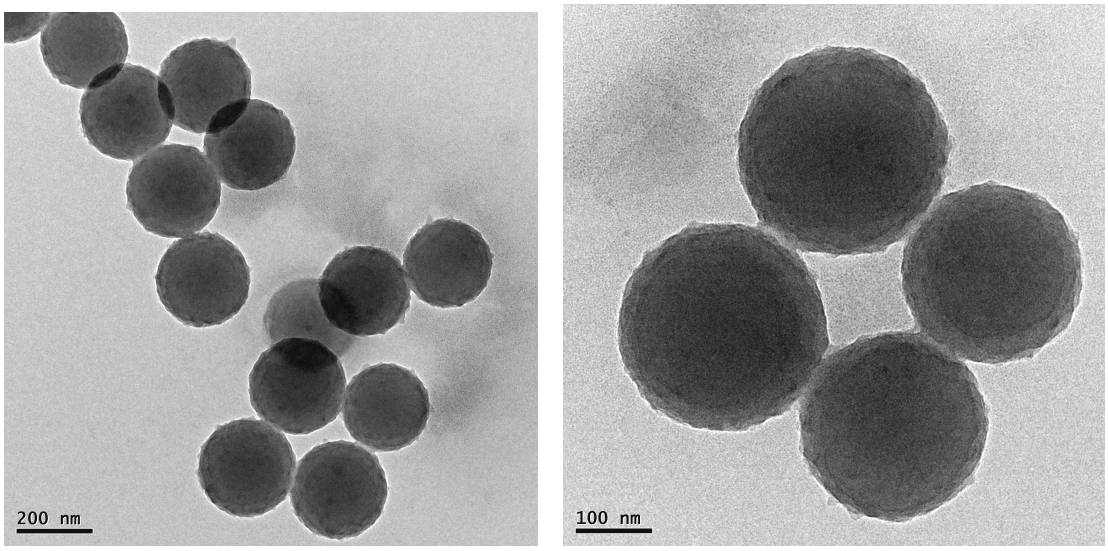

Fig.1 TEM images of PS @ UTi with sulfonation time of polystyrene particles for 1 h.

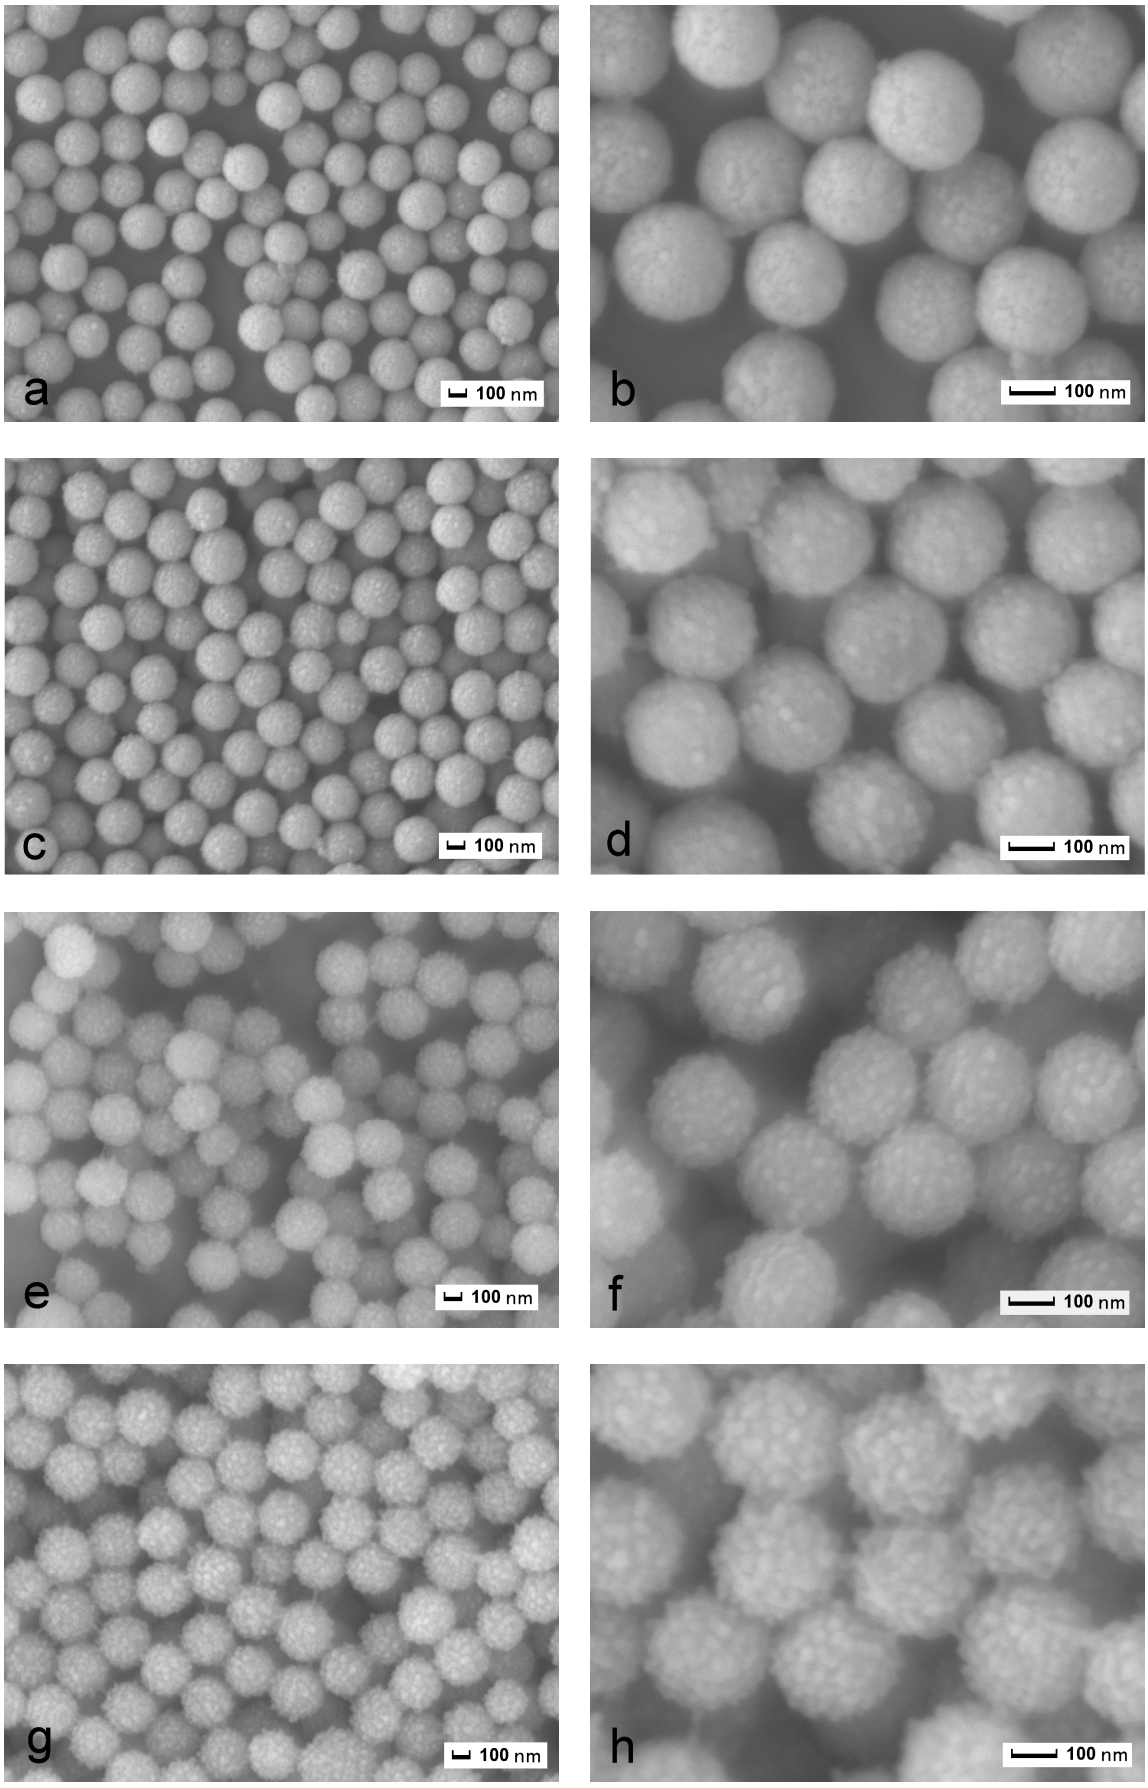

Fig.2 SEM images of PS @ UTi with different sulfonation time of polystyrene particles. (a) (b) 1h, (c) (d) 2 h, (e) (f) 4 h and (g) (h) 6 h.

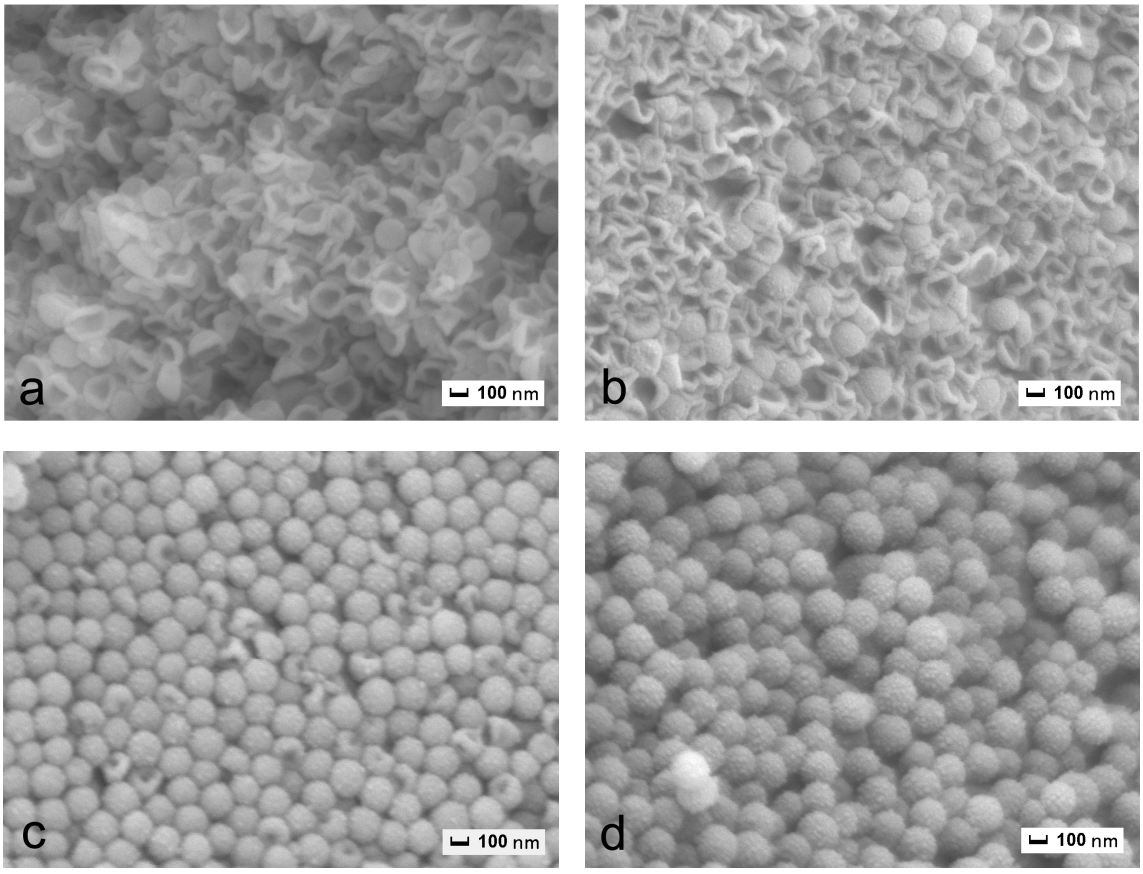

Fig.3 SEM images of PS @ UTi after calcined with different sulfonation time of polystyrene particles. (a) 1 h, (b) 2 h, (c) 4 h and (d) 6 h.

Conclusions

The core @ shell composite particles of PS @ UTi was successfully prepared through in-situ reaction between tetrabutyl titanate coated on the surface of sulfonated polystyrene microspheres and urushiol. The thickness of UTi shell of PS @ UTi core @ shell composite particles was tunable by changing the sulfonation time. Further investigations on the application of PS @ UTi are underway in our laboratory.

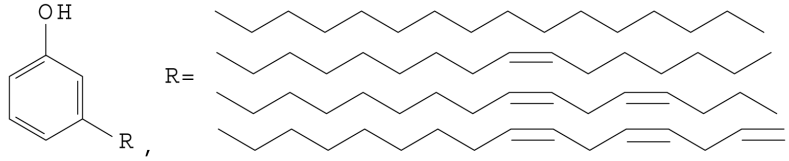
Keywords: poly (propylene) (PP); reactive extrusion; cardanol; renewable resources; compabilization; anti-aging

Abstract: The polypropylene-graft-cardanol (CAPP) was prepared by reactive extrusion with polypropylene (PP) and natural renewable cardanol which could improve the inherent defects of PP such as chemical inertness and hydrophobicity. Moreover, the cardanol grafted onto PP could resolve the degradation of PP during the process of reactive extrusion. In this paper, CAPP was prepared in the presence of three different kinds initiator. The compatibilization and the anti-aging performance of cardanol grafted onto PP were studied. Results showed that the initiator dicumyl peroxide (DCP) exhibited the optimum initiated efficiency. Cardanol grafted onto PP was benificial for the composite of bamboo powder and PP.The initiator of DCP caused the degradation of PP chains during the aging processing. After aged for 24 h, the yield strength decreased from 28 MPa to 15 MPa and the elongation at break reduced by 795 %. The CAPP possessed outstanding anti-aging performance owing to the cross-linking and entanglement of the side chains of cardanol grafted onto PP. The yield strength, tensile strength and the elongation at break of CAPP-DCP changed lightly even when it was in long-term irradiation for 480 h.



Introduction

Polypropylene (PP) is a kind of non-polar crystal polymer. In order to improve the surface energy of PP, researchers have done their best in many modifications[1-6]. In particular, the graft modification of reactive extrusion, which has advantages due to its solvent-free properties, continuity in producing process and ease in reaction time manipulation, has shown remarkable results and thus aroused widespread interest[7-10]. However, the tertiary carbon atom in the PP structure is prone to cause molecular chain's β rupture and severe degradation during the reactive extrusion process[11-13]. Natural cardanol (a liquid extracted from cashew nutshell) is a phenolic compound containing long unsaturated alkyl side chain [9] (Scheme 1). In this study, the polypropylene-graft-cardanol (CAPP) was prepared by reactive extrusion in order to improve the surface activity. The compatibilization and the anti-aging performance of cardanol grafted onto PP were also investigated.

Experimental

A certain proportion of PP, cardanol and intiator (dissolved in ether) (Table 1) was mixed evenly in a high-speed mixer (2600 r/min). The mixture was then extruded at 180 °C, 50 r/min using the co-rotating twin-screw extruder (HAAKE, Polylab Rheomix PTW24/28, Germany), and pressed into a CAPP sheet with 0.6 mm thickness using the tri-roll calendar. The rolled sheets were cut into 130 mm × 10 mm rectangular samples and placed in the accelerated aging chamber with mercury lamp for aging experiments. The content of CAPP was quantified by UV-vis spectrometer (TU-1900, Beijing Purkinge General Instrument Co., Ltd, China). CAPP was dissolved in boiling n-octane and then kept in 90 ^{o}C of water bath. The grafting ratio of CAPP was measured at the temperature of 90 ^{o}C. Standard curve was decided by a series of cardanol standard solution at 273 nm and 90 °C after dissolved in 1-octane. Using the LR5K universal testing machine of LLOYD British Company, the

yield strength, elongation at break and tensile strength of the material were tested with tensile rate of 5 cm/min and preload of 5 N. Each kind of sample was tested in parallel five or more times, and the average was obtained.

Scheme 1 Chemical structure of cardanol

Results and Discussion

Effect of Initiator on Grafting Ratio

The effect of initiator type on grafting ratio was investigated in order to select the optimum initiator (Table 1). Results showed that grafting reaction couldn't carry out during reactive extrusion in the absence of initiator, e.g. CAPPm. In the presence of 0.2 % DCP, the grafting ratio reached the value of 5.20 %. The grafting ratio initiated by benzoyl peroxide **(**BPO) and ditert-butyl peroxide (dTBP) is lower than that by DCP. The reactive materials would remain in extruder for 1 min at a screw speed of 50 rpm and at the temperature of 180 ^{o}C. According to the literature of[14], the decomposition temperature of BPO and dTBP is 133 ^{o}C and 190 ^{o}C when the calculated value of half-life ($t_{1/2}$) was 1 min, whereas that of DCP is 171 ^{o}C. The reactive temperature of PP-graft-cardanol was too high for BPO. BPO decomposed rapidly at the selected temperature, when all kinds of components in extruder didn't mix completely. Therefore, the number of reactive sites decreased. However, the processing temperature was too low for dTBP. Most of dTBP had left the extruder before it decomposed, so the initiated efficiency wasn't good. In a word, DCP exhibited better initiated efficiency than the other two kinds of initiator.

TABLE1 FORMULA AND GRAFTING RATIO OF PP-GRAFT-CARDANOL AND ITS MIXTURE

Samples	PP	Cardanol	Initiator	Mass of initiator	Grafting ratio
PP	100	0	DCP	0	0
CAPPm	100	5			0
CAPP0	100	0	DCP	0.2	0
CAPP-DCP	100	5	DCP	0.2	4.45
CAPP-BPO	100	5	BPO	0.2	0.92
CAPP-dTBP	100	5	dTBP	0.2	1.01

Compatibilization of Cardanol Grafted onto PP on the Composite Materials of Bamboo Power and PP

Fig. 1 was the polarization microphotos at the magnification of 50 of bamboo plastic composite materials. It could be found that the compatibility of bamboo power and PP was bad. Bamboo powder aggregated at the matrix of PP and the interface between bamboo powder and PP was very distinct. Bamboo powder couldn't be pregnant into PP because of the different polarity between them. The chemical structures of the hydroxyl groups and phenyl groups in cardanol which was grafted onto polypropylene were the same as that of lignin in bamboo powder. Grafting reaction increased the compatibility between bamboo powder and PP, so bamboo powder dispersed in the matrix of PP uniformly.

Effect of Anti-aging Performance of Cardanol Grafted onto PP

To investigate the improvement of grafting reaction during the destruction of PP materials, the destruction of PP and 5 % cardanol blend (CAPPm) was studied as reference (Figure 2). Cardanol in CAPPm reduced the crystallinity of PP, which decreased the intermolecular forces among PP. The yield strength of CAPPm was lower than that of pure PP. However, cardanol played the role of plasticizer in the blend of PP and cardanol, thus shifting the deformation of CAPPm from brittle one

to plastic one. The tensile strength and elongation at break of CAPPm showed an increase. As compared with CAPP-DCP, no chemical bonds existed between cardanol and PP chains; instead cardanol was just dispersed in PP molecular gaps. The elongation at break for such blends of CAPPm was smaller than that of CAPP-DCP with intermolecular interactions. Secondly, when CAPP-DCP was in long-term irradiation under high-pressure mercury lamp (480h), the cardanol side chains underwent cross-linking reactions to form sequential interpenetrating polymer networks with PP. Because of the combined results of the degradation of PP chains in CAPP-DCP and the polymerization of cardanol side chains, the tensile strength and elongation at break of CAPP-DCP changed lightly during the aging process. Overall, the melted graft-modified products of CAPP-DCP with intermolecular forces had better anti-aging properties than the blend products of CAPPm.

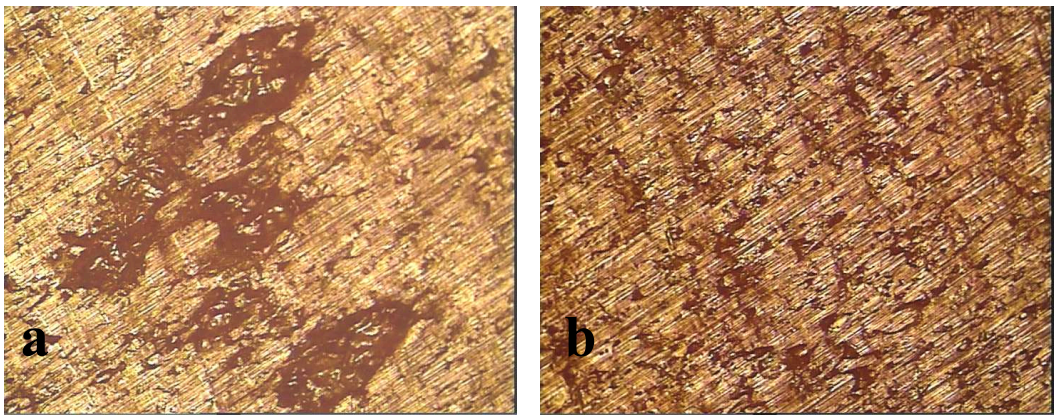


Fig. 1 Polarization Microphotos at The Magnifications of 50 of Bamboo Plastic Composites (a: Bamboo Powder/PP; b: Bamboo Powder/CAPP-DCP)

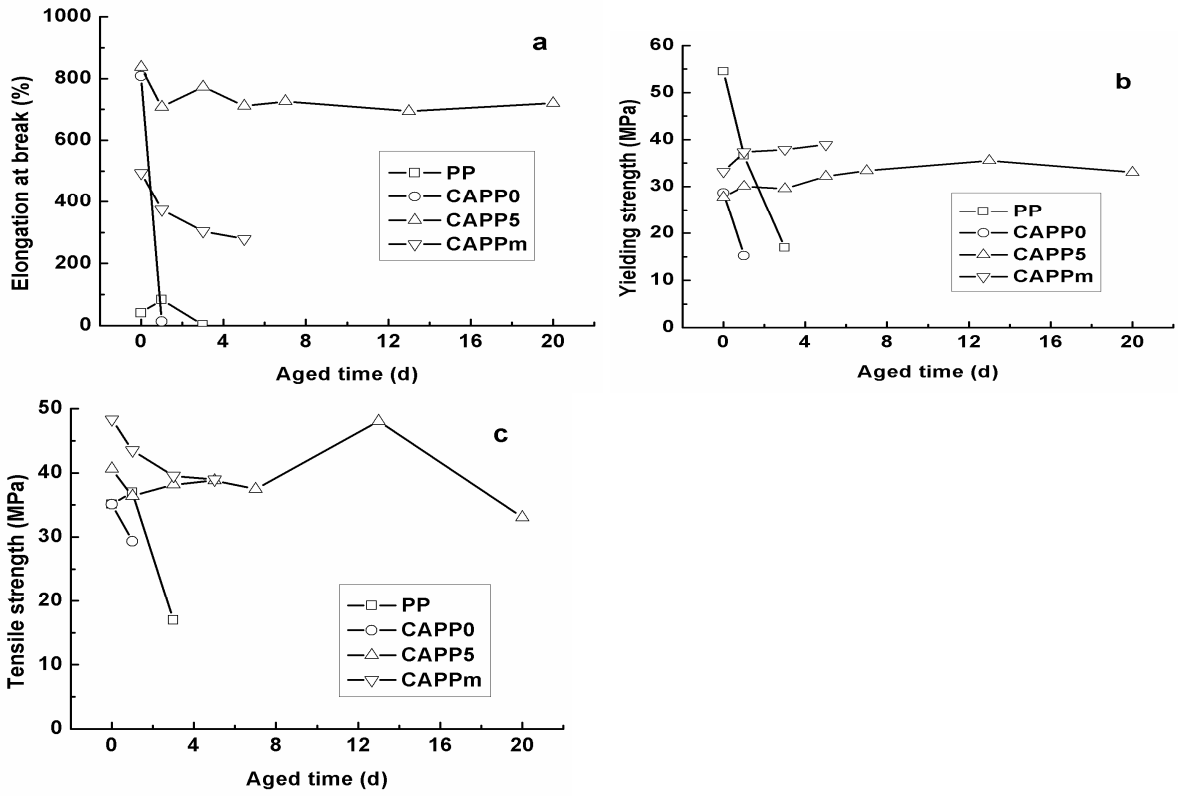

Figure 2 Mechanical Properties of Unmodified and Modified pp vs. Aged Time

Conclusions

The initiator of DCP exhibited the optimum initiated efficiency. Cardanol grafted onto PP was benificial for the composite of bamboo powder and PP.The initiator of DCP caused the degradation of PP chains during the aging processing. After aged for 24 h, the yield strength decreased from 28 MPa to 15 MPa and the elongation at break reduced by 795 %. The CAPP possessed outstanding anti-aging performance owing to the cross-linking and entanglement of the side chains of cardanol grafted onto PP. The yield strength, tensile strength and the elongation at break of CAPP-DCP changed lightly even when it was in long-term irradiation for 480 h.

Keywords: finite element; composite laminates; compressive residual strength; progressive damage analysis; stiffness degradation

Abstract: Experiment and Finite element analysis were used to study the strengths of composite laminates with and without holes. Finite element progressive damage analysis with Tsai-Wu criteria was applied to calculate the compressive residual strength of composite laminate. Abaqus and its user subroutine USDFLD were used for the finite element analysis. Tsai-Wu criteria as the failure criteria was realized in USDFLD as a Fortran program segment, and the stiffness degradation for the damaged elements was also realized by USDFLD. Analytic results gotten by progressive damage method were very close to the experimental results.

Introduction

Composite materials are wildly used in many industries, especially in aviation and aerospace industries because of their fantastic mechanical property. Composite laminates and sandwich structures are used to manufacture more and more components of aircraft. In some structures of aircraft, one or more holes need to be opened on them. And the strength of the main or secondary bearing structures containing holes should meet design requirements. Thus, analyses and experiments of these structures are used to assess their strengths. The major challenge in design and analysis of composite structures containing stress concentrators is the size effect on the strength of composite structures[1]. Many studies on tensile and compressive residual strength of composite laminate were done in recent years, especially studies on laminates with holes. And there also be many studies on residual strength of composite after impact. Chun H. Wang et al have researched the residual strength of composite laminates containing scarfed holes and straight-sided holes, and they found that scarfed holes produce a significant increase in the strain concentration and substantial reduction in the residual strength[1]. The residual strength of glass fibre reinforced vinyl-ester laminates with multiple holes was investigated by S. Kazemahvazi et al[2]. The quasi-static tensile strength of the laminates with different amount of holes and different hole arrangements was investigated, and three different failure modes were found by S. Kazemahvazi et al[2]. The tensile residual strength of repaired CFRP composite plates were assessed by R. D. S. G. Campilho et al using a two-dimensional numerical analysis[3]. Jun-Jiang Xiong[4], S. Sánchez-Sáez[5], F. Cesari[6], Shi-Xun Wang[7] et al have studied the compressive and tensile residual strength of composite after impact . Jun-Jiang Xiong[4],T.P. Philippidis[8] et al also studied fatigue residual strength of composite. The second rank expression of Tsai-Wu criteria was used to calculate the strength of 3D braided composite beam by Zuo Weiwei et al[9]. Engineering evaluation and FEM prediction were used to study the compressive residual strength of composite laminates after the impact by Jia Jiandong et al[10]. The 3D progressive damage theory was applied in residual strength calculation of composite[11, 12].

Finite element analysis (FEA) and experiment were used to study the compressive residual strength of composite laminates containing holes, and the second rank expression of Tsai-Wu criteria as used by Zuo Weiwei et al[9] was applied as strength criteria in this paper. USDFLD, a Fortran program of Abaqus user subroutine, was used to realize the progressive damage process of composite laminates. Stiffness degradation method used in this paper is the same as that used by Kong Xianghong et al[12]. Nine kinds of experimental samples of composite laminates with different geometrical dimensions were manufactured for experiment research, and there were six samples for each kind in order to exclude the effect of uncertainties of the samples. There also be nine kinds of finite element (FE) models of composite laminates created with Abaqus for FEA. In order to compare the results of FEA, three different load increments were applied on each kind of FE models respectively for FEA with progressive damage.

Experimental samples and FE models

Material of composite laminates.

The UD-composite layer material of laminates used in experiment and FEA is T700/BA9916, and the thickness of a composite layer is 0.15mm. The composite laminates of experimental samples have the same ply number, ply stacking sequence and thickness. There are 25 plies with the total thickness of 3.75mm for each laminate, and the ply stacking sequence of each composite laminate is $(0°/45°/-45°/45°/90°/-45°/0°/0°/-45°/0°/0°/45°/\overline{90°})_s$. The mechanical property and strength of UD-composite layer are shown in Table 1.

Table 1. Mechanical property of T700/BA9916

Elastic properties	E_{11} [GPa]	E_{22} [GPa]	E_{33} [GPa]	μ_{12}	μ_{13}	μ_{23}	G_{12} [GPa]	G_{13} [GPa]	G_{23} [GPa]
	114	8.61	8.61	0.3	0.3	0.45	4.16	4.16	3
Strength [MPa]	X_t	X_c	Y_t	Y_c	Z_t	Z_c	S_{xy}	S_{xz}	S_{yz}
	2688	1458	69.5	236	55.5	175	136	136	95.6

Geometrical shape of experimental samples and FE models.

The geometrical shape of composite laminate with a hole for experiment and FEA is shown in Fig. 1. There are four parameters for a composite laminate containing a hole: diameter (D) of the hole, length (L), width (W) and thickness (T) of the composite laminate. The hole center is at the geometrical center of the composite laminate.

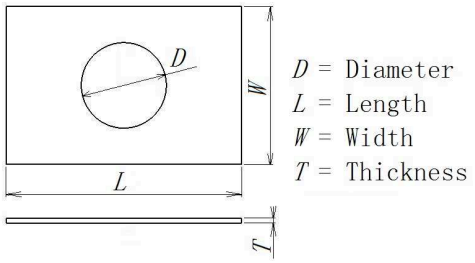

Fig. 1. Geometrical shape of composite laminate

The FE models of composite laminates with holes for compressive strength analyses are similar to those shown in Fig.2 and Fig. 3. Three-Dimension stress elements are used in the FE models. The ply's orientation of 0° is along the X-axis, and the 90° along the Y-axis in Fig. 2.The degree of

freedoms (DOF) of the nodes on the left side of the FE model are constrained, and the compressive loads are loaded on the nodes of the right side as shown in Fig. 2. There are 25 plies of elements of each FE model as shown in Fig. 3. The thickness of the elements along Z-axis is 0.15mm, and the total thickness of a FE model is 3.75mm. That is one layer of elements for one layer of composite laminates. The red elements named “Elem-0” belong to the plies of which the orientation is 0°, the other elements named “Elem-45N”, “Elem-45P” and “Elem-90” belong to -45°, 45° and 90° plies respectively.

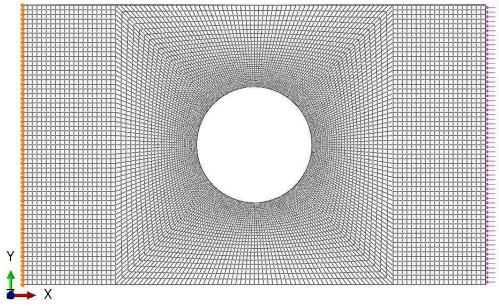

Fig. 2. FE model of composite laminate with hole

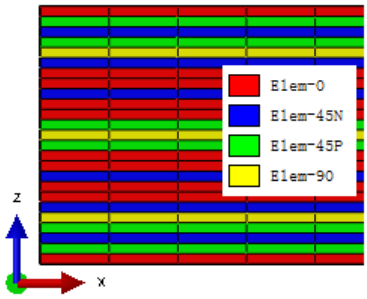

Fig. 3. FE model along thickness direction

Geometrical parameters of experimental samples and FE models.

There are nine groups of experimental samples with different parameters shown in Table 2. The first group named “NoHole” in Table 2 contains six composite laminates without holes, and these composite laminates are used to study the mechanical property for comparison with those composite laminates containing holes. The rest groups contains the composite laminates with holes, and the “W” & “D” in the group names mean the width and hole diameter of the composite laminates of each group. FE models have the same geometrical parameters as the experimental samples have.

Table 2. Geometrical parameters of composite laminates

No.	Group	*D* [mm]	*W* [mm]	*L* [mm]	*T* [mm]	*Q*
1	NoHole	0	12	140	3.75	6

D = Diameter, *W* = Width, *L* = Length, *T* = Thickness, *Q* = Quantity

Experimental results

Experiments were done according to Standard Test Mehod for Compressive Properties of Polymer Matrix Composite Materials Using a Combined Loading Compression (CLC) Test Fixture, ASTM D 6641. The manufacture of composite laminates for compressive experiment, measuring and testing technique and data processing method for these compressive experiments were directed by ASTM D 6641.

The compressive loads are loaded on experimental samples along the length direction of composite laminates, and the ends of the samples were fixed by fixtures as ASTM D 6641 requires.

Experiment of composite laminates without hole.

Experimental data of composite laminates without hole are giver in Table 3. The data are gotten by compressive experiment of six samples. The area (A) is the area of transverse section of each sample, and it is calculated by Eq. 1. W and T in Eq. 1 are measured.

$$A = W \times T \tag{1}$$

Theoretically, A is equal to 45mm^2, but because of the manufacturing technique, there are some differences between the sample's area and theoretical area. The max loads (F_{max}) are the damage loads of samples during experiment, and they are measured values for experimental data. The strength (S) is calculated with Eq. 2 for each sample, and this strength is UD-compressive strength along the length direction of composite laminate.

$$S = 1000 \times F_{max}/A \tag{2}$$

Table 3. Experimental data of composite laminates without holes

Experimental data analysis.

Experimental data of nine groups of composite laminates given in Table 3, Table 4 and Table 5 illustrate the relationship between the mechanical properties and geometrical parameters of composite laminates. The samples of W36D6 and W60D30 have the same area of the minimum bearing transverse section, and the damage loads of them are similar as Fig. 4 shows.

There is the same phenomenon between the samples of W60D10 and W120D65, though the minimum bearing transverse section areas of the two groups have a little difference. The area (Amin) of the minimum bearing transverse section is calculated with Eq. 3.

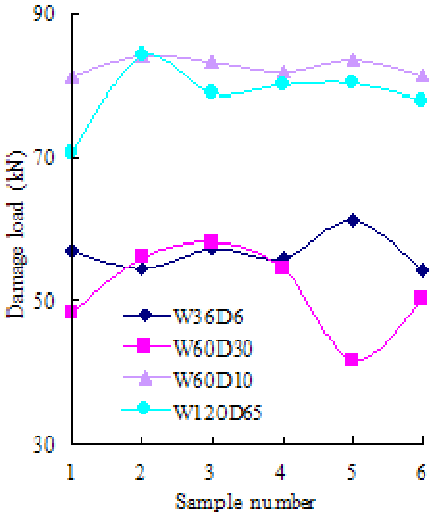

Fig. 4. Damage loads of the samples with similar A_{min}

$$A_{min} = (W - D) \times T \quad (3)$$

Hole diameter has an important effect on compressive residual strength of composite laminate as Fig. 5 shows. The residual strength of samples of NoHole group is much bigger than the other samples with holes, even the hole is small. From the data of the five groups of samples with the same width and different holes, it is proved that the bigger the hole diameter is, the smaller the compressive residual strength is. The compressive residual strengths of samples with the same relative minimum transverse section area (A_r) and different hole diameters are also different. The relative minimum transverse section area (A_r) is calculated by Eq. 4. There are two pairs of samples with the same A_r respectively shown in Fig. 6.

$$A_r = A_{min}/A \times 100\% \quad (4)$$

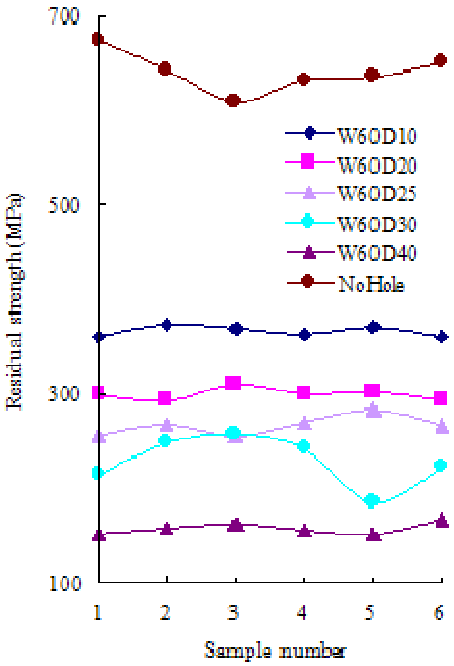

Fig. 5. Residual strength of samples with different D

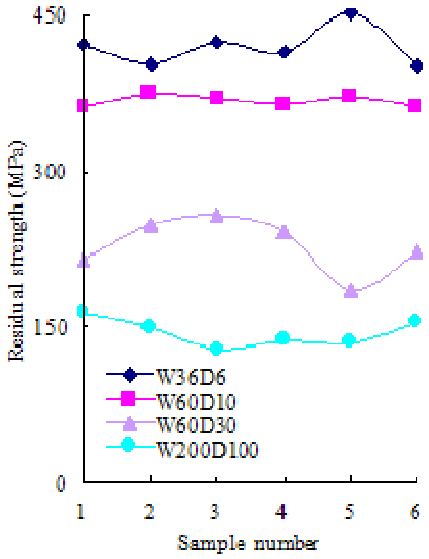

Fig. 6. Residual strengths of samples with the same A_r

The A_r of the groups of W36D6 and W60D10 is 83.33%, and for the other pair it is 50%. It is obvious that the bigger the hole diameter is, the smaller the compressive residual strength is for the samples with the same A_r, and the bigger the A_r is, the bigger the compressive residual strength is.

Finite element analysis

Composite laminate FEA process.

Compressive residual strength analysis of composite laminate using FE method contains two main processes: the stress analysis and the strength analysis. The stress analysis is a common static analysis, and the strength analysis is realized by an Abaqus user subroutine USDFLD. USDFLD is a Fortran subroutine, and it can be used to introduce solution-dependent material properties since such properties can easily be defined as functions of field variables[13]. The whole analysis process is shown in Fig. 7. There are one loop and two select statements in an iteration of the loop. Compressive displacement load is loaded on FE model for static analysis, and the displacement load increases in each iteration of the analysis loop. And the reference load (RF) can be given by Abaqus. The RF increases while the displacement load increases before there is no failure element. When there are failure elements, the stiffness of these failure elements will be degraded by USDFLD, and then the RF will decreases. The composite laminate is considered damaged and loses bearing capacity when the current RF is much smaller than the maximum value of RF as it appeared during analysis.

Tsai-Wu criteria is applied in USDFLD for strength analysis, and it will be used for every element using the current stress of a element in every iteration of the loop. The workflow of USDFLD in an iteration is as Fig. 8 shows. As a Fortran subroutine, in order to pass some values and calculate some coefficients, some parameters are defined in USDFLD. State varieties are used to mark field values which decide the material property type assigned to each element. And field values of next iteration are decided by the element stress of last iteration, they also reflect the current failure type of the element.

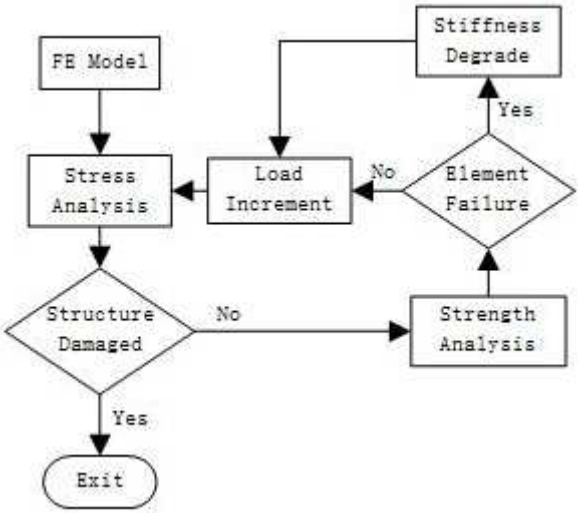

Fig. 7. FE strength analysis process

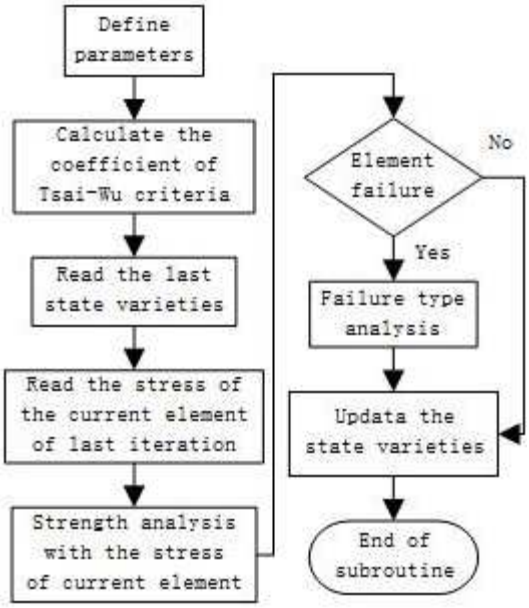

Fig. 8. Workflow of USDFLD

Composite laminate damage process.

Composite laminate damage process can be shown in two methods: use Load-Equivalent strain curves and use element progressive damage figures. The max load (F_{max}) appeared during compressive process can be found easily by Load-Equivalent strain curves. The max load is the damage load of corresponding composite laminate. And the compressive residual strength (S) of composite laminate can be calculated with Eq. 2. From element progressive damage figures, the initial damage position and progressive damage process can be easily illustrated.

There are three curves in Fig.9. These curves are the Load-Equivalent strain curves of composite laminate without hole. The data of three curves are gotten by FEA using different displacement load increment (ΔU). In Fig.9, the three curves have different equivalent strain increment ($\Delta\varepsilon$). The equivalent strain increment is calculated by Eq. 5.

$$\Delta\varepsilon = \Delta U/L \tag{5}$$

Where, L is the length of the FE model of the composite laminate. While the equivalent strain (ε_L) can be calculated by Eq. 6.

$$\varepsilon L = U/L \tag{6}$$

Where, U is the displacement load along the length direction of the composite laminate. The equivalent strain increments of the three curves with the number of 1, 2 and 3 in Fig. 9 are 0.0002, 0.0004 and 0.0006 respectively. It illustrates that the smaller the $\Delta\varepsilon$ is, the smaller the Fmax is.

During the process of compressing of the composite laminate without hole, the elements of "Elem-0" of which plies the orientation is 0° were first damaged. When the 0° plies of the composite laminate were completely damaged, the composite laminate lose its bearing capacity, thus the composite laminate was treated as damaged. The progressive damage process of the elements of "Elem-0" is shown in Fig. 10. The load condition of Fig. 10 is the same as that of No. 2 in Fig. 9. The red elements in Fig. 10 are damaged elements, and the FE model in Fig. 10 is part of the FE model of the composite laminate without hole. The X-axis direction is the length direction of composite laminate, and that is the 0° direction.

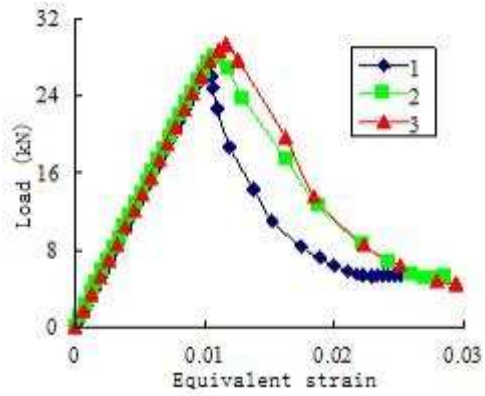

Fig. 9. Load-equivalent strain curve of composite laminate without hole

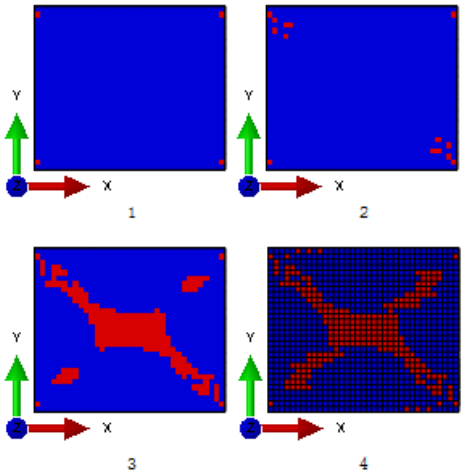

Fig. 10. Progressive damage process of composite laminate without hole

FEA data of composite laminate without hole is shown in Table 6. There are three groups of FEA data numbered with 1, 2 and 3. The three groups of data correspond to the three curves in Fig. 9 by their number. Comparing with the data of Table 3, it is obvious that the FEA data are similar to the experimental data. It proves that progressive damage analysis with FE method can get the relative accurate compressive strength value of composite laminate.

Table 6. FEA data of laminate without hole

No.	F_{max} [kN]	S [MPa]

FEA results of composite laminates with holes.

The damage loads and compressive residual strengths of composite laminates with holes are shown in Tables 7. The strength (S) is calculated using the max load (F_{max}) by Eq. 1 and Eq. 2. The data with different column number in Tables 7 were gotten by different equivalent strain increments. The data with column number 1, 2 and 3 were gotten by FEA with the equivalent strain increments of 0.0002, 0.0004 and 0.0006 respectively. The comparisons of experimental results and FEA results are shown in Fig. 11 and Fig. 12.

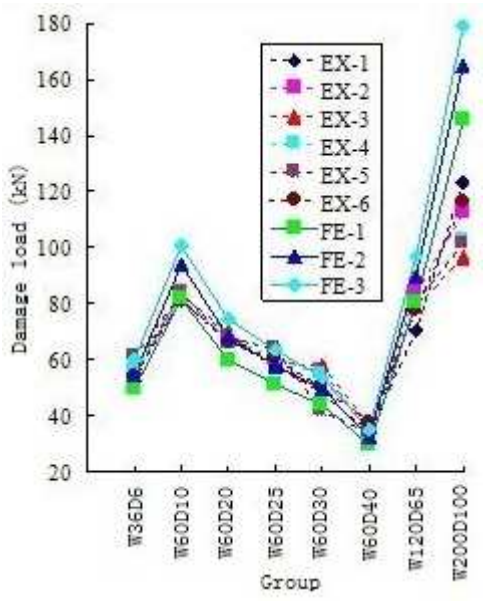

Fig. 11. Damage loads of composite laminates with holes

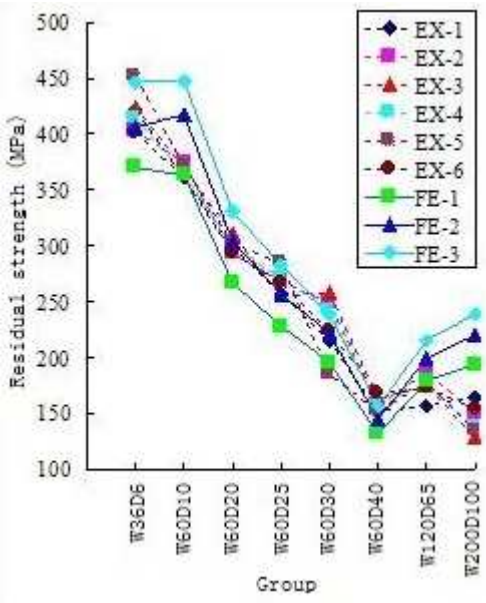

Fig. 12. Residual strength of composite laminates with holes

The damage loads of composite laminates with holes gotten by experiment and FEA are shown in Fig. 11. "EX-" and "FE-" in Fig. 11 are experimental data and FEA data respectively. And the number after them is the sample number, for instance, the data of "EX-1" are the damage loads with the column number of 1 in Table 4, and the data of "FE-1" are the damage loads with the column number of 1 in Table 7. From the curves shown in Fig. 11, it can be proved that most of the FEA data are similar to the experimental data, but there is obvious difference between the data of "W200D100" gotten by experiment and FEA.

The compressive residual strengths of composite laminates with holes shown in Fig. 12 illustrate that the data calculated with FE progressive damage analysis are much close to the experimental results except the data of W200D100. It is because that the element size and load increment size can affect the FEA result. More study need to be done for composite laminates with big holes to make clear the relationship between the FEA result and the sizes of element and load increment.

During the process of compressing of the composite laminates with holes, the elements at the hole side along the transverse direction were first damaged, and then the damage elements extend to both sides of laminates. For the layers of Elem-0, fiber compressive failure is the main damage type; for the layers of Elem-45P and Elem-45N, fiber-matrix in-plane shear failure is the main damage type; and for the layers of Elem-90, matrix compressive failure is the main damage type.

Conclusions

1) Compressive experiments of composite laminates with holes illustrate that holes can decrease the compressive strengths of composite laminates greatly.

2) The damage loads of the composite laminates with the same minimum bearing transverse section (A_{min}, Eq. 3) are approximately equal.

3) For the composite laminates with the same width and different hole diameters, the bigger the hole diameter is, the smaller the compressive residual strength is.

4) For the composite laminates with the same relative minimum transverse section area (A_r, Eq. 4), the bigger the hole diameter and the width are, the smaller the compressive residual strength is.

5) The FEA results gotten by progressive damage analysis with Tsai-Wu criteria are much close to the experimental results.

6) There are three main failure modes for laminates:
fiber compressvie failure for 0° layers;
matrix compressive failure for 90° layers;
fiber-matrix in-plane shear failure for 45° and -45° layers.

Keywords: self-assembly, conjugated polymer, microsphere

Abstract. In this research, the microspheres of poly (9'9-dihexylfluorene) were fabricated with dichloromethane as a good solvent by self assembly methods. The effects of poor solvent vapor, polymer concentration, and the temperature of environment on the formation of the sphere patterns were investigated. It was found that the microsphere could be easily prepared in the ethanol non-solvent vapor atmosphere. Besides, increasing the environment temperatures was advantageous to fabricate microspheres. Furthermore, the property of non-solvent vapor was a key role to the formation of the sphere.

Introduction

In recent years, conjugated polymers have attracted much attention due to their widespread applications. They can be used in displays, sensors, photovoltaic cells, thin-film transistors, nonlinear optics, and solar cells because of their low-cost, large-area electronics [1, 2]. For instance, a series of the conjugated polymers have been synthesized and their properties have been investigated. There have two main ways to prepare conjugated polymers, namely, via a reduction oxidation process or via a metal-catalyzed coupling method [3].

It is noteworthy that the optoelectronic properties of conjugated polymers in the solid state are highly affected by their structure of the molecules chains and the decree of order [4]. In addition, the optical and transport properties of conjugated polymers are intimately related to their nanometer scale morphology [5]. Therefore, it is necessary to control the degree of order when obtaining thin conjugated deposits from solution. At the same time, nanostructures conjugated polymers have potential applications in separation, drug delivery, photonic band gap, electronic, catalysis, and lithography [6]. As a result, polymer nanostructures, such as nanotubes, nanofibers, nanowires, nanorods, and other arrays are prepared by various methods.

Several methods like dispersion polymerization miniemulsion polymerization, solution synthesis, template methods, electrospinning technology, and self-assembly have been used to fabricate the nanostructure conjugated polymers. [7-10]. Among the above methods, self-assembly of conjugated polymers into nanostructures and microstructures is importance. However, the design and self-assembly nanostructures conjugated polymer remains a challenging and attractive target in nanoscience and nanotechnology [11]. Herein, we attempted to fabricate microspheres of conjugated polymers by non-solvent vapor self-assembly.

Experimental

Materials

N-bromohexane, fluorene， anhydrous ferric chloride ($FeCl_3$), Dichloromethane (CH_2Cl_2), methylbenzene, acetone, ethanol, and ethyl acetate were all A. R. and purchased from Sinopharm Chemical Reagent Co., Ltd. The poly(9,9-dihexylfluorene) used in this work was synthesized by solid-state oxidative coupling polymerization using our previous reported avenue [14].

Self-assemble of the Poly(9,9-dihexylfluorene)

The glass substrates (1×1 cm^2) were cleaned by detergents, demineralized water, ethanol, and acetone successively, and then dried in air before positioning them in a glass vessel. The atmosphere of ethanol nonsolvent was obtained by adding 3 mL of nonsolvent into a hermetic glass bottle and then the bottle would be full of saturated vapor after 2 h. The poly(9,9-dihexylfluorene) was dissolved in good solvent. Then, its solution was dropped onto a clean glass substrate in the nonsolvent vapor After the solvent evaporated completely, a thin layer was obtained on the substrate.

Characterization

The morphologies of the poly(9,9-dihexylfluorene) by the non-solvent vapor method were performed on a JSM-7500F scanning electron microscope (SEM) at an accelerating voltage of 5 kV.

Results and Discussion

Influence of Concentration on Microspheres Formation

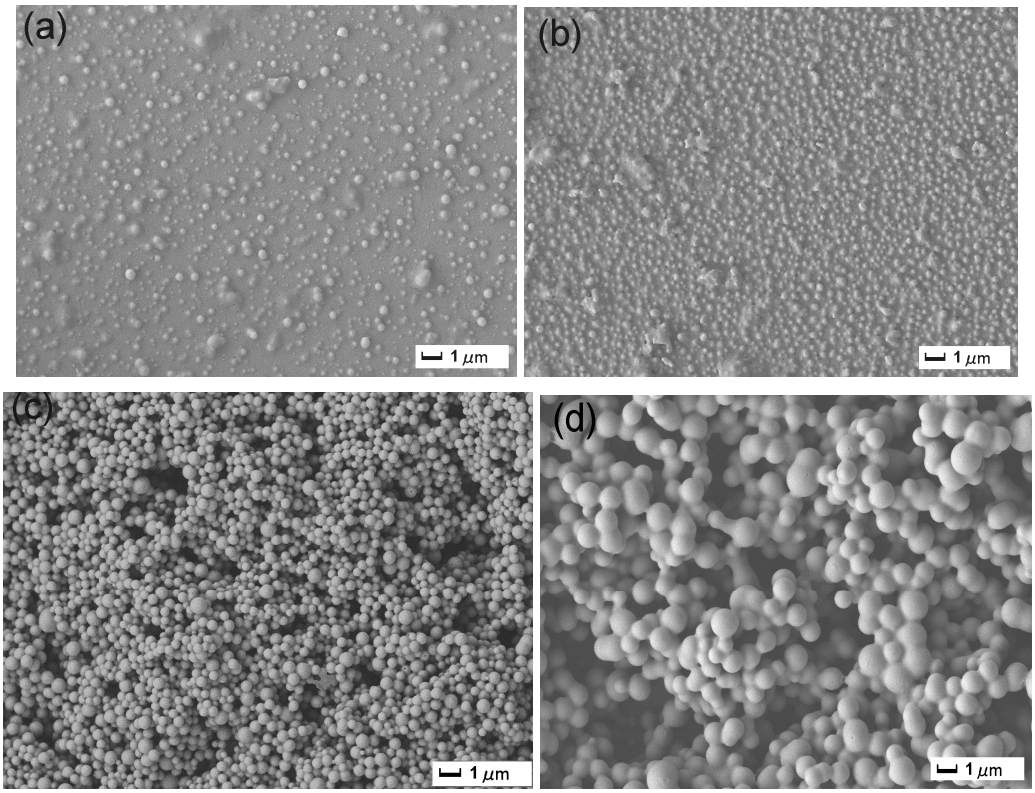

Fig. 1. SEM images of the poly(9,9-dihexylfluorene) microsphere patterns prepared from CH_2Cl_2 in the ethanol vapor atmosphere under the following concentration: (a) 0.1 mg/mL, (b) 0.5 mg/mL, (c) 1.0 mg/mL, (d) 2.5 mg/mL.

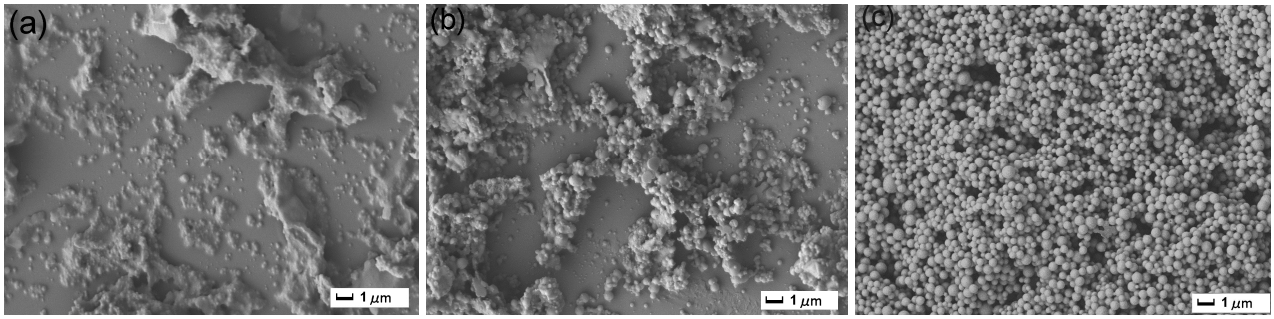
The influence of the polymer concentration on the morphologies of poly (9'9-dihexylfluorene) was shown in Fig.1. Some microsphere pattern could be obtained when the poly (9'9-dihexylfluorene)/CH_2Cl_2 concentration was 0.1 mg/mL and 0.5 mg/mL.When the concentration was 1 mg/mL, it was found that discrete and quite well-shaped spheres could be formed. As the concentration further increases to 2.5 mg/mL, the spheres patterns still could be obtained as shown in Fig. 1 (d). But, the spheres size increased and heavily fused with one another.

Why do spherical assemblies in the non-solvent ethanol vapor atmosphere? It could be explained by two parts: the decrease of temperature and crystallinity of polymers [12]. When the poly (9'9-dihexylfluorene)/CH_2Cl_2 solution was drop into the glass surface, the good solvent of CH_2Cl_2 would evaporate quickly. So, the temperature gradient between the solution surface and the surrounding would form. Because of the existence of temperature gradient, ethanol non-solvent vapor

could be condensed onto the solution. As a result, the good solvent would be turned to non-solvent for the poly (9'9-dihexylfluorene) and the molecular of the poly (9'9-dihexylfluorene) was precipitation. On the other hand, crystallinity of polymers was another important factor. The poly (9'9-dihexylfluorene) was a random regularity structure, which was synthesized by the solid-state oxidative coupling polymerization. It was advantageous to the assembly of spherical geometry. With the increase of the concentration of polymer, the much molecular and the higher solution viscosity make condensation so slow that the ethanol vapor droplet infused into solution more slow, indirectly causing the sphere growth, as shown in Fig.1.

Influence of Temperature on Microspheres Formation

As discussed above, microspheres could be self-assembled by casted the poly(9,9-dihexylfluorene)/CH_2Cl_2 solution into ethanol vapor. In order to study the impact of the environmental temperatures on the pattern formation, -18°C, 5°C, and 25°C was investigated, as shown in Fig. 2. It was found that the temperature was a key role to controlling the formation of the sphere pattern. When the temperature was -18°C, the sphere patterns could not be formed. When the temperature was 5°C, some sphere patterns was observed. When the temperature was 25°C, the regular spheres were formed. With the increase of temperature, the good solvent of the solution was evaporated quickly, and then the non-solvent vapor ethanol would condensate fast. The good solvent would turn to a poor solvent for the infusing of the ethanol vapor. So, the poly(9,9-dihexylfluorene) ould be precititate to sphere.



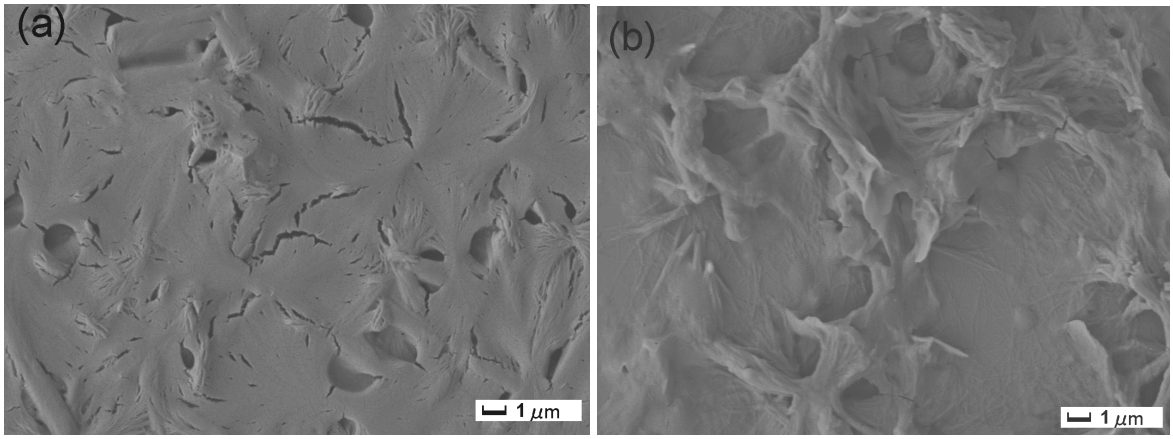


Fig. 2. SEM Images of the Poly(9,9-dihexylfluorene) Microsphere Patterns Prepared from CH2Cl2 in the Ethanol Vapor Atmosphere under the Following Temperatures: (a) -18, (b) 5, and (c) 25 °C.

Influence of Non-solvent Vapor on Microspheres Formation

Fig.3 illustrates the mogphologies of poly (9'9-dihexylfluorene)/CH_2Cl_2 with a concentration of 1 mg/mL under different nonsolvent vapors. Fig.3(a), Fig. 3(b), and Fig. 3(d) showed that the spheres could not be fabricated in the methylbenzene, ethanol, and ethyl acetate vapor. However, it was easily formed in the ethanol non-solvent vapor atmosphere, as shown in Fig.3 (c). The result showed that the spheres formation had affinity with the property of the non-solvent.

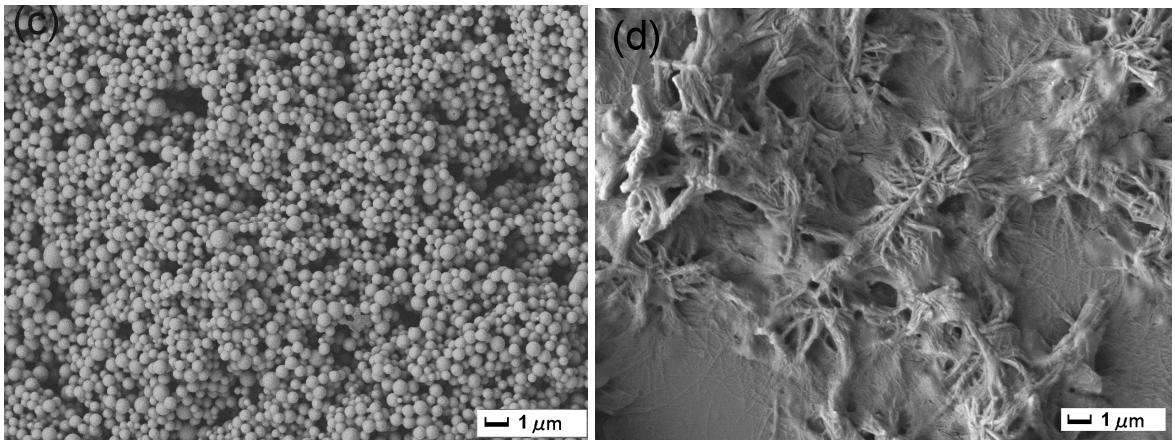

Fig.3. SEM Images of the Self-assembly of Poly(9,9-dihexylfluorene)/CH2Cl2 Solution in the Different Vapors: (a) Methylbenzene, (b) Acetone, (c) Ethanol, and (d) Ethyl Acetate.

Conclusion

The well-ordered spheres poly(9,9-dihexylfluorene) were successfully obtained by the self assembly method of non-solvent vapor with good solvent CH_2Cl_2. The experiments demonstrated that non-solvent vapor atmosphere played a key role on the morphology of the poly(9,9-dihexylfluorene) microspheres film during the formation. From SEM, the sizes and the dispersion of the sphere of poly(9,9-dihexylfluorene) increased with increasing of concentration. The relativity uniform sphere patterns could be easily formed with 1 mg/mL in the ethanol vapor at 25^{o}C.

Keywords: waterborne polyurethane; polypropylene carbonate polyols; polyethylene-1,4-buthylene adipate glycol；Polytetramethyleneether glycol

Abstract: Different kinds of anionic polyhydric alcohols water-borne polyurethane(WPU) emulsion and films were prepared by separately taking polypropylene carbonate polyol(PPC), polyethylene-1,4-buthylene adipate glycol (PBA) and polytetramethylene ether glycol(PTMG) with the same molecular weight as soft segment. Their structure and properties were characterized with Fourier transform infrared spectrometry(FT-IR), X-ray diffraction(XRD), rigidity, adhesive power, contact angle and water absorption. Comparing their properties, it was found that the rigidity, adhesive power and water resistance of PPC WPU were similar to those of PBA WPU.

Introduction

PPC is a kind of aliphatic polycarbonate polyols copolymerized by carbonate dioxide and epoxy. Since PPC was firstly synthesized by Shohei Inoue at the end of 1960s, it had drawn a lot of attention to the investigation of its synthesis and properties as a type of eco-friendly materials[1-3]. Compared with polyester polyurethane, the better water-resistance ability, inoxidizability and barrier property of WPU prepared by taking PPC as soft segment were reported[4-6]. But, there leaves a blank area about the research report of PPC WPU[7]. In this presentation, different kinds of anionic polyhydric alcohols WPU emulsion and films were prepared by separately taking PPC, PBA and PTMG as soft segment and adopting dimethylolpropionic acid (DMPA) as the hydrophilic chain extender agent. The structure of WPUs were characterized by FT-IR. The properties' difference between PPC WPU and the typical polyether WPU, PPC WPU and the typical polyester WPU were characterized by XRD, adhesive strength, rigidity, water contact angle and water absorption.

Experimental

Materials employed**.** PPC (Mn=2000g/mol, hydroxyl value=56.1mgKOH/g) was obtained from Jiangsu Zhongkejinlong Chemical Co., Ltd. (China). PBA (Mn=2000g/mol) and PTMG (Mn=2000g/mol) were bought from Jininghuakai resin Co., Ltd. (China). Isophorone diisocyanate(IPDI)was obtained from Bayer (Germany). DMPA, 1, 4-butanediol (BDO), triethanolamine (TEA) were supplied by Sinopharm Chemical Reagent Co., Limited (China).

Preparation of WPU. In the preparation of the WPU emulsions running in bulk, dehydrated polyol and IPDI were placed in a 500mL 3-neck flask equipped with a stirring apparatus, a thermometer and a condenser and the reaction was last for 2h at 70℃. DMPA and BDO were added subsequently as the chain extender and the reaction was continued for 2h at 70℃. When the amount of NCO reached a certain value, the PPC WPU polymer emulsion was obtained after neutralizing the system with a certain amount of TEA in 30min and emulsifing it for 50min with deionized water under vigrous stirring. The compositions for the preparation of polyurethane were shown in Table 1.

TABLE 1 COMPOSITION FOR THE PREPARATION OF POLYURETHANE

Code	Compositions (g)	Polyolscontent (%)	DMPA content (%)
WPU1	IPDI/PPC/DMPA/BDO(10.00/37.95/1.00/0.52)	79.5	2.0
WPU2	IPDI/PPC/DMPA/BDO(10.00/31.60/1.54/0.44)	72.5	3.5
WPU3	IPDI/PPC/DMPA/BDO (10.00/26.54/1.96 /0.38)	68.3	5.0
WPU4	IPDI/PBA/DMPA/BDO(10.00/31.60/1.54/0.44)	72.5	3.5
WPU5	IPDI/PTMG/DMPA/BDO(10.00/31.60/1.54/0.44)	72.5	3.5

The certain amount of WPU emulsions were coated onto a teflon plate which was stored for 96h under room temperature and then dried for 24h at 60℃to prepare WPU films.

Testing and Characterization. The WPU films were tailored into samples sizing 2cm×2cm with a weight M_1. The samples were dried with filter paper and weighed M_2 after being immersed into water for 24h under room temperature. The water absorption was calculated according to the following formula [8]:

$$\text{water absorption}=\frac{M_2-M_1}{M_1}\times 100\%$$

To determine the water contact angles a drop of deionized water was placed on the film surface and after 1min. The test was conducted using a G-1 contact angle meter (Kyowa Corporation, Japan). Each sample was tested 3 times and the average of the three data was taken as the water contact angle.

The rigidity and adhesive strength of WPU films were tested separately according to GB/T6739-2006 and GB/T9286-1998.

In the determination of FT-IR spectrometry the FT-IR spectra of the films were obtained by using a Nicolet 5700 Fourier transform infrared spectrometer (Nicolet Instrument Inc., USA) in the transmission mode. The films were evenly grinded with potassium bromide (KBr) to perform the testing.

The crystallinity of WPU films were tested by a D/Max-2550 PC X-ray diffraction instrument (RIGAKU., Japan).

Results and Discussion

Infrared Spectroscopic Analysis.Fig.1 showed the FT-IR curves of different kinds of polyols WPU. In Figure 1, the absorption peaks around 3330cm^{-1} represented the N-H stretching vibration peaks of carbamido and the absorption peaks around 1540cm^{-1} characterized the N-H deformation vibration peaks of carbamido in WPU2， WPU4 and WPU5. The vibration peak at 1750cm^{-1}~1620cm^{-1} of WPU2 referred to the overlapping of C=O stretching vibration peak of carbamate and C=O stretching vibration peak of the ester group in PPC WPU soft segment, while to WPU4, the vibration peak at 1750cm^{-1}~1620cm^{-1}represented the overlapping of C=O stretching peak in carbamate and C=O stretching vibration peak of the ester group in PBA WPU soft segment. The absorption peak in WPU5 at 1720cm^{-1}~1620cm^{-1} characterized the C=O stretching vibration peak of carbamate. The attribution analysis and the qualitative analysis of FT-IR spectra indicated that the polymers were characterized as kinds of polyurethane.

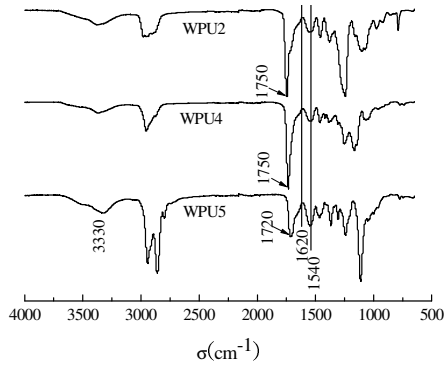

Fig.1 FT-IR Spectra of WPU Films

X-ray diffraction analysis. The XRD curves of different kinds of polyhydric alcohols WPU films were shown in Fig. 2. It could be seen from Fig. 2 that the X-ray diffraction of all the WPUS belonged to dispersion diffraction and had diffraction peaks around 20°.It was concluded there didn't existed an obvious crystallinity in the PPC WPU, PBA WPU and PTMG WPU, and the structure regularity of WPU5, WPU4 and WPU2 declined by order as the diffraction peaks of these WPUs declined by order. The crystallinity of WPU was generally considered to be caused by the gathering and the ordering arrangement of the soft segment, while the hard segment dispersing in the soft segment could weaken the crystallinity of polyurethane[9]. The structure regularity of WPU2 and WPU4 was lower than that of WPU5 as the polarity of PPC and PBA was stronger than PTMG and the stronger inter-force between the hard segment and the soft segment compelled the hard segment disperse evenly into the soft segment to decrease the order arrangement and restrained the micro-phase separation between the hard segment and the soft segment.

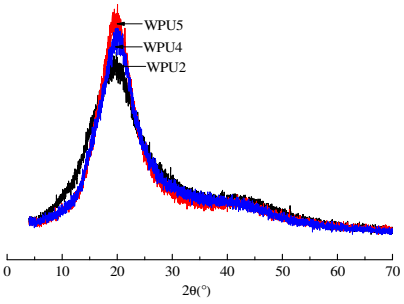

Fig.2 XRD Patterns of WPU Films

Rigidity and adhesive strength analysis of WPU films. From the results of rigidity and adhesive strength tests for WPU films shown in Table 2, it was found the rigidity of PPC WPU film was promoted from 4H to 5H and its adhesive strength was promoted from 1 level to 0 level when the DMPA amount of WPU was improved from 2.0 percent to 5.0 percent. The improvement of rigidity and adhesive strength was accounted for the increase of ester-group amount and hard segment when promoting the DMPA amount. It was concluded that the carbonic ester group in PPC could provide WPU with a better adhesive strength and rigidity. It was found when the DMPA amount of WPUs were the same, the rigidity and adhesive strength of PPC WPU film was similar to the counterparts of PTMG WPU and PBA WPU.

TABLE 2 HARDNESS AND ADHESION OF WPU FILMS

Sample code	Hardness	Adhesion
WPU1	4H	1 level
WPU2	5H	0 level
WPU3	5H	0 level
WPU4	5H	0 level
WPU5	4H	0 level

Water absorption and water contact angles of WPU films. The water absorption and water contact angles of WPUs were shown in Tab. 3. From Table 3 it was found that the water absorption of PPC WPU film was improve from 30.8 percent to 69.8 percent while its water contact angle declined from 80.1°to 63.7°when the DMPA amount of WPU was improved from 2.0 percent to 5.0 percent as the increase of DMPA amount improve the hydrophily of PPC WPU film. When the DMPA amount of WPUs were the same, the water absorptions of PPC WPU film, PBA WPU film and PTMG WPU film were 55.4 percent, 51.6 percent and 28.3 percent separately, and their water contact angles were 74.5°, 78.2° and 77.8° separately. From the phenomena mentioned above it was concluded that the water resistance of PTMG WPU was significantly better than that of PPC WPU and PBA WPU, while the water resistance ability of PPC WPU was a little poorer than that of PBA WPU, as the water resistance ability of the ether group in PTMG was better than that of the ester group in PPC and PBA, and the water resistance ability of the carbonic ester group in PPC was poorer than that of the ester group in PBA.

TABLE 3 WATER ABSORPTION AND WATER CONTACT ANGLES OF WPU FILMS

Sample code	Water absorption(%)	Contact angle(°)
WPU1	30.8	80.1
WPU2	55.4	74.5
WPU3	69.8	63.7
WPU4	51.6	78.2
WPU5	28.3	77.8

Conclusions

PPC, PBA and PTMG with the same molecular weight were chosen as soft segment to prepare different kinds of polyols WPU emulsion and their films. It was found that the adhesive strength, rigidity and water resistance ability of PPC WPU film were similar to the counterparts of PBA WPU film.

The soft segment gathering and ordering arrangement of PPC WPU was poor and there didn’t existed a significant crystallinity.

Keywords: Epoxy resin; Low molecular polyamide 651 (PA651); Curing time; Curing agent content; Dynamic mechanical behavior

Abstract. In this paper low molecular polyamide 651(PA651) is used as the curing agent of epoxy resin. The optimum curing conditions and dosage of the curing agent are obtained by DMA and FT-IR analysis. Based on the dynamic mechanical temperature spectra of samples test, the best curing conditions are room temperature 2 hours, 70℃ 2 hours, 125℃ 2.5 hours and 150℃ 1 hours (RT / 2 h + 70 ℃ / 2 h +125℃ / 2.5 h + 150 ℃ / 1 h). The best dosage of curing agent PA651 is 50 wt %. Since the analysis of Fourier Infrared spectral verified that epoxy groups react completely, the curing conditions are the best curing process.

Introduction

Epoxy resin is a thermoplastic oligomer, the molecular weight between 300-2000 and performance is very bad. Epoxy resin can form three-dimensional network structure when adds the second component (curing agent), and become insoluble and infusible high polymer, and it appears excellent electrical insulation, chemical resistance, adhesion and a series of excellent performances. Epoxy resin is widely used in coatings, adhesives and engineering materials, EP adhesives have good adhesion to most all kinds of metals and nonmetal materials. With the improved performance of modified epoxy resin and new epoxy resin which have unique properties continue to be synthesized, the application fields of epoxy resin are further expanded in biology, medicine, environmental protection and the other fields such as: Protein fixed [1], Enzyme load [2], Ion recognition [3], Tooth filling agent [4], The fabric finishing agent [5] and the other new fields.

Curing agent is indispensable in application of the epoxy resin. There are many kinds of epoxy resin curing agents, however the modified amine curing agents account for 71% of the amount of curing agents. In this paper curing agent is low molecular polyamide resin 651(PA651). The structure of epoxy resin cured by PA651 contains long carbon chain fatty acid and amino，and allows the cured product having high elasticity and adhesive strength and water resistance.

Experiment

Different cure conditions

Epoxy 51 (E-51) and low molecular polyamide 651 (PA651) heat for two hours at the temperature of 60℃. Then the E-51 and PA651 are mixed in the ratio of 2:1 and stired evenly. Put the mixture into the heating PTFE mold which is covered with mold release agent. Set three kinds of curing conditions, RT/7 d+60 ℃/2 h， RT/2 h+70 ℃/2 h+125 ℃/2.5 h, RT/2 h+70 ℃/2 h +125 ℃/2.5 h+150 ℃/1 h。

Different content of curing agent

Taking 50g E-51 and a certain amount of PA651 (30 wt%, 35 wt%, 40 wt%, 45 wt%, 50 wt%, 55 wt%, 60 wt%) respectively heats at 60℃ for 2h. Putting the mixture into the heating PTEF mold which is covered with mold release agent in the certain curing condition of RT/2 h+70 ℃/2 h+125 ℃/2.5 h+150 ℃/1 h.

Results and discussion

DMA detection of epoxy resins which in the different curing conditions

Fig.1 shows tanδ-T curves of epoxy resin in different curing conditions. In Fig.1 line a, line b, and line c respectively represents the curing condition is RT/7 d+60 ℃/2 h，RT/2 h+70 ℃/2 h+125 ℃/2.5 h，RT/2 h+70 ℃/2 h +125 ℃/2.5 h+150 ℃/1 h. Tanδ is known as the loss factor, used to indicate the size of the internal friction. Tanδ maximum corresponding temperature is the glass transition temperature (T_g). Fig.1 shows with the increase of temperature internal friction curve line a, line b, and line c are complete and symmetrical peak shapes. This proved epoxy resin can be cured completely in these three kinds of curing conditions, epoxide groups almost completely react. Line a, line b and line c corresponding T_g gradually increased and the internal friction peak is gradually reduced, this shows in the process of thermal curing and post-curing treatment that there are chemical reactions resulting thermosetting compound three-dimensional network structure has changed and a small amount of residual epoxy groups react with the curing agent. Comparing with line a, line b and line c can conclude that the best cure condition is RT/2 h+70 ℃/2 h +125 ℃/2.5 h+150 ℃/1 h.

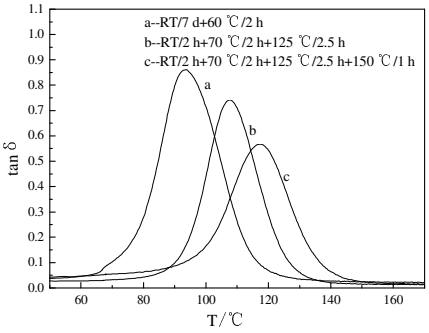

Fig.1 tanδ-T curves of epoxy resin in different curing conditions.

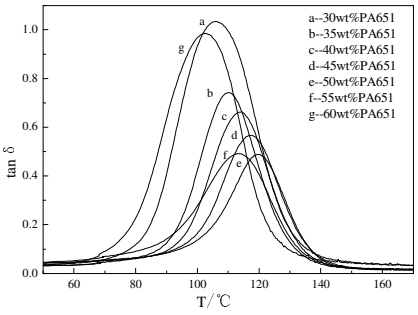

Fig.2 tanδ-T curves of the epoxy resin which in different amount of curing agent,

DMA detection of epoxy resins which under the condition of different curing agent percentage

PA651 dosage range widely, epoxy resins of different curing agent percentage are prepared at the best curing condition in order to determine the optimal dosage of PA651.

In Fig.2 line a, line b, line c, line d, line e, line f and line g are epoxy resin friction curves which curing agent amount respectively is 30w%, 35w%, 40w%, 45w%, 50w%, 55w% and 60w%. In the picture it shows that when the content of curing agent below 50%, the cured epoxy resin of T_g increase with the increasing content of PA651. The reason of this phenomenon is the dosage of PA651 increasing makes epoxy resin crosslink density increase. However T_g of cured epoxy resin decreases with the increase of PA651 dosage when the amount of PA651 above 50w%. The reason is epoxy groups almost completely react when the PA651 dosage at around 50w%, and the excess curing agents play the role of plasticizer makes the T_g lower if continue to increase the amount of PA651. Therefore, the optimum amount of curing agent PA651 is 50w%.

Infrared spectrum analysis of cured epoxy resin

Epoxy resin sample cured in the condition of RT / 2 h + 70 ℃, 2 h + 2.5 h + 125 ℃ / 125 ℃ / 1 h and dosage of curing agent is 50w%.

Fig.3 shows the full FTIR spectrum of cured epoxy resin. The strong absorption at 3379.09 cm^{-1} is assigned as stretching vibration peak of N-H from amide and O-H from alcohol. The absorption peak at1648.3 cm^{-1} is stretching vibration peak of C=O from amide. The vibration stretching peak of carbon skeleton of benzene appears at1608.14 cm^{-1} and 1509.94 cm^{-1}, besides that the characteristic absorption band of benzene ring surface of the inner and outer deformation vibration is found at 1106.48 cm^{-1} and 828.14 cm^{-1} . Absorption peak at 1460.74 cm^{-1} is C-H deformation vibration peak. Absorption peak at 1296.95 cm^{-1} is C-N deformation vibration peak and absorption peak at 1248.19 cm^{-1} is aromatic ether deformation vibration peak. The absorption peaks at 1036.02 cm^{-1} and 1181.95 cm^{-1} are caused by fatty ether deformation vibration peak. Compared with standard spectra of pure epoxy resin, absorption peak of epoxy groups at 910-920 cm^{-1} disappeared. It proves that the epoxy groups completely react.

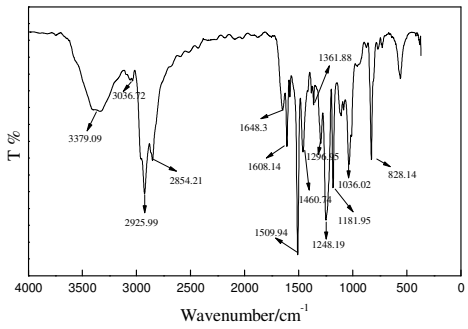

Fig.3 FTIR spectrum of cured epoxy resin

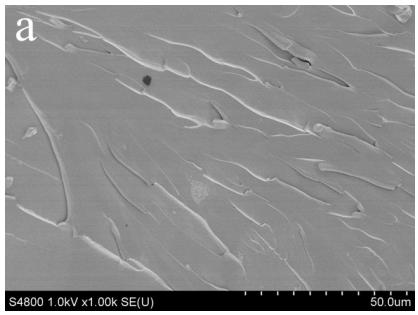

Fig.4 SEM test result of cured epoxy resin

Scanning electron microscopy images of cured epoxy resin

Fig.4 shows the SEM test result of cured epoxy resin. In the picture the section of cured epoxy resin is neat and crack distribution is uniform, so it proves that epoxy resin is a typical brittle fracture. This shows cured epoxy resin itself is very brittle.

Conclusion

In this work the best curing conditions and optimum amount of curing agent is found. The best curing condition is RT/2 h+70℃/ 2h+125℃/ 2.5 h+150℃/1 h and the optimum amount of curing agent is 50w%.

Keyword: *p*-aminophenol; dimethyldichlorosilane; silicone-containing diamine; optimum synthesis process; bis(*p*-aminophenoxy)dimethylsilane(*p*-APDS)

Abstract: Bis(*p*-aminophenoxy)dimethylsilane(*p*-APDS) was prepared by the reaction of *p*-aminophenol or 4-acetamidophenol with dimethyldichlorosilane in the presence of triethylamine or pyridine through four different means. The structure of diamines was examined by melting point apparatus, FT-IR and nuclear magnetic resonance apparatus ^{1}H-NMR. The productivity, process and cost of four means were compared. The results showed that benzene as a solvent, triethylamine as acid, *p*-aminophenol and dimethyl dichlorosilane at 40℃ for 4h is the most economical and reasonable process for synthesis of bis(*p*-aminophenoxy)dimethylsilane (*p*-APDS).

Introduction

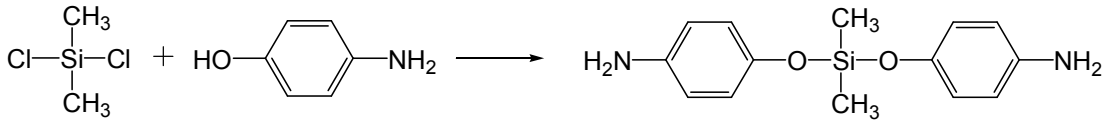
As a kind of resin system which is derived from polyimide, bismaleimides(BMI) is more important because of its relatively low cost, high thermal stability, non-volatility and non-flammability among the addition type polymides[1,2,3]. Such kind of resin can supply higher operating temperature than that of the epoxy resin, simultaneously still can maintain epoxy-like processing property. Thus, they are widely used as high heat-resistance materials in the aerospace industry, in multilayer printed-circuit boards and in surface mounting devices, as well as high-temperature adhesive agents and in many other applications[4]. However, the cured resins are brittle due to the aromatic nature and the high crosslinking density of the network. At present, many methods have been employed to overcome the inherent brittleness of bismaleimide resin[5]. For example, the linear chain extension reaction of the constituent prior to crosslinking with aromatic diamines via Michael addition reaction, the incorporation of engineering thermo-plastics such as polyimide, polyethersulfone or polyether-ketone, polyhydantoin etc [6-8], or natural rubber[9].

Using diamine to modify BMI is an earlier method and also a convinent way to improve its toughness. The modifying mechanism is based on BMI and diamine Michael addition reaction. The linear polymer was synthesized by double bond in BMI reacting with primary amine in diamine which elongated the space of cross-linked points[10,11]. The application of diamines, for example, DDS, extends the backbone of BMI, but reduces the heat resistance. In recent years, using diamine containing siloxane attracted researchers' attention due to the physical and chemical characteristics of the Si-O bond. The siloxane unit is characterized by a lower intermolecular force, ease of retation and the relatively long Si-O bond, and these characteristics enable the siloxane to be flexible and to display properties which are fairly constant over a wide temperature range[12]. Consequently, a series of silicone-containing BMI had been prepared as a thermal stable resin[13]. Thus, we take attention to explore a kind of diamine-bis-(*p*-aminophenoxy)dimethyl silane, which can provide a higher thoughness, while still maintaining heat resistance because of the existance of Si-O bond and benzene rings at the same time.

We explored four processes to synthesize (*p*-APDS). The main objection of this research was to optimize a synthetic route of (*p*-APDS) based on compromising yield, cost and purify. The structure of the resultant was characterized by FT-IR, ^{1}H-NMR, melting point.

Experimental

Materials and Reagents.

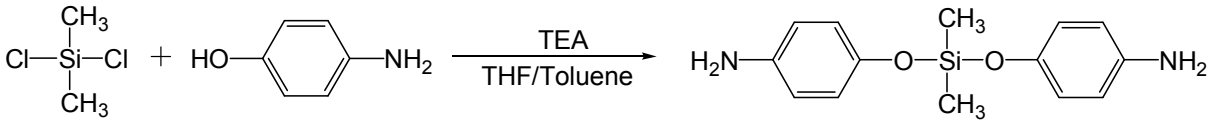


All chemicals were used after removal of water and were dried. *P*-aminophenol (Aladdin Industrial Co.), 4-acetamidophenol (HWRK Chem Co.,Beijing), dimethyldichlorosilane (Alfa Aesar Chem. Co., Tianjin). Triethylamine (TEA), tetrahydrofurane and dichloromethane were purchased from Guanghua Science and Technology Co., Ltd. Guangdong. Benzene and pyridine were purchased from Tianjin Fu Chen Chemical Reagents Factory. N,N-Dimethylformamide (DMF) and petroleum ether were purchased from Tianjin Fuyu Fine Chemical Co., Ltd.. Diethylamine and toluene were purchased from Tianjin Tianli Chemical Reagent Co., Ltd.. Hydrochloric acid (Beijing Chemical Plant). Sodium hydroxide (Paini, Zhenzhou).

Instruments.

Infrared measurements were performed on a Nicolet Avatar 360 FT-IR spectrometer (America). The ^{1}H NMR spectra were recorded in $CDCl_3$ solution using a Bruker Avance 400 MHz (Germany). The melting point was performed by a X-5 micro melting point apparatus (China).

Experiments

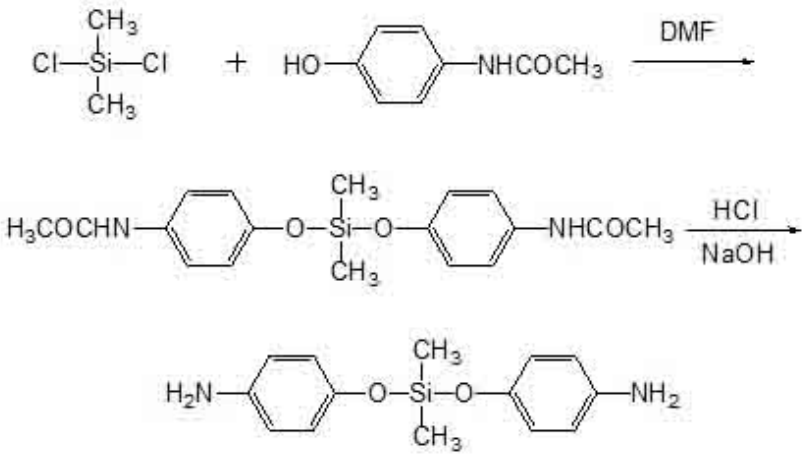


Method A

Scheme 1 The Principle of method A

A mixture of 10.9g (0.1mol) of *p*-aminophenol, 10.12g (0.1mol) triethylamine, and 100ml anhydrous benzene were introduced into a three-necked flask to which 6.966g (0.054mol) of dichlorodiphenylsilane was added drop-wise in 2h at 40℃. When the addition was completed, the reaction was continued at 60℃ for another 4h. The mixture was then filtered to remove salt. The filtrate was purified by water-washing and got the lower liquid. The liquid was then concentrated on a rotary evaporator. The residue was dissolved in the mixture of petroleum ether and benzene (1:1 of Volume ratio) at heating condition and filtrated. The product was crystallized from the mixture at 2~5℃ to yield brown-yellow crystals and dried under reduced pressure -0.01MPa at 50℃ for 24h or more. The yield was 41.25%.

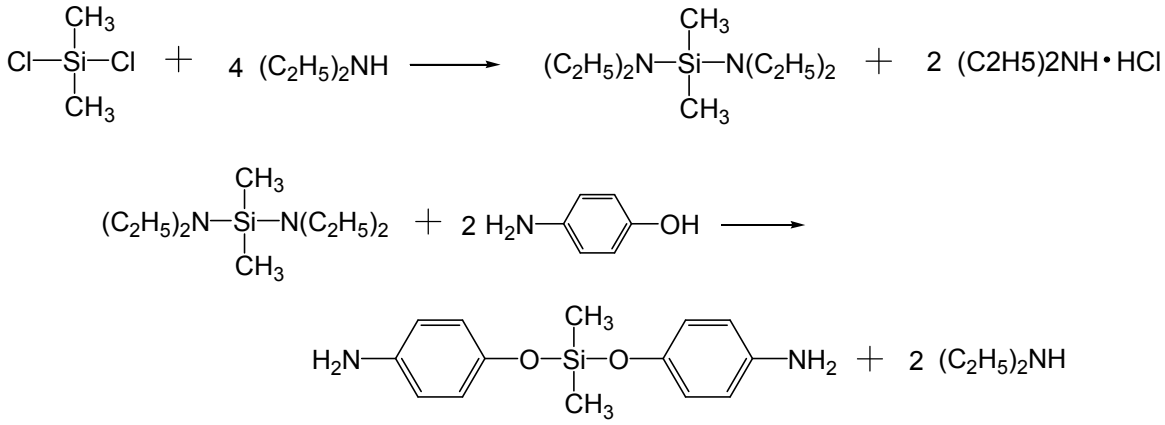
Method B



Scheme 2 The Principle of Method B

Into a three-necked flask, mixture of *p*-aminophenol (10.9g, 0.1mol), triethylamine (10.12g, 0.1mol), 25ml of tetrahydrofurane and 5ml of toluene were introduced. A solution of dichlorodimethylsilane (6.45g, 0.05mol) was added into the mixture drop wise over a period of 2h at 60℃. The reaction mixture was refluxed at 70℃ for 6h. Then formed salt was removed from the mixture by filtration and the filtrate was concentrated by a rotary evaporator. The residue was dissolved in ether and the insolubles were isolated by filtration. The product was crystallized from

ether at 0℃ to yield brown-yellow crystals and dried under reduced pressure -0.01MPa at 50℃ for 24h or more. The yield was 36.8%.



Method C

Scheme 3 The Principle of Method C

To a solution of 4-Acetamidophenol (15.1g, 0.1mol) in DMF(60ml) and pyridine(7.91g, 0.1mol), dichlorodimethylsilane (6.45g, 0.05mol) was added by drop wise at -10℃~-6℃ in 2h. Then the reaction mixture was proceeded 2h at room temperature, and heated at 40℃ for 4h. After cooling at temperature, the reaction mixture was filtrated and the filtrate was added into hydrochloric acid of 5 mol/L. The mixture was refluxed a period of time and then evacuated under reduced pressure. The crude product was crystallized from cold water and filtrated. After regulating pH to 10 with a solution of NaOH of 5 mol/L, the liquid was refluxed for 1h. The brown products was crystallized when cooling down and was dissolved at heated temperature in ethanol. The products was crystallized after decolored with active carbon. The yield was 32.67%.

Method D

Scheme 4 The Principle of Method D

Into a three-necked round bottom flask equipped with a magnetic stirrer and a dropping funnel, 29.2g (0.4mol) of diethylamine and 50ml of anhydrous dichloromethane were placed. The mixture reaction was vigorously stirred at -17℃~-20℃. Dichlorodimethylsilane (12.9g, 0.1mol) was added dropwise for 2h. The reaction was kept at this temperature for 2h. The white suspension was filtered to obtain a transparent solution that was concentrated at normal pressure, then collected fraction of 17mm Hg under 81~82℃. The viscous liquid was bis (N,N-diethyl amine) dimethylsilane.

10.9g (0.1mol) of *p*-aminophenol dissolved in 80 ml of anhydrous benzene were introduced into a 250 ml three-necked flask containing a magnetic stirrer and a reflux condenser. 10.1g (0.05mol) of

bis(N,N-diethylamine)dimethylsilane was introduced into reaction flask via a dropping funnel for 60min. The reaction mixture was kept 2h at this temperature. The mixture was filtered and the filtrate was concentrated by a rotary evaporator. The residue was dissolved in the mixture of petroleum ether and benzene (4:6 of volume ratio). The yellow product was crystallized from the liquid at 2~5℃. The yield was 29.58%.

Results and discussion

In the present work, four types of synthesis process of a kind of silicone-containing diamine—bis-(*p*-aminophenoxy) dimethylsilane(*p*-APDS) are used, and a better synthesis method is decided by comparising the productivity, the cost, and the structure-property of their products.

Confirm of structures.

Common spectroscopic methods including FT-IR (Fig 1), ^{1}H-NMR (Fig 2) were used to confirm the structures of (*p*-APDS) and the results were collected in Table 1. From the figure 1 and figure 2, it can be determined that the resultants of four methods are the same. In the FT-IR spectra of diamine, peaks at about 1239cm^{-1}(Si-O asymmetrical stretching), 1093 cm^{-1}(Si-O symmetrical stretching), and 973 cm^{-1}(Si-O asymmetrical stretching) approved the Si-O bonds formation. Additionally, band at 3650-3590 cm^{-1} that was related to the O-H bond of hydroxyl group in the *p*-aminophenol was disappeared. Furthermore, the evident presence of absorption bands at 3275-3345 cm^{-1}(N-H stretching) and no peaks at 1650 cm^{-1}(C=O stretching of acylamino) demonstrated structure of target product. ^{1}H-NMR spectra of bis(*p*-aminophenoxy)dimethylsilane (Fig 2) exhibited the chemical shifts characteristic for Si-CH_3 signal at 0.21-0.23 ppm, amine protons at 3.36-3.52 ppm, aromatic protons appearing as doublet at 6.51 ppm and 6.68 ppm. The amino peaks existed in the diamine spectrum shifted to higher fields as a result of appearing of electrondonating oxygen groups. From the above, we can determine the resultant of four methods is bis(*p*-aminophenoxy)dimethylsilane.

Table 1 Characterization of bis(p-aminophenoxy)dimethylsilane

spectroscopic methods	A	B	C	D

FT-IR(KBr), cm^{-1}	3275-3340(NH_2) 3037(CH, Aromatic) 2958-2818 (CH, Methyl) 1614(C-N, N-H) 1517 (C=C, Aromatic) 1482(Si-Ph) 1256(Si-CH_3) 1087(Si-O)	3284-3345(NH_2) 3028(CH, Aromatic) 2958-2818 (CH, Methyl) 1614(C-N, N-H) 1508 (C=C, Aromatic) 1482(Si-Ph) 1256(Si-CH_3) 1095(Si-O)	3275-3345(NH_2) 3028(CH, Aromatic) 2962-2814 (CH, Methyl) 1614(C-N, N-H) 1508 (C=C, Aromatic) 1473(Si-Ph) 1256(Si-CH_3) 1087(Si-O)	3284-3345(NH_2) 3028(CH, Aromatic) 2962-2814 (CH, Methyl) 1614(C-N, N-H) 1508 (C=C, Aromatic) 1473(Si-Ph) 1256(Si-CH_3) 1087(Si-O)

Melting point measurement.

The synthetic resultant of the above four processes are the (p-APDS) crystals. Generally speaking, the narrower the melting temperature range is, the higher purity the resultant has. It is convenient to obtain the melting point of the products with melting point detector. The results are listed in table 2. According to the references, the melting point of the (p-APDS) crystals is 64℃, and the melting points of the resultants listed in table 2 are all close to this figure. Thus, the resultants are (*p*-APDS).

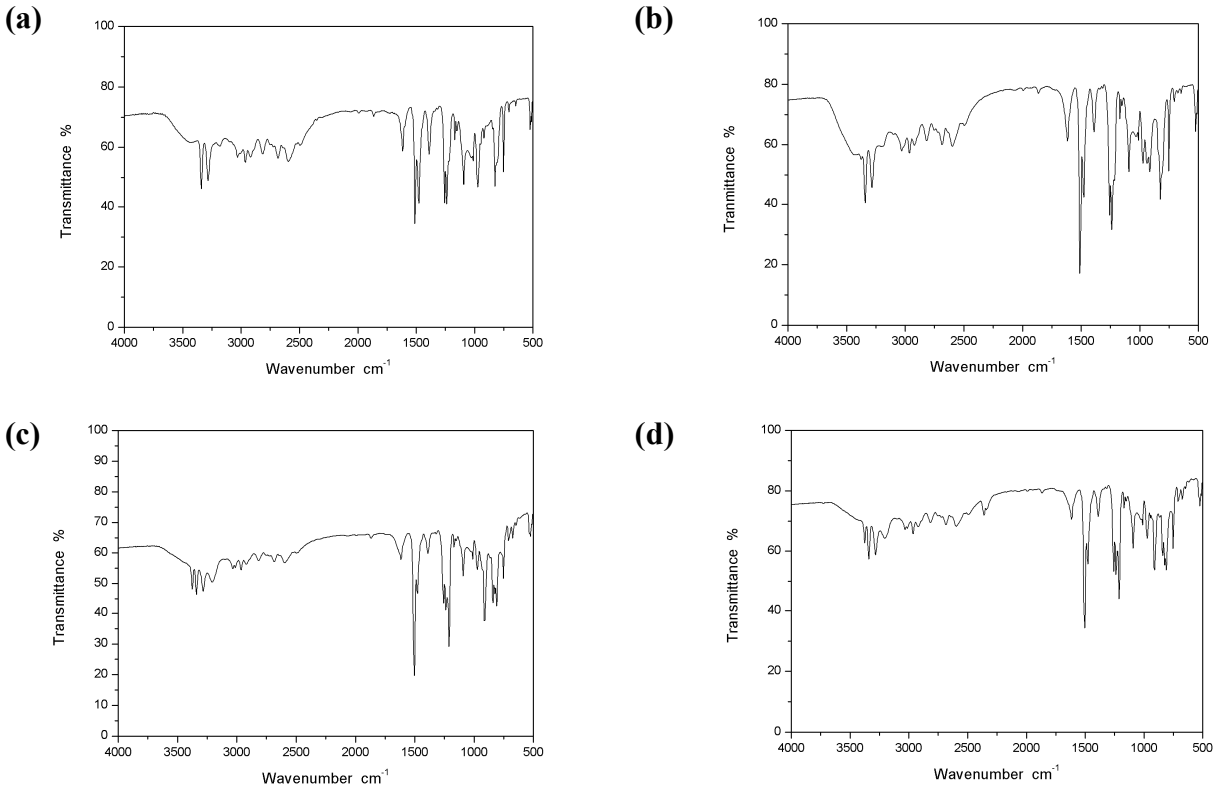

Fig 1 FT-IR of Four Methods of bis-(p-aminophenoxy)dimethyl silane

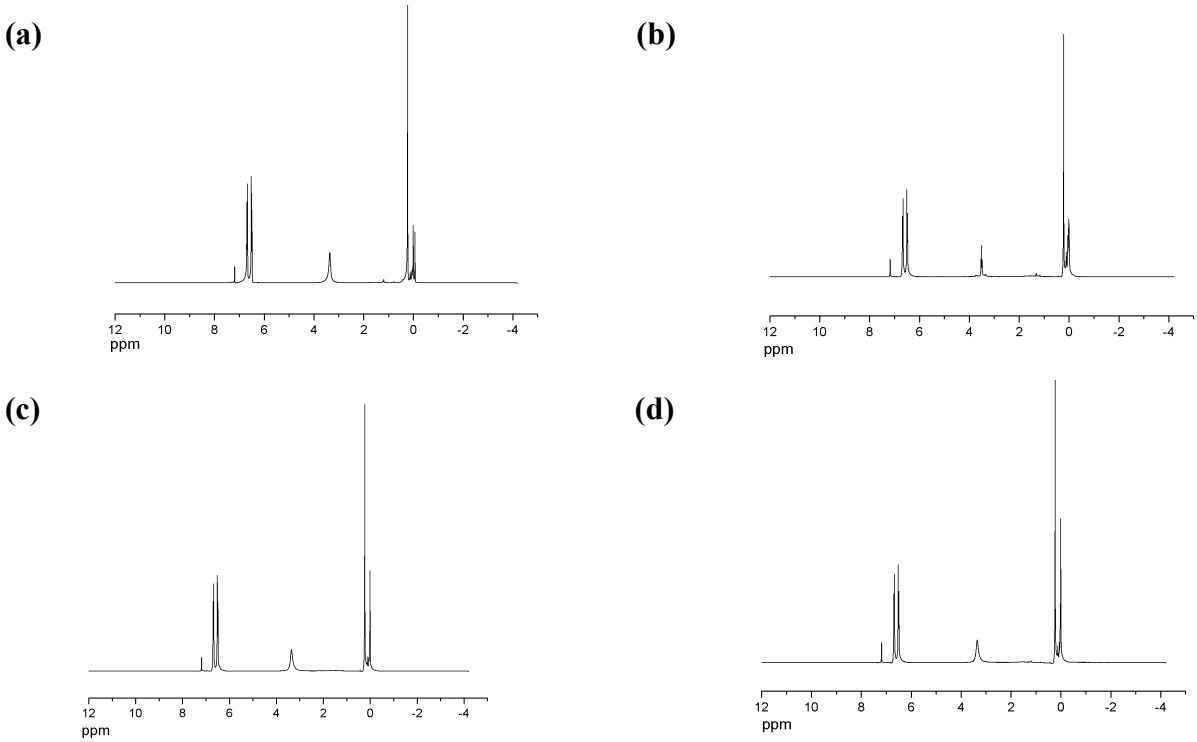

Fig 2 H-NMR of Four Methods of bis-(p-aminophenoxy)dimethyl silane

Table 2 The melting point of bis(p-aminophenoxy)dimethylsilane

	A	B	C	D
Melting Point/℃	58.5~63.8	59.7~64.6	62~64	62.5

Yield of product.

Since four synthetic methods of (*p*-APDS) were used in this paper, the optimal synthesizing technology was determined by optimizing the synthetic conditions of four synthetic ways and we obtain the optimum yield ultimately. Four synthesis processes are listed in table 3.

Table 3 Synthetic processes of four methods

	Solvent	T/℃	Ratio(A:B)	Time/h	Yield/%
A	Benzene	40	1:2.05	4	41.25
B	THF+Toluene	70	1:2.05	6	36.8
C	DMF	Room temperature+40	1:1.7	6	32.67
D	Dichloromethane+Benzene	-20+80	1:2.4	2	29.58

Note: A in the table is dimethyldichlorosilane, and B is *p*-aminophenol.

We studied the influence of different factors on the process of each method, and ultimately determined their optimal synthesis before. In this paper, method A, B and C are one-step synthetic processes and the product of method D is synthesized by a two-step method. Method A in yield is greater than method B, on account of the differences in their solvent, the reaction temperature and the time. We had taken the same conditions as process A during process B, such as in the proportion of 1:2.05(A:B) at 40℃ for 4 hours, however, the yield is lower than 36.8%. This may be present by-products because of reaction degree is not enough, which is caused by lower temperature and shorter reaction time. In addition, we applied a mixed solvent of benzene and petroleum ether when recrystallization in method B that is same as method A, the result showed us the yield is only 11.36% and there are more by-products than when using ether as a recrystallization solvent. The yield of method C which use acetaminophen as raw material and reactive at room temperature and 40℃ for 2 hours respectively is only 32.67%. In this reaction, we gave protection of amino group in *p*-aminophenol and ensured that hydroxyl group was priority to react with dimethyldichoride and this made it easier for the reaction. However, this process is too complicated due to it includes too many procedures and the conditions of reaction are hard to control, so the yield is lower relatively.

The reaction product of dimethyldichlorosilane and diethylamine was reacted with the *p*-aminophenol in Method D, leading Si-Cl bond into Si-N bond, which decreased its activity and reacted with hydroxyl group. This process is easy to achieved, however the course of reaction is more miscellaneous than others at the same time and get lower yield at last.

From the above, the reactive process and yield of one-step method are much better than two-step one, and method A is a desired synthetic process of bis(*p*-aminophenoxy) dimethylsilane.

Costs of four methods.

Silicon-containing diamine is very expensive in the past, for example, bis(3-aminopropyl) tetramethyl disioxane, which is currently commercialized in the United States, is worth more than $ 500 per 100g. Therefore, the emphasis of the synthetic work is to improve the yield and to reduce the cost. According to the upper analysis of yield and structure, we calculate the cost of per gram of each method. The data is listed in table 4. We can conclude method A is the lowest cost of them from the table.

Table 4 The cost of four methods

	A	B	C	D
cost/¥	1.76	5.48	4.09	3.83

Conclusion

With dimethyldichlorosilane and *p*-aminophenol as the main raw materials, bis(*p*-aminophenoxy)dimethylsilane was synthetized through four kinds of methods. The discussion about structure, the melting point, the process and the costs make us to determine the optimal synthetic method of the product. With benzene as solvent, bis(*p*-aminophenoxy) dimethylsilane(*p*-APDS) was prepared by the reactions of *p*-aminophenol and dimethyldichlorosilane(1:2.05) in the presence of triethylamine at 40℃ for 4h, at last using a mixed of benzene and petroleum ether as recrystallization solvent, recrystallizing to obtain the product. The melting point of product is 58.5~63.8℃.

Keywords: Starch, Migration, Phase separation, Co-continuity, Mechanical properties, Perera approach

Abstract: The structure of the starch/styrene-butadiene latex composites was characterized using Scanning Electron Microscopy (SEM). In order to get a better contrast between starch and latex, OsO_4 were used to stain latex. Ion-beam cutting and liquid nitrogen cracking were employed to fabricate qualified cross-sections for SEM characterization. During drying, starch and latex migrate, creating non-uniform structure with latex dominated in the lower surface (next to the substrate) and starch in the upper surface (open to the air). The film formation of latex is slower than the starch/latex film forming. Phase separation occurs with starch granules embedded in the latex-starch matrix, reinforcing the composites. The analysis of composite structure and use of Perera approach indicate that good adhesion is present between latex phase and starch phase, starch granules and latex-starch matrix. When the latex is substituted by starch, the elastic modulus and tensile strength increase whilst the elongation at break decreases. When the volume fraction of starch is higher than 41.7 %, increasing starch content, the increase of ultimate tensile strength and elastic modulus accelerate, whereas the elongation at break decreases slower, which may arise from the phase co-continuity of starch.

Introduction

Since styrene-butadiene (SB) latex was emulsion polymerized in the World War II [1], SB latex is widely used as a binder. However, the fluctuations of crude oil raw materials and the increasing environmental concerns put stress on SB latex industry. Starch is an eco-friendly, sustainable, low-cost natural polymer, which can partly substitute SB latex in synthesized rubber and paper coatings [2].

The blends of starch and SB latex need to form a film to execute the binding power. The migration of starch and SB latex during the film formation in the paper coating is acknowledged [3]. However, there are some contradict conclusions on the effect of starch on the latex migration. Ikeda et al. [4] and Hamada et al. [5] found that starch induced the latex migration in the starch-latex dual binder system, while the opposite result was achieved by Du et al. [6] and Zang et al. [7]. This contradiction has not been addressed due to the lack of study on the interactions between latex and starch. Meanwhile, the inclusion of more starch in the paper coating can give rise to various mechanical failures, such as picking and cracking [8]. Therefore, it is advantageous to investigate the interactions between the latex and starch and their contributions to the mechanical properties.

In this study, morphologies of the surfaces and cross-sections of the starch/ SB latex composites were investigated by using Scanning Electron Microscopy (SEM). Together with mechanical tests and the use of Perera approach [9], interactions between SB latex and starch were qualified. This study can be further used to analyze and understand the problems caused by using more starch as mentioned in the context.

Experimental

Materials.

The latex is a low Tg (2 °C) styrene-butadiene latex with a density of 1.0 g/cm^3, produced by Styron. The starch is a thermo modified starch from Cargill, the density of which is 1.4 g/cm^3.

Sample Preparation.

Starch was dispersed into distilled water at 20 % solid concentration in a beaker. The dispersion was put into a preheated (93 °C) water bath and cooked for 60 minutes with continuous stirring at 450 rpm. Pre-calculated amount of starch and latex were mixed by stirring at 450 rpm for 30 minutes. The mass ratios between starch and latex are 0/100, 10/90, 20/80, 30/70, 40/60, 50/50, 60/40, 70/30. A vibration mesh with the mesh diameter of 38 μm was used to remove the air bubbles in the blends. The filtered blends were drawn onto a Mylar film using a laboratory-made applicator driven by a rod coater. The thickness of wet coating films was adjusted by using different applicator slots to obtain dry films with the thickness of 100-150 μm. The wet films were dried in a conditioned room at 23 °C and 50% relative humidity (RH) for 24 hours. The dried films were carefully peeled off from the Mylar substrate. The films for the mechanical tests were annealed in a hot air oven at 70 °C for 1 hour. The annealed films were kept in the condition room for at least 2 days before measuring the mechanical properties.

Scanning Electron Microscopy.

The selected un-annealed samples were stained with 1 g osmium tetroxide crystals in a fume hood for 48 hours, referring to Chinga et al. [10]. In order to get a satisfactory cross-section for SEM imaging, liquid nitrogen cracking (refer to Landreau [11]) and ion-beam cutting were employed. The surfaces and the cross-sections of the stained samples were then imaged with Zeiss Leo 1530 Gemini SEM. In-lens, secondary electron imaging (SEI) and back-scattered electron imaging (BSI) modes were used.

Mechanical Tests. S

amples were punched out from the annealed film using a steel barbell cutting die with a total length of 75 mm, the gauge length of 25 mm and the central width of 4 mm. The mechanical measuring was performed on an Instron 8872 with a deformation rate at 10 mm/min.

Results and Discussion

Surface Topography.

The morphology of the upper surface (open to air) and lower surfaces (next to the Mylar substrate) of the composites was shown in Figure 1. The white dots in Fig. 1 are the OsO_4 stained SB latex particles. There are clear differences between the lower surfaces and upper surfaces. The Mylar surfaces have a monolayer of latex particles whilst the air surfaces are dominated by starch with only a few latex particles. This difference indicates that starch and latex particles migrate in the starch/SB latex composite and that the migration ability and directions are different. Because that Mylar film is a non-absorbent substrate of water, water can only be evaporated at the upper surface during the drying. Starch is a water soluble polymer, therefore larger migration tendency to the upper surface compared to latex particles [12, 13], dominating the upper surface. The latex particles may migrate to the lower surface induced by the attraction between the Mylar substrate and latex particles, accumulating at the lower surface. The different migration abilities may result in the non-uniform distributions of latex and starch, which may further affect the properties of the composites.

As the addition level of starch increases from 40 wt% to 70 wt%, the latex amount in the upper surfaces increases, while the opposite result is observed at the lower surface. Furthermore, the latex amount in the upper surface (Fig. 1(b) and 1(d)) is always smaller than its fraction in the formula. This may imply that starch can hinder the migration of latex to the lower surface when the starch addition is high enough. This may attribute to the increased viscosity of the blends induced by starch, which can restrict the movement of latex particles.

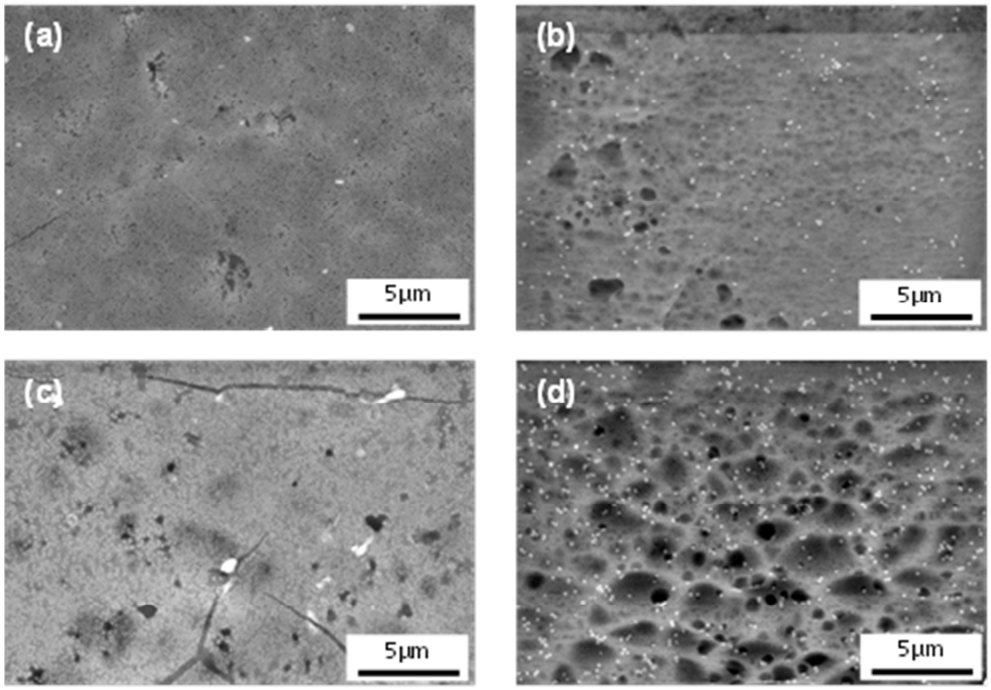

Fig. 1 BSI-SEM images of OsO_4 stained surfaces of starch/latex composites. a, b: lower and upper surface, 40 wt% starch; c,d: lower and upper surface, 70 wt% starch.

As shown in Fig. 2, these latex particles are in the shape of dodecahedron and separated from each other with clear gaps. In the current drying condition (23 ^{0}C), the film formation of late stops at the deformation of the latex particles and that the molecules inter-diffusion and entanglement have not yet taken place [14]. This may also indicate that the film formation of latex is slower than that of the composite.

Cross-section Morphology of the Composites.

The ion-beam cutting cross-sections were characterized using the BSI mode of SEM, as shown in Fig. 3. Grey scale particles can be clearly identified in Fig. 3(a) and 3(c). These grey particles seem to be the starch granules, due to the following reasons. Firstly, both the shape (round or oval) and the diameter (1-10 µm) of the grey particles are approximate to that of starch granules. Secondly, the amount of the grey particles increases with increasing the starch content from 40wt% to 70wt%, by comparison 3(a) with 3(c). Furthermore, the grey particles are more easily damaged (burnt out) by the electron beam during SEM imaging than the remaining matrix and more damaged areas are present when the starch content increases from 40wt% to 70wt%, as shown in Fig. 3(b) and 3(d). However, it is still unclear where these granules come from. It is improbable that all the granules are undispersed granules left during the cooking, since the starch was cooked long enough (60 minutes at 93 °C). Some of the granules may come from retrogradation due to the drying at low temperature (23 °C) [15]. Additionally, starch and latex are incompatible. The presence of

incompatible phase can accelerate the formation and growth of the starch crystals, therefore increasing the retrogradation of starch [16].

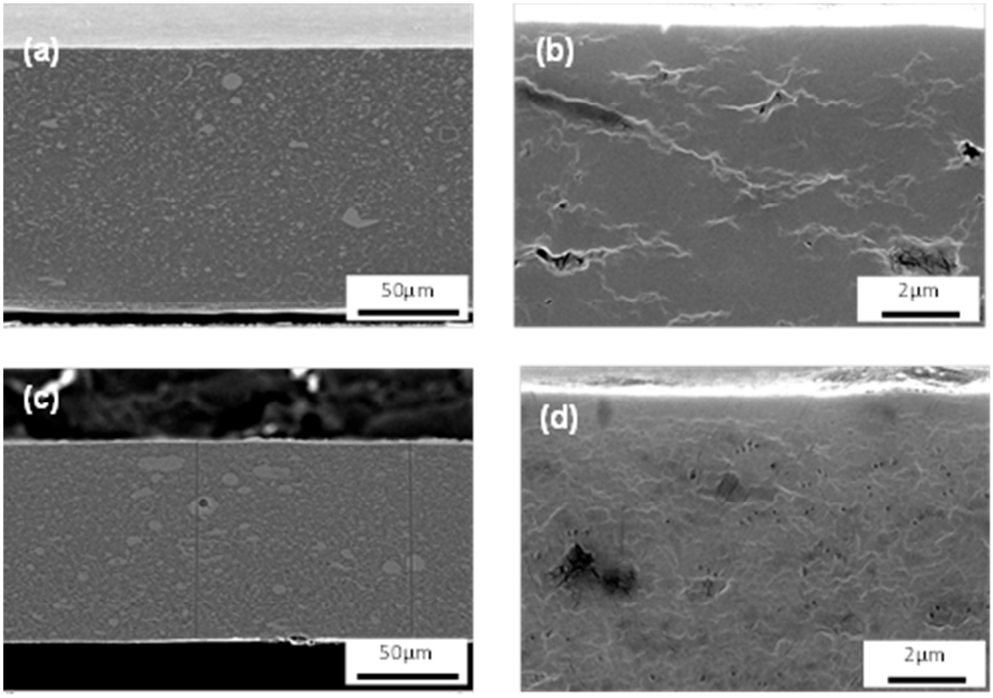

Fig. 3 Ion-beam cut cross-section images captured by BSI-SEM. a: 40 wt% starch; b: Partial magnification of (a); c: 70 wt% starch; d: Partial magnification of (c).

These gray scale particles imply the possibility of phase separation of latex and starch. Phase separation is commonly present in the starch-polymer composites, resulting from the incompatibility of hydrophilic starch and hydrophobic polymer [17, 18]. The phase separation can be clearly seen in Fig. 4. The gray particles are embedded in the matrix without clear gap between the two (as shown by the arrows in Fig. 4), which may indicate that good adhesion is present between the particles and the surrounding matrix [17]. This good adhesion may result from the hydrogen bonds between the particles and the starch in the surrounding matrix. In addition, the remaining surfactants in the latex may also improve the adhesion at the interphase. The area of starch particles in the Fig. 3 is smaller than the starch volume fraction in the formulas, which may indicate that only part of the starch is present as particles reinforced in the composites and the remaining starch, together with latex, is working as matrix.

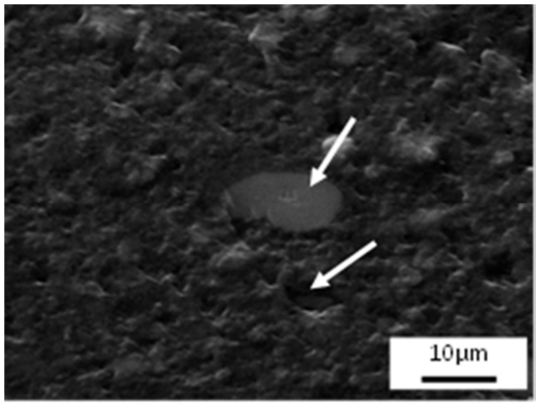

Fig. 4 SEI-SEM image of the cross-section created by liquid nitrogen cracking (starch content: 40 wt%)

Mechanical Properties of the Composites.

The stress-strain curves of the composites containing various starch mass ratios are shown in Fig. 5. The mechanical properties of the composites change a lot with the increasing substitution of latex by starch. The ultimate tensile strength and elastic modulus increase, whereas the elongation at break decreases. However, it should be noted that samples containing 0-20 wt% starch did not break when the Instron machine reached its maximum extensional strain. Therefore, the elongation at beak and ultimate tensile strength should be bigger than the test results.

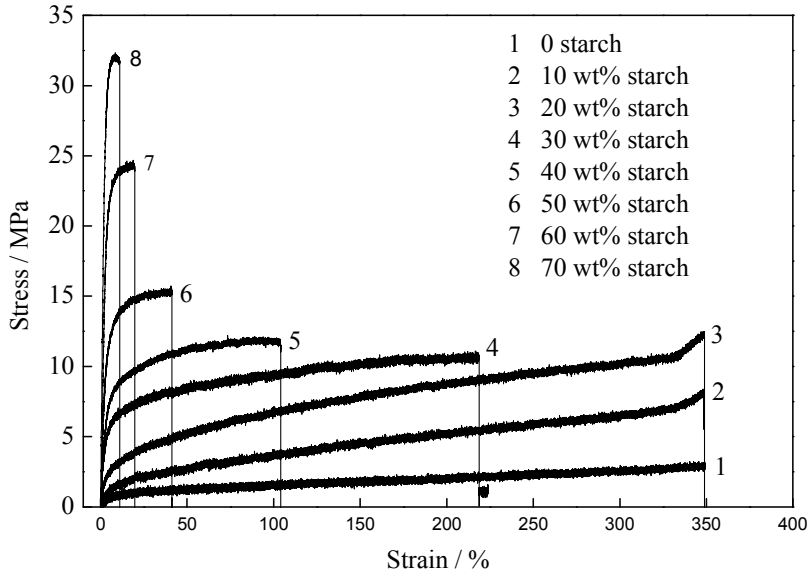

Fig. 5 Stress-strain curves of starch/ latex composites

The effects of starch content on the ultimate tensile strength, elastic modulus and elongation at break are shown in Fig.6. As illustrated in Fig.6(a), the ultimate tensile strength increases with more starch inclusion in the composites. The exception point (30 wt% starch) may result from the restriction of current test method, as stated above. The reinforcing function of starch in the composites can attribute to the following two reasons. Firstly, the starch molecules in the matrix can form hydrogen bonds, which can further develop into dense networks of starch in the composites, improving the tensile strength. Secondly, the starch granules (as shown in Fig. 3 and Fig. 4) can transfer the stress of the starch-latex matrix, reinforcing the composites [19].

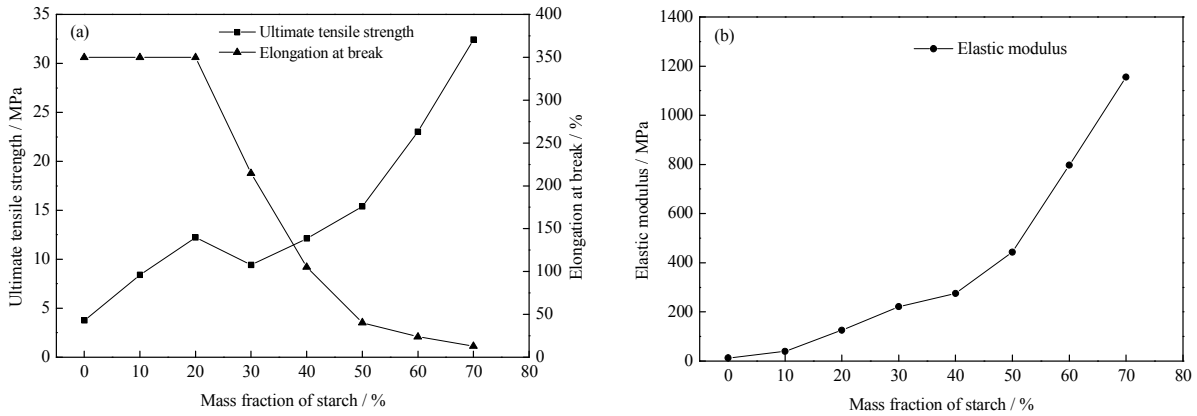

Fig. 6 Effect of starch content on the ultimate tensile strength (a■), elongation at break (a▲) and elastic modulus (b)

As shown in Fig. 6(a), increasing the starch content can decrease the elongation at break sharply. The reason for the exception points (0-20 wt% starch content) has already been mentioned in the context. The elongation of the film is related to the mobility of the molecule chains under stress [20]. The hydrogen bonds between the starch restrict the movement of the starch molecule chains, therefore lowering the elongation of the composites. Additionally, the presence of starch molecules

and starch granules may reduce the mobility of latex molecules, which can furthermore decrease the elongation at break of the composites.

The elastic modulus increases with the addition of starch, as shown in Fig. 6(b). This may attribute to the much higher elastic modulus of starch (2.3 GPa [21]) than that of latex (0.012 GPa).

It seems that the effect of starch content on the mechanical properties strengthens when the starch addition is higher than 50 wt%, as illustrated by the accelerated increasing tendency of the ultimate tensile strength and elastic modulus, and the slower decreasing tendency of elongation at break. This cannot be explained by the dominant phase because the volume fraction of starch is 41.7 % at this point and latex is still the dominant phase. Therefore, the concept of co-continuity [11,22] is introduced. Although the starch has not become the dominant phase, the starch molecule chains in the composite are networking, forming the co-continuous phase. After that, the effect of starch on the mechanical properties becomes more prominent.

Perera Approach.

Perera approach was adopted to evaluate the adhesion force between the starch phase and latex phase. Perera approach was initially used in the pigment/ latex composites, using the ratio between the ultimate tensile strength of the pigmented film (σ) over that of the unpigmented film (σ_0) as an indicator for the adhesion between the pigment and latex [9, 23]. If the ratio, σ/σ_0, is bigger than 1 and increases with increasing pigment volume, good adhesion is present between the two phases. Therefore, the pigment can reinforce the composites, and vice versa.

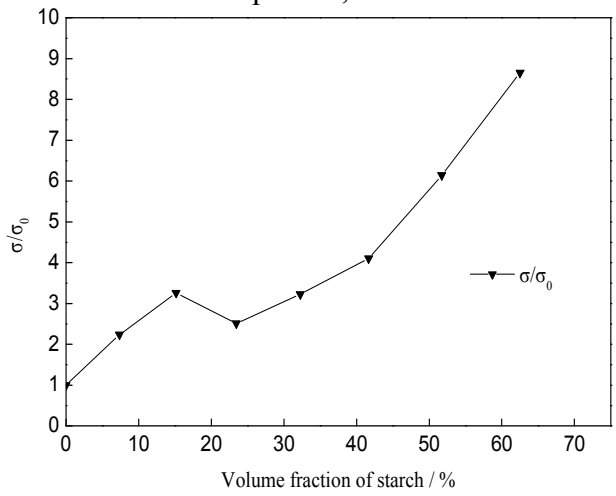

Fig. 7 Effect of volume percentage of starch on σ/ σ0

The ratios between the ultimate tensile strength of starch/ latex composites (σ) and that of latex film (σ_0) are plotted against the starch volume fractions, as shown in Fig. 7. The σ/σ_0 of composites is bigger than 1 and increases with the addition of starch. This indicates that there is good adhesion between starch phase and latex phase. This conclusion develops the conclusion from Fig. 4. Therefore, it may conclude that good adhesion is present between starch granules and starch-latex matrix, and between starch phase and latex phase.

Conclusions

(1) In the experiment condition (drying at 23 ^{0}C), the starch/ SB latex can form a cohesive film, but the film formation of the latex particles are uncompleted.

(2) During drying, the relative migration of starch and latex takes place in the starch/ SB latex composites. Starch dominates the upper surface and a monolayer of latex particles is accumulated at the lower surface. The use of abundant starch may hinder the migration of latex particles to the lower surface.

(3) Phase separation of starch and latex is present in the dried composites. Part of the starch is in the form of granules, reinforcing the starch-latex matrix. Good adhesion is observed between starch granules and starch-latex matrix, and between starch phase and latex phase.
(4) Increasing the starch content, the ultimate tensile strength and the elastic modulus increase, whilst the elongation at break decreases.
(5) Starch may become co-continuous phase when the starch content is 50 wt% (e.g. 41.7 % in volume fraction). After that, the effect of starch content on the mechanical properties of the composites becomes more prominent.

Keywords: waviness; composite materials; fabrication technique; characterization; failure mode

Abstract: Categories, fabrication techniques, characterization techniques, and effect of waviness on properties of fibre reinforced composite materials and structures are reviewed. Waviness exerts a great affluence on properties of composite materials and structures, which leads to a significant degradation or reduction of mechanical performances, such as static compressive/tensile strength, compressive fatigue life, and so on. Various factors related to waviness nested into the composite materials and structures, including wave geometry, thickness position of the wavy layer, percentages of layers with waviness, are considered and stated in detail. Failure mode of laminate containing waviness and the reasons for their failure initiation are analytically stated. At last, some prospects about this study are presented.

Introduction

In recent decades, composite materials are commonly and widely used in all walks of life due to their high specific strength and stiffness coupled with low cost. No matter that it is intentional or unintentional, defects are inevitably introduced in the process of manufacture and service. Waviness is one of the most frequently encountered flaws in large and thick composite structures. It results from manufacturing processes or from local buckling of prepreg or from wet hoop-wound filament strands under the pressure exerted by the overwrapped layers during the filament winding process or from the lamination residual thermal stresses [1] which are induced by the different thermal expansion rates between fibre and matrix materials during curing. Waviness has little effect on thin composite materials while greatly affects properties of the large and thick composite structures [2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12]. So it is gradually received attention and becomes a research focus in composites research field.

Only one review upon effect of fibre waviness on the mechanical properties of unidirectional fibre composites has been finished by Piggott since 1995 [12]. Additionally, in a review literature by Chou in 1989 [13], the effect of waviness on the linear and nonlinear elastic behavior of flexible composites is also considered. This paper mainly presents the experimental advances in effect of waviness on fibre reinforced composite materials after 1995.

Category and Characterization

A variety of defects are frequently produced in manufacture and service of composite materials and structures. However, only the flaw with fibre waviness induced by infusion processes and inherent in fabric architectures is focused here, including in-plane waviness, out-of-plane waviness and a particular waviness which is entirely different from in-plane waviness and out-of-plane waviness [3, 4, 11, 14, 15]. In-plane waviness, or fibre waviness, describes the fibre deviations from straight 0° in the plane of the fabric sheet. Out-of-plane waviness, or layer waviness, involves the entire layer of a multidirectional laminate undulating in the through-thickness direction. The through-thickness waviness in woven fabric such as A130 woven fabric, which is inevitably caused

by the woven architecture, is a typical unintentionally induced or inherent waviness [9, 14, 16]. It is neither in-plane waviness, nor the case of entire layer undulating in the through-thickness direction. In nature, the woven architecture it uses causes the fibre strand distortion in the thickness direction of layer.

Most researchers usually idealize the waviness geometry with a sinusoidal curve along one spatial coordinate direction of composite laminate (x axis is commonly chosen) and adopt the following four factors to characterize the waviness geometry in literatures [4, 9, 11, 14], the wavelength, amplitude, wave severity (the ratio of wave amplitude to wavelength) and the maximum angle of fibre rotation (the angle of wavy fibres inclined to the nominal fibre direction). It is noted that there is a so close relationship between wave severity and the maximum angle of fibre rotation for all cases throughout most literatures that they are deemed the equivalent waviness parameter.

The methods to measure the geometric parameters of waviness nested into composite materials and structures are developed, for example, the direct measuring technique by means of a protractor on micrographs or an angular reticule in a microscope [10, 17], the Yurgartis sectioning technique [18], the Clarke CLSM (i. e. Confocal Laser Scanning Microscope) technique [19], Digital image analysis (such as a multiple field image analysis method and a Fourier transform misalignment analysis method) [20, 21], and so on. Before measuring, the waviness geometric profile must be obtained by NDT (i. e. non-destructive testing) technique. To date, there have been a number of studies on characterizing the waviness geometry using NDT, such as ultrasonic testing [22, 23, 24, 25], radiographic testing [22, 26], electromagnetic testing [27], thermography [22], and shearography [28]. However, both the measuring methods and the NDT techniques mentioned above are not universal. Direct measurement is no doubt the simplest and the most convenient method to measure amplitude, wavelength and the maximum off-axis fibre angle, while the ultrasonic technique developed by Smith et al. was the most successful one in obtaining a high-resolution waviness profile. Multi-method is combined together to measure the object in actual experimental operation.

Fabrication Techniques

In order to simulate the realistic conditions of laminate with waviness, various fabrication techniques are developed to product representative artificial in-plane and out-of-plane waviness in a laboratory specimen. First of all, the basic criteria for a fabrication technique to generate waviness are flatness of the laminate, ease of fabrication, controllable waviness parameters, ease of varying the maximum misalignment angle and its location, controllable volume of fibre waviness (fraction of wavy fibres relative to straight ones), uniformity of laminate thickness, and symmetry. In fact, these factors related with both waviness geometry and attribute are challenging for any manufacture method, seen in the following section.

Adams and Hyer [3] developed a three-step fabrication method of making a flat laminate with one 0˚ wavy layer in the mid-plane, using a thermoplastic prepreg. Based on this, a single-step method was then established by Adams and Bell [4] to manufacture both single-layer and multiple-layer out-of-plane waviness into a wave-free thermoset crossply composite laminates. Their results indicated that producing a high wave severity (greater amplitude and shorter wavelength) was proved difficult as the applied consolidation pressure tended to flatten the wave, decreasing the amplitude while increasing the wavelength. Hsiao and Daniel [5] developed a prepreg-winding method for fabrication of thick specimens with controlled waviness, which the prepreg was wound a rectangular mandrel with rounded ends. The unidirectional composites with plies of sine-wave shape of uniform amplitude waviness across thickness were obtained. By using a three-step method differing from the previous one [3], they manufactured flat unidirectional composite laminates which the amplitude of sine-wave changed gradually from maximum to zero on the outer layers. Wang et al. [11] developed three methods (i. e. transverse-strip method, ply-drop method and constant-thickness ply-drop method) to produce waviness of various parameters at a mesoscale or a ply level. Different parametric waviness specimens according to the

requirements of a variety of tests were made by these techniques. It demonstrated that the most remarkable advantages are ease of fabrication with basic manufacturing knowledge and simplicity of experimental setup with no delicate or sophisticated equipment. However, voids or porosities even cavities were formed in the wavy regions due to lack of resin flow into gap between the base and the wavy layers, and warpage was caused by residual stress induced during cool down. Wang [14] chose a hand-made process to induce in-plane waviness into the 0˚ reinforcing fabrics which were then fabricated into [0/±45/0]s laminates. Composite specimens with various wave geometries, thickness position of the wavy layer, and percentage of 0˚ wavy layers were made and tested. Nelson et al. [10, 17] designed a process to product of layer panels containing waviness, which were infused under vacuum with one layer of peel-ply on the top and bottom surfaces and one layer of flow medium on the top surface of the laminate. In-plane waves were introduced by pulling the fibres manually for a one entire wavelength. Out-of-plane wave forms, also for one entire wavelength, were created by casting resin into a CNC machined mold and placing the castings under the laminate. On the basis of this, they improved their design and fabrication process to ensure flaw with waviness was as similar as possible to those found in composite structures (wind turbine blades) [15]. Then, the two kinds of waves were manufactured by the novel methods improved.

Furthermore, fabrication methods of waviness appeared in some analytical literatures in order to validate their numerical predictions. Chun et al. [8] used several sets of two half molds with curved surfaces to produce thick composites with controlled fibre waviness with various wave severities, which was similar in principle to Kuo's method [29] where a sinusoidal matching mold was used. The prepreg tapes were cut and layered on top of a half mold. After the lay up, the other half mold was place on top of it. The sandwiched prepregs together with the molds as one piece were then placed inside the curing mold. The sandwiched prepregs and integrated molds were cured in an autoclave following a curing cycle developed for thick composites [30]. Wisnom and Atkinson [31] manufactured a unidirectional composite panel with a transverse out-of-plane wave using a unidirectional prepreg strip as a kink former. Khan et al. [32] fabricated laminates with transverse out-of-plane waves using similar ideas to the kink former, matching mold and Chun et al.'s methods.

Review the fabrication techniques stated in the previous section, it was found that only two techniques to manufacture fibre reinforced plastics composite materials and structures containing in-plane waviness were developed, respectively by Wang [14] and by Nelson et al [15, 17].. The other ones were primarily aimed to introduce out-of-plane waviness into composite laminates. Most fabrication methods are not enough accurate to fabricate wave expected due to absolutely hand lay-up and may be introduce other defects such as porosity, inclusion, etc. Moreover, some manufacture methods are suitable for thermoplastic experimental materials of prepreg, others are appropriate for thermoset prepreg, only Wang and Nelson' methods could be applicable to dry fabrics. Further efforts are required to develop innovative fabrication methods for wavy laminates based on dry fabrics. More attention should be also paid to the third inherent waviness mentioned previously which was formed in the productive procedure.

Effect of Waviness on Properties of Composite Materials

Effect of Waviness on Mechanical Performances

Effect of waviness on mechanical performances was performed by many researchers [1, 3, 4, 5, 7, 8, 9, 12, 14, 15, 33]. Adams and Hyer [3] fabricated flat specimens of 0°/90° carbon fibre/polysulphone thermoplastic containing isolated layer waves. A central zero degree wavy layer in a 22-layer bidirectional laminate produced reduction of between 1 and 36% in quasi-static IITRI compression fixture tests, although the wavy 0˚ layers accounted for only 20% of the load carrying capacity of the laminate. For moderate layer wave geometries ($\delta/\lambda < 6\%$, the Greek letters δ and λ denote amplitude and wavelength respectively), failure approximately occurred at 88% of the strength of control specimens either in the tabs or within the wavy layer, while for $\delta/\lambda > 6\%$ (more

severe waviness), failure occurred at an average 63% of control strength. Thereafter, Adams and Bell [4] produced multiple-nested wavy 0˚ layers into other wave-free thermoset crossply laminates, which both the ratio of 0˚ wavy layers to 0˚ normal layers and wave severity were constant. The tests were performed by the same fixture as before, which determined the effect of multiply-layer wavy regions on compression strength. Results demonstrated if the volume fraction of 0˚ layers containing waviness to all 0˚ layers was 33% and larger, the strength decreased by 35% and kept relatively constant. And, the percentage reduction in compression strength was approximately equal to the percentage of 0˚ wavy layers when not more than 33%. Hsiao and Daniel [5] employed a new test method/fixture (i. e. NU fixture) based on a modified IITRI compression fixture to conduct on unidirectional laminates with uniform and graded waviness. It was shown that in unidirectional composites both major Young's modulus and compressive strength were degraded seriously with increasing waviness. To be specific, it caused serious degradation of compressive strength and appreciable reduction of 42% in modulus for specimens with uniform fibre waviness, while it leaded to a significant 30% reduction in compressive strength and only a slight reduction of 6% in modulus for specimens with graded fibre waviness.

Compared with out-of-plane, experimental and analytical investigations about effect of in-plane waviness on composite materials are fewer. Static compressive test, compressive fatigue test and static tensile test were all performed on an Instron 8501 servo hydraulic testing machine with a load capacity of 100 kN in Wang's research [14]. For waviness in one surface ply of the specimen, compressive strength converged to a single decreasing trend with the increase of wave severity, but it was little loss in compressive strength when wave severities was below 0.062. For specimens with undulating fibre fraction ranged from 0 to 1, a larger fraction of 0˚ layers with waviness resulted in a greater reduction in compressive strength for each specific wave severity, and greater wave severity produced a greater reduction in compressive strength for each in-plane waviness layer fraction. In-plane waviness showed a roughly proportional effect on the compressive strength over the entire range to 100%, which was quite different from the results of out-of-plane waviness cases in reference [4]. For specimens embedded with in-plane waviness, a considerable reduction in the compressive fatigue life occurred. When results of compressive fatigue tests were normalized by the static compressive strength, the changing trend was similar for most specimens. Additionally, from the testing results, it can be concluded that very moderate in-plane waviness does not influence the tensile strength significantly while severe in-plane waviness remarkably reduces the tensile strength. Besides, similar results are obtained by others [16, 34, 35, 36, 37].

Nelson et al. [15, 17] investigated the influence of both in-plane and out-of-plane waviness on static tensile and compressive properties. Ultimate stress values for the each of the 0˚ in-plane wave groups tested in tension were found to have a significant decrease in ultimate stress and the modulus of elasticity accounted for 85% to 106% of the control, while the same trend happened in compression. Nevertheless, for the ±45˚ groups with in-plane wave, ultimate stress values slightly decreased by 2% to 4% and the modulus of elasticity increased by 3% to 16% in comparison with the control group for tension, while the ultimate compressive stress was significantly higher compared with control groups, reaching to 112% to 133%. For the out-of-plane cases, ultimate failure stress for 0˚ and ±45˚ tension groups were decreased compared with the control, but were still increased compared with the in-plane waves results [15], while compressive strength was significant decreases in ultimate strength.

It is concluded that the fabrication techniques of in-plane and out-of-plane developed by different researchers have some shortcomings and limitations in simulating the realistic composite materials and structures with waviness as these manufacture methods are completely hand-made and easily induce new defects. So exploring innovative and novel techniques is very necessary for furthering the investigation of composite with waviness.

Failure Modes

Failure mode is relatively single for the laminate with the same waviness type. Adams and Hyer [3], and Adams and Bell [4] pointed out brooming was the common and pronounced failure mode,

which was characterized by through the thickness direction splaying of layers and numerous delamination near the waviness. An angled fracture plane through the specimen thickness was evident, suggesting the presence of shear failure mode. The wavy 0° layers commonly were fractured at or near an inflection point of the layer wave, midway between the crest and trough of the wave. Hsiao and Daniel [5] proved that the dominant failure mode of out-of-plane wavy laminate under axial compression was interlaminar shear failure. Interlaminar shear stress concentrated in the local region at first, delamination and layer buckling ensued. In Wang's research [14], it was proved that an angled fracture across the specimen width was observed in most of the failed specimens by a shear failure mode. It was very interesting that the angled fracture planes through the width were found to pass through the inflection point of the in-plane wave, being consistent with Adams and Hyer's [3] and Adams and Bell's conclusions [4]. The majority of compressive fatigue specimens had the same failure mode, but one failure plane was oriented at an angle through the specimen width which was similar to static compression failure, while others were perpendicular to the load direction near the grip position. Failure in tensile specimens, whether with or without in-plane waviness, were characterized by numerous fibres fracture and delamination through the gauge length of the specimen. Nelson et al.' results [15] manifested that initial failure occurred at low loading levels in areas where fibres were not continuous through the length of the in-plane sample. As strain levels increased, cracks initiated in the resin at the end of the wave before delaminating and grew through the entire wave section resulting ultimately in fibre failure. For specimens embedded into out-of-plane wavy layer, cracks also initiated in the resin at the end of the wave before delaminating in the first stage. However, after delamination the failure area was concentrated at the peak area of the wave.

In a word, these results indicate whether in-plane or out-of-plane waviness, delamination is bound to occur near the wavy region in the course of failure and the fibre fracture incline to initiate at or near the inflection point of the wave in the form of shear mode. These failure modes and observations of fibre reinforced composites with flaw of waviness were commonly found in current investigations.

Obviously, fibre waviness has been shown to play an important role in static compressive/tensile strength and fatigue endurance. Of course, these results listed above are only a small part of all researches in this field, and deviate from real situations, but it indicates that the degradation of strength and modulus are more or less occurred due to waviness exiting in the composite materials and structures.

Summary

The effect of both in-plane and out-of-plane waviness on the fibre reinforced composite materials and structures are reviewed. Also, the various fabrication techniques and the failure modes of composite laminate containing waviness are stated in detail. Although the failure mechanism of composite materials containing waviness is not very clearly by now, and there are some disadvantages among the different fabrication techniques, the works are most significant. In fact, they could provide experience for further study and inspire new ideas and innovative methods for other researchers who are interesting in this field.

Many new works are not done and not mentioned in this research. For example, the influence of wet and hot conditions on the laminate with waviness is not taken into account. Moreover, the new manufacturing methods improved are worth exploring for further studies, such as a deeper investigation of the effect of waviness on mechanical performance of composites, validation of theoretical models, and application for improvement of thick low cost structures quality like wind turbine blades.

Keywords: superabsorbent, crosslinker type, acrylic acid, compressive strength, salt sensitivity.

Abstract. A series of poly(sodium acrylate) superabsorbents hydrogels were synthesized through aqueous solution using *N*,*N*-methylenebisacrylamide (NNMBA), pentaerythritol triacrylate (PETA), ethylene glycol dimethacrylate (EGDMA) and dimethyl diallyl ammonium chloride (DMDAAC) as crosslink agents separately to investigate the effect of crosslinker type on the properties of acrylic-based superabsorbents. Furthermore, the polymers were surface-crosslinked using trimethylolpropane triglycidyl ether to improve the properties of swollen hydrogel. The morphology of the samples was characterized by scanning electron microscope (SEM). The swelling behaviors in 0.9 wt% NaCl aqueous solution and synthetic urine were investigated, and the compressive strength, salt sensitivity and water retention ability were also investigated. The results showed that the superabsorbent crosslinked by PETA which was a three-functional agent had the most water absorbency under load and the highest compressive strength compared with others, while the superabsorbent crosslinked by DMDAAC which was a cationic crosslinker had the best salt resistance and the most water absorbency under atmospheric pressure.

Introduction

Superabsorbent polymers (SAPs), which can absorb and retain large amounts of aqueous fluids even under some pressure due to the exist of hydrophilic groups in their three-dimensional networks, are well known materials with everyday applications such as personal hygiene products, soil and water conservation, drug-delivery systems and so on [1,2]. Among them, poly(acrylic acid) (PAA) has long been the most important part of the absorbent resin because of its low costs, relatively simple technology and the stable quality in use. However, the poor salt-resisting, as well as the low gel strength, resilience, dispersion and surface-drying, turns out to be ubiquitous in the traditional preparation of PAA SAPs, which seriously affects the quality of products and restricts their wide application.

For the past few years, a number of effective methods have been taken out to improve overall performance of poly(acrylic acid) SAPs such as being copolymerized with other monomers [3], grafted to the natural macromolecules [4], and composited with inorganic substance [5]. Besides that, some researchers focused on the change of crosslinkers because the structure and amount of crosslinking agent also played an important role in the properties of SAPs [6,7,8]. In this work, three kinds of crosslinkers with different structures and functional groups (shown in Fig. 1), which have never or seldom been used in the preparation of SAPs, were used compared with the most common crosslinker NNMBA to investigate the effect of crosslinker structure on the properties of poly(sodium acrylate) superabsorbents. Among which, pentaerythritol triacrylate (PETA) is a three-functional agent while the others are two-functional agents, ethylene glycol dimethacrylate (EGDMA) has hydrophilic ester group, and dimethyl diallyl ammonium chloride (DMDAAC) is a cationic crosslinker. We hope to find out excellent crosslinking agents to improve the performance of acrylic-based superabsorbents.

Experimental

Materials

Acrylic acid (AA, CP, Beijing Eastern Chemical Works, Beijing, China) was distilled under reduced pressure before use. *N*,*N*-methylenebisacrylamide (NNMBA, CP, Shanghai Chemical Reagent Co., Shanghai, China) was recrystallized with 95% ethanol before use. Pentaerythritol triacrylate (PETA, AR, Guangzhou Sunlake Trading Co., Ltd., Guangzhou, China), ethylene glycol dimethacrylate (EGDMA, AR, Afaaisuo Chemical Co., Ltd., Tianjin, China), dimethyl diallyl ammonium chloride (DMDAAC, 60% solution, Aladdin reagents Co., Ltd., Shanghai, China), trimethylolpropane triglycidyl ether (TMPTGE, industrial grade, Taizhou Whaley Synthetic Materials Co., Ltd., Jiangsu, China) and ammonium persulfate (APS, AR, Xi'an Chemical Reagent Factory, Xi'an, China) were used directly. Other reagents were of analytical grade and used without purification. All the solutions were prepared with distilled water.

Preparation of superabsorbent polymers (SAPs)

NaOH aqueous solution with the concentration of 6 mol/L was added slowly to 5mL acrylic acid (AA) for neutralization in a four-necked flask with ice-bath. Then, adding exact amounts of NNMBA and APS as well as distilled water to the flask and stirring until the materials dissolved completely. After being purged with nitrogen for half an hour, the reactor was heated to 75ºC and kept for 3 hours. The shredded products were dried at 80ºC in an oven to a constant weight and then milled through 26-60 mesh screens, which was noted as SAP01. The synthesis process of SAP02, SAP03 and SAP04 is similar to that of SAP01 just using PETA, EGDMA and DMDAAC as crosslinker instead of NNMBA respectively. All of the four SAPs were confirmed by FTIR. In order to improve the overall performances of superabsorbents, the samples were surface crosslinked with TMPTGE, and the final product was noted as SAP1, SAP2, SAP3 and SAP4, respectively.

Water Absorbency under Atmospheric Pressure

The accurately weighed 0.200g sample was immersed in 0.9 wt% NaCl aqueous solution or synthetic urine [9] and allowed to swell at the temperature of 20ºC under atmospheric pressure for 1 hour. The swollen hydrogel was filtrated through an 80-mesh nylon screen for 10 minutes to remove the excess water and weighed. Each sample was measured three times and the average value was selected as the final result. The water absorbency (WA) was calculated by the following equation:

$$WA = (M - M_0) / M_0 \quad (1)$$

Where, M is the weight of swollen hydrogel and M_0 is the weight of dry sample.

Water Absorbency under Load (WA_p)

Accurately weighed 0.400g sample was evenly spread in the bottom of a plastic tube with the diameter of 25.9mm and the height of 35.0mm, which sealed by a 240-mesh polyester fabric at one end. And then a polytetrafluoroethylene cylinder with the diameter of 25.3mm and the mass of 106.4g was loaded on the sample and placed in a hollow porous support which in a beaker. Afterwards, 0.9 wt% NaCl aqueous solution or synthetic urine was added into the beaker making sure the liquid level high enough to immerse the sample but below the top edge of the plastic tube about 0.5cm. Non-absorbed liquid was removed and the plastic tube with the swollen hydrogel was weighed after 1 h.

Each sample was measured three times and the average value was selected as the final result. The water absorbency of sample in 0.9 wt% NaCl aqueous solution or synthetic urine (WA_p) was calculated using the following equation:

$$WA_p = (M_2 - M_1 - M_0) / M_0 \quad (2)$$

Where, M_2 is the weight of plastic tube with swollen hydrogel, M_1 is the weight of plastic tube and M_0 is the weight of dry sample.

Measurements of the Compressive Strength of the Hydrogels

Uniaxial compression measurements [10] were performed on the hydrogels swollen in synthetic urine to determine the compressive strength, and the apparatus used were showed in Fig. 2. Briefly, 1.000 g of the swollen hydrogel was placed in a sample cell, while a polytetrafluoroethylene rod was put on the hydrogel. The initial height h_0 was recorded after the sample was compressed with the initial load for 5 min. Then the pressure was increased to m_i and the corresponding height h_i was noted after compressing for 5 min. Each sample was measured three times and the average value was selected as the final result. The modulus E was determined from the slope of the plot of m_ig/A versus h_i/h_0. A was cross-sectional area of the sample cell.

Water Retention Test

A piece of swollen gel (noted as M_0) was spreaded in the bottom of a 200 mL beaker and placed in an oven at 37℃. The gel was weighed every 30 minutes (noted as M_i) and the water retention rate (WR) was calculated by the following equation (M_d is the weight of xerogel):

$$WR = (M_0 — M_i) / (M_0 — M_d) \quad (3)$$

Results and Discussion

Water Absorbency in NaCl aqueous solution and synthetic urine

Fig. 2 shows the water absorbency in NaCl aqueous solution and synthetic urine with various amounts of crosslinkers under atmospheric pressure. Water absorbency of polymer shows a relation to the crosslinking density, ionic osmotic pressure, and affinity of the hydrogel with water. The crosslinker content which influence the crosslinking density also plays an important role in the formation of a three-dimensional network and significantly affects the water absorbency of the SAPs. When the crosslinker content was lower, the swollen hydrogel was poorly crosslinked and became slimy gel without good dimensional stability, for the soluble noncrosslinked polymer dissolved in water and the network was insufficiently formed. As the crosslinker content increased, more crosslinked points in polymeric chains occurred, causing a higher crosslinking density and more insoluble polymers to hold the water, and the swelling capacity increased up to a certain level. However, when the crosslinker content increased high enough, the excessive crosslinker would result in a decrease in the space between the polymer chains and would lead to a highly crosslinked rigid structure that could not be expanded to hold a large quantity of water [11,12].

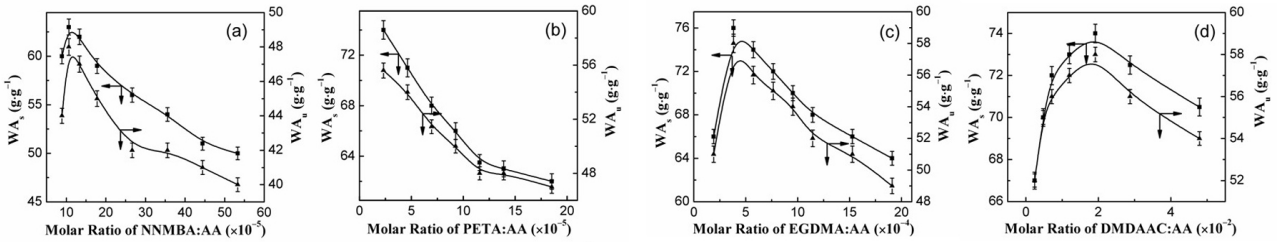

Fig. 2 Effect of the crosslinker amount on the water absorbency of superabsorbents. (a) NNMBA as crosslinker, (b) PETA as crosslinker, (c) EGDMA as crosslinker, (d) DMDAAC as crosslinker.

Surface morphology analysis of superabsorbents

Fig. 3 shows the surface structures of dried hydrogels. The cross-sections of the samples exhibited pores architecture, which was the typical structure of hydrophilic polymer. Compared with the photographs of other samples, the pore size of SAP2 appeared more uniformly, and the porous structure was well-distributed and more difficult to collapse. This was because there were three reactive functional groups in the PETA molecule, and the distance between double bonds was large

enough, leading to the small steric effect and high reactivity, which was usually used to synthetize multibranched polymers. The pore size of SAP1 was small and fragile, while the pore size of SAP2 was big and with uneven distribution. That was attributed to the steric effect of methyl in the EGDMA molecule, which influenced the crosslinking effect. The morphology of SAP4 had more linear structure, it could be speculated the crosslinking effect of DMDAAC was not good as others. These were verified subsequently in the water absorbency and mechanical strength experiments.

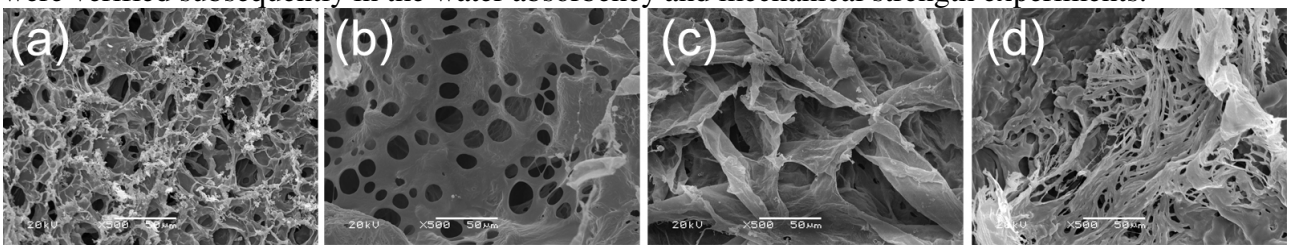

Fig. 3 SEM photographs of dried superabsorbents: (a) SAP1, (b) SAP2, (c) SAP3, (d) SAP4.

Swelling kinetics in synthetic urine

Fig. 4(a) displays the swelling kinetic behaviors of the optimized final products synthesized using NNMBA, PETA, EGDMA and DMDAAC separately as crosslinker in synthetic urine. The swelling increased with time and reached a limiting value which is the swelling equilibrium in 20 minutes, which sugguested it was suitable to allow the samples swollen more than 30 minutes to determine the swelling ratio in each experiment. The absorption rate of superabsorbent was mainly influenced by swelling ability, surface area, particle size and density of the polymer [13]. It can be seen from figure 8 that the water absorption and swelling rate of the four samples are close. That's because the amount of crosslinkers is relatively less than that of structural units in the polymer, and the different type of crosslinkers just change the crosslinking density but not the hydrophily of network. Plus, it is noteworthy that the equilibrium water absorption of the four samples in synthetic urine are all less than 60 g g^{-1}, which indicates the change of crosslinker can not improve the salt resistance of superabsorbents fundamentally.

Salt sensitivity

In order to further study the salt sensitivity of superbasorbents prepared using different crosslinkers, the effect ionic strength on the water absorbency of samples in saline solution has been investigated and the results are shown by the water-absorbing curves presented in fig. 4(b). The trends of the water-absorbing curve of superabsorbents crosslinked by different crosslingers are similar, and decrease as the ionic strength of the saline solution increases. Generally, the swelling ability of anionic hydrogels in various salt solutions is appreciably decreased in comparison with the swelling values in distilled water [14]. This well-known undesired swelling loss is often attributed to a charge-screening effect of the additional cations causing a nonperfect anion–anion electrostatic repulsion. Therefore, according to the Donnan membrane equilibrium theory, the osmotic pressure resulting from the mobile ion concentration difference between the gel and aqueous phases decreased, and consequently, the absorbency decreased. In addition, SAP4 had the best salt resistance among all of the samples as shown in fig. 4(b). That is maybe attributed to the nitrogen cationic in DMDAAC crosslinker.

Water Retention Capacity of Superabsorbents

It is important to investigate the water retention capacity of SAPs in view of practical applications. In this work, water retention (WR) of superabsorbent swollen in synthetic urine was determined at 37°C which closes to the body temperature. Fig. 4(c) shows that the water retention curves of the four samples all decreases with time, which is due to the evaporation of water in the swollen hydrogel. The water in the hydrogel can be classified into bound water, half-bound water and free water, and the free water has high mobility and can easy be lost. The percentages of bound water and half-bound water are related to the number of hydrophilic groups in a unit volume in the SAPs [15]. In our work, although the type of crosslinker used in the preparation of SAPs is different, monomer and monomer amount in all four samples is the same, which leads to the water retention capacity of the four samples

is similar to each other. This sugguests that the type of crosslinker has little effect on the water retention capacity. By the figure it also can be seen that even dried at 37°C for 7 hours, the water retention is still up to 80%, which is expected to be used in personal care materials and agriculture.

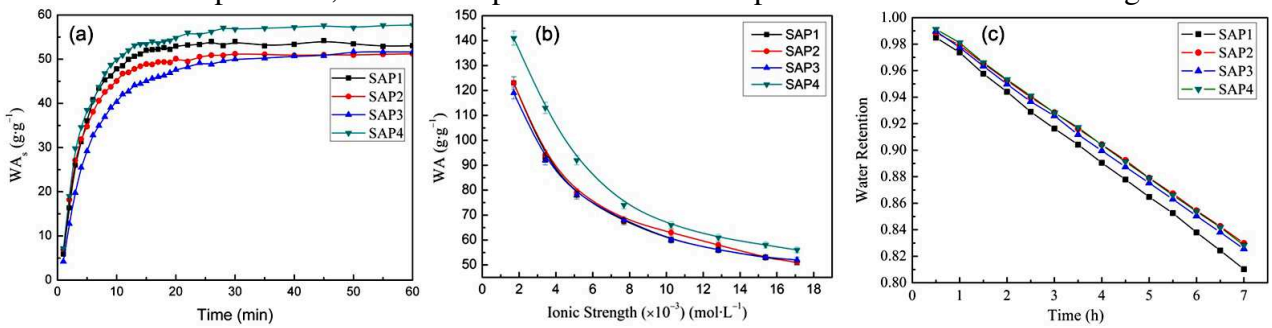

Fig. 4 (a) Swelling kinetic behaviors of the optimized final products in synthetic urine, (b) Effect of the ionic strength of the NaCl solution on the water absorbency of superabsorbents, (c) Water retention capacity of superabsorbents at 37°C.

Mechanical properties of the SAPs

Mechanical strength is an extremely important property for the application of hydrogels, usually given in the patent literature and technical data sheets offered by industrial SAP manufacturers[16,17]. The water absorbency under load (WA_{ps} and WA_{pu}) and compressive strength (compressive modulus E) is measured to denote mechanical strength of hydrogels, and the data of different samples are listed in Table 1. The influences types of crosslinker on compressive strength of the hydrogels have been studied. The results showed that SAP2 which was crosslinker by PETA maintains the highest WA_p and E among the four kinds of samples. This could be attributed to the increasing of the cross-linking points. There are three reactively double bonds in one PETA molecule, but only two in others.

Table 1 The water absorbency under load (WAps and WApu) and compressive strength (E) of superabsorbent hydrogels using different crosslinkers.

Parameters \ Sample code	SAP1	SAP2	SAP3	SAP4
WA_{ps} ($g \cdot g^{-1}$)	11	12	8	6
WA_{pu} ($g \cdot g^{-1}$)	10	11	7	6
E ($\times 10^4$) (Pa)	11.49	12.06	5.92	4.77

Summary

In this work, effect of crosslinkers types on the superabsorbent performance has been studied, and four kinds of crosslinkers, NNMBA, PETA, EGDMA and DMDAAC have been used to synthesize poly(sodium acrylate) superabsorbent polymers. SEM photograghs showed the samples crosslinked by PETA which was a three-functional agent had the uniform pore size, and the porous structure was well-distributed and more difficult to collapse, which led to the most water absorbency under load and the highest compressive strength compared with others. And at the meanwhile, due to the nitrogen cationic in DMDAAC crosslinker, the superabsorbent crosslinked by DMDAAC had the best salt resistance and the most water absorbency under atmospheric pressure.

Keyword: atomic transfer radical polymerization; amphiphilic diblock polymer; polystyrene; poly(ε-caprolactone)

Abstract: Amphiphilic diblock copolymer poly(styrene-*b*-ε-caprolactone) were synthesized. Firstly, polystyrene was synthesized via sequential atomic transfer radical polymerization (ATRP), and then the tetra hydro lithium aluminum (LiAlH4) was used as a reducing agent in tetra hydro (THF) to reduce polystyrene to the pre-polymer monohydroxy-terminated polystyrene (PS-OH). As following, amphiphilic diblock were obtained by ring opening polymerization. And the structure of diblock polymer was investigated by FTIR. Furthermore, the block copolymers were added into the mixture of epoxy and Me-THPA. And the optical microscopy(OM) shows that the microphase separation occured in this system and the PS-*b*-PCL can promote the phase separation in the system.

Introduction

Well-defined compositions, architectures, and functionalities copolymers were usually synthesized by ionic polymerization, free radical polymerization and living/controlled free radical polymerization[1,2]. Typically living/controlled free radical polymerization are employed because the ability of controlling the copolymer architectures of the free radical polymerization are weak and the monomers of ionic polymerization are usually limited [3,4].

Poly(styrene-b-ε-caprolactone) is one of the amphiphilic copolymer with well-defined composition and architecture[5,6]. One of the main method is to synthesize PCL macroinitiator and use click chemistry to obtain the block copolymer[7]. Another method is to synthesize PS through free radical polymerization or azide reaction to get the hydroxyl terminated polystyrene, which react with ε-caprolactone as followed[8].

Roderic P. Quirk[9] prepared hydroxy-terminated styrene (HO-PS-OH) by anionic polymerization，which used propylene oxide , sodium naphthalene and THF as initiator.

Z.Yin[10] synthesized hydroxy-terminated initiator by 2-bromoisobutyryl bromide and ethylene glycol, then atom transfer radical polymerization was used to obtain hydroxy-terminated PS.

Wenchun Fan[11] synthesized star-shaped macroinitiators(PS) through pentaerythritol tetrakis(2-bromoisobutyrate). They obtained well-defined architecture copolymers through synthesis of well-defined initiator. After mixing with diglycidyl ether of bisphenol A (DGEBA), reaction-induced phase separation occurred in the thermosetting blends of epoxy.

In this paper, PS-b-PCL was synthesized. At frist, polystyrene was synthesized via sequential atomic transfer radical polymerization (ATRP). A simple reduction reaction with LiALH4 was used to obtain monohydroxyl terminated polystyrene(PS-OH). As followed, amphiphilic diblock were

obtained by ring opening polymerization. And the block copolymer was mixed with DGEBA and polyimide-siloxane(PI-siloxane). It was found that the block copolymer is able to promote the system's phase separation of the thermosetting blends of epoxy resin with PI-Si block copolymers.

Materials

Diglycidyl ether of bisphenol A (DGEBA) with epoxide equivalent weight of 182-192 was purchased from DOW Chemical Company. The curing agent is methyl tetrahydrophthalic anhydride (Me-THPA), which is supplied by Shanghai Reagent Co.,China. Polyimide-siloxane(20%) (Siltem STM1500) was supplied by Sabic innovative plastics.

Styrene (St), ε-caprolactone and LiAlH4 were purchased from Shanghai Reagent Co.,China as analytically pure grade.

Synthesis of the Block Copolymer PS-b-PCL

For the synthesis of PS-b-PCL, a 200ml round-bottom flask, mono-functional initiators, ethyl bromoacetate, CuBr, Bpy, styrene were charged. The system was connected to a standard Schlenk line system. The reactive mixture was degassed via three pump-freeze-thaw cycles and then immersed in a thermostated oil bath at 110 ºC. After the polymerization, the Br-PS-COOC2H5(Mn = 4000 g /mol, PS-Br) was obtained. Then the LiAlH4 was used as a reducing agent in THF to reduce polystyrene to the pre-polymer monohydroxy-terminated polystyrene (PS-OH). By using PS-OH as an initiator and Sn(OEt)2 as a catalyst, the mediate controlled ring-opening polymerization of ε-caprolactone(ε-CL) (ROP) leaded to the block copolymer polystyrene-b-poly(ε-caprolactone) (PS-b-PCL, Mn= 9600 g /mol).

FTIR of the Synthesized Copolymers

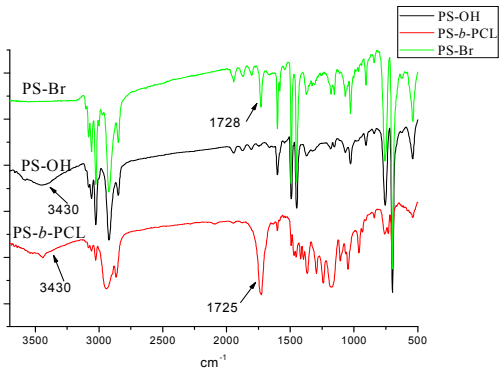

Fig.1. FTIR of Polymers Synthesized

Fig.1 shows the FTIR spectra of the macroinitiators and the block copolymer. The peaks at 700 cm-1 and 750 cm-1 in the PS-Br spectrum are consistent with stretching vibration of benzene and at 1450 cm-1,1490 cm-1are consistent with bending vibration. And the peak at 1728 cm-1 is consistent with the stretching vibration of C=O. In the spectrum of PS-OH, the peak at 1728 cm-1 disappeared. And meanwhile, the peak at 3430 cm-1 appeared, which means monohydroxy-terminated polystyrene was obtained. These spectra indicate that PS-b-PCL was successfully synthesized

Effect on the Phase Separation

DGEBA, Me-THPA, PS-b-PCLand PI-siloxane were mixedand investigated using OM. It shows that the PS-b-PCL can promote phase separation in the system(Fig.2).

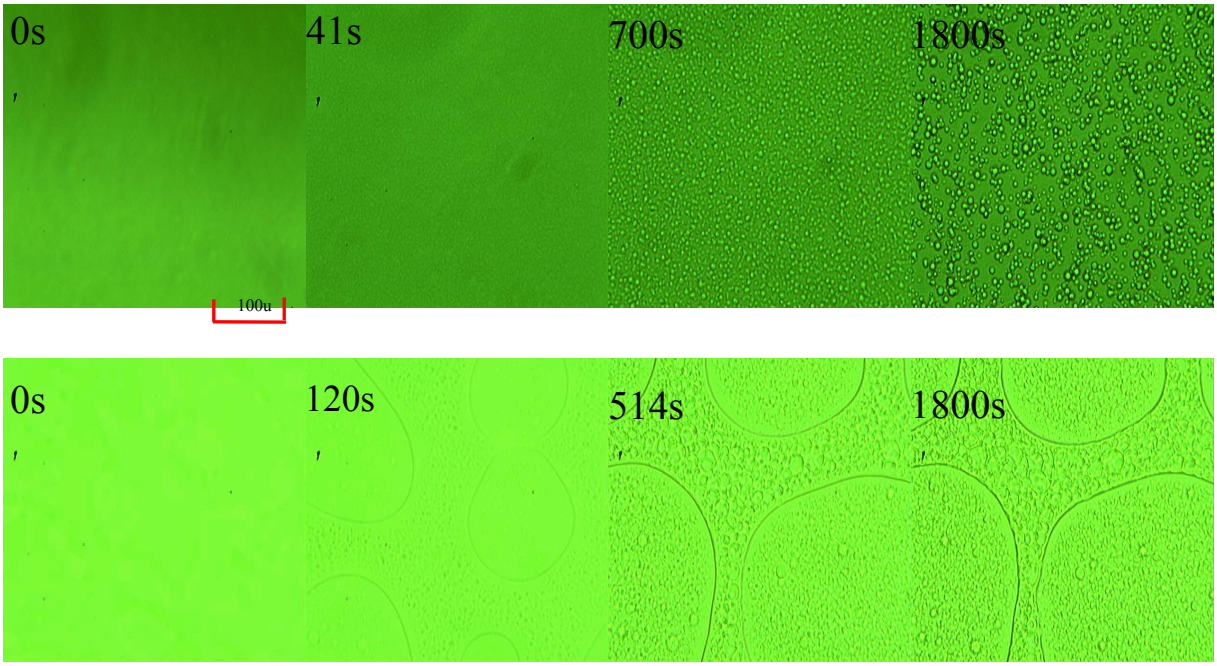

Fig.2 OM images of the phase morphology development of DM-AS1020 system cured at 150℃;the frist group of pictures are PI-siloxane 20 phr and the other group of pictures are PI-siloxane 20 phr and PS-b-PCL 10 phr.

Those images cleared showed that reaction-induced separation occurred in the system, and with the block copolymer PS-b-PCL added, phase separation changed significantly. The dispersed phase alter to reverse phase.

Conclusion

Monohydroxy-terminated polystyrene (PS-OH) was obtained through a simple reduction reaction by using LiAlH4 as a reducing agent in THF. The phase separation of the blend of epoxy with PS-b-PCLand PI-siloxane were investigated. It was found that PS-b-PCL can promote the phase separation in the system.

Keywords: PZN–PZT, Dielectric properties, Piezoelectric properties and Ferroelectric properties

Abstract: Ceramics in the $xPb(Zn_{1/3}Nb_{2/3})O_3$–$(1-x)Pb(Zr_{1/2}Ti_{1/2})O_3$ [xPZN–(1-x)PZT] solid solution system are expected to display excellent dielectric, piezoelectric, and ferroelectric properties in compositions close to the morphotropic phase boundary (MPB). The dielectric behavior of ceramics with $x = 0.1 - 0.5$ has been characterized in order to identify the MPB compositions in this system. Combined with x-ray diffraction analysis, dielectric, piezoelectric and ferroelectric measurements, it was consistently shown that an MPB exists around x = 0.3 in this binary system. When $x \leq 0.2$, the tetragonal phase dominates at ambient temperatures. In the range of $x \geq 0.4$, the rhombohedral phase dominates.

Introduction

Lead zirconate titanate, $Pb(Zr,Ti)O_3$ or PZT, is a well known piezoelectric that has been widely employed in a large number of sensing and actuating devices. PZT ceramics have very high Curie temperature (~ 390 ^oC). Lead zinc niobate, $Pb(Zn_{1/3}Nb_{2/3})O_3$ or PZN, which exhibits a perovskite structure and a Curie temperature of ~140 ^oC, is one of the most important relaxor ferroelectric materials with a high dielectric constant and large electrostrictive coefficient. They have excellent dielectric, piezoelectric and elastic properties suitable for wide range of practical applications [1-3]. Though the PZN-PZT based ceramics have excellent electrical properties, poor mechanical properties such as fracture strength and toughness have been reported [4].

Lead zirconate titanate, $Pb(Zr,Ti)O_3$ or PZT, is a well known piezoelectric that has been widely employed in a large number of sensing and actuating devices. PZT ceramics have very high Curie temperature (~ 390 ^oC). They have excellent dielectric, piezoelectric and elastic properties suitable for wide range of practical applications [1-3]. Lead zinc niobate, $Pb(Zn_{1/3}Nb_{2/3})O_3$ or PZN, which exhibits a perovskite structure and a Curie temperature ~ 140 ^oC, is one of the most important relaxor ferroelectric materials with a high dielectric constant and large electrostrictive coefficient [4-5].

Recent work by Fan and Kim [5-6] has shown that the perovskite phase of $Pb(Zn_{1/3}Nb_{2/3})O_3$ (PZN) ceramics was stabilized by adding a Ti-rich side tetragonal phase of $Pb(Zr_{0.47}Ti_{0.53})O_3$ (PZT) located across the morphotropic phase boundary (MPB). When 40% PZT was added, a rhombohedral perovskite phase was formed without any trace of the pyrochlore phase. The rhombohedral phase fraction decreased markedly with increasing PZT concentration. This work has shown promise in producing pure perovskite phase PZN–PZT ceramics with the conventional mixed-oxide method make the perovskite phase structure stable and give the significantly improved piezoelectric properties.

Vittayakorn et al. [7-8] has shown processing conditions on phase-pure perovskite PZN–PZT ceramics with the conventional mixed-oxide method and B-site precursor. The resulting ceramics were are expected to display excellent dielectric, piezoelectric, and ferroelectric properties in

compositions close to the morphotropic phase boundary (MPB). It was consistently shown that an MPB exists around x = 0.25 in this binary system. Excellent piezoelectric properties were found in 0.3PZN–0.7PZT, the composition closest to the MPB with a rhombohedral structure.

The aim of this work was to study the influence of vibro-milling methods (conventional mixed oxide) at synthesizing pyrochlore-free lead zinc niobate – lead zirconate titanate ceramics PZN-PZT ceramics, and to correlate the presence of pure perovskite phases with the dielectric, piezoelectric, and ferroelectric properties.

Experimental Procedure

The specimens studied in this research were fabricated according to the formula: $xPb(Zn_{1/3}Nb_{2/3})O_3$-$(1-x)Pb(Zr_{1/2}Ti_{1/2})O_3$, where x= 0.1-0.5 . Raw materials of PbO, ZrO_2, TiO_2, ZnO and Nb_2O_5 with >99% purity were used to prepare samples by a conventional mixed oxide process. The obtained mixture was used zirconia ball media with isopropanal as a medium in a polyethylene jar for 30 min via vibro-milling technique. The mixed slurry was dried and calcined at 900°C for 2h. The calcined powders were ball-milled again with additives and consolidated into disks of 12.5 mm diameter using isostatic pressing about 150 MPa. PbO-rich atmosphere sintering of the ceramics was performed in a high-purity alumina crucible at varied sintering temperature between 1150 to 1250 °C depending upon the compositions. The crystal structure and symmetry of the sintered bodies were examined by X-ray diffraction (XRD) and sintered densities were measured by the Archimedes method.

For electrical properties characterizations, Electrode (Dupont, QS 171) was printed on the lapped surfaces for electrode. The electrode was fired by infrared furnace at 850°C for 45 min. The specimens were poled in silicone oil at 150°C by applying a DC field of 3kV/mm for 30min. The dielectric properties of the sintered ceramics are studied as functions of both temperature and frequency with an automated dielectric measurement system. The computer-controlled dielectric measurement system consists of a precision LCR-meter (Hewlett Packard, model 4284A), a temperature chamber, and a computer system. The capacitance and the dielectric loss tangent are determined over the temperature range of 50 and 450 °C with the frequency ranging from 100 Hz to 100 kHz. The piezoelectric constant (d33) was measured using a quasi-static piezoelectric d33 meter (Model ZJ-3d, Institute of Acoustics Academic Sinica, China). The planar coupling coefficient (kp) and the mechanical quality factor (Qm) were determined by the resonance and anti-resonance technique using an impedance analyzer (Model HP4294A, Hewlett-Packard, CA). Ferroelectric switching measurements were made using a modified Sawyer-Tower circuit4 with a linear variable differential transducer (LVDT) for strain measurement, DSP lock-in amplifier (SR830, Stanford Research), high voltage power supply (TREK 609C-6, Trek), and computerized control and data acquisition.

Results and Discussion

The XRD patterns of $xPb(Zn_{1/3}Nb_{2/3})O_3$-$(1-x)Pb(Zr_{1/2}Ti_{1/2})O_3$, where x= 0.1-0.5 specimens with perovskite structure for all compositions are shown in Fig.1a. Perovskite phase formation, crystal structure and lattice parameter was determined by XRD at room temperature as a function of x. The pyrochlore phase was not observed in this system at all. The crystal symmetry for $Pb(Zn_{1/3}Nb2/3)O_3$ at room temperature is rhombohedral R3m with a lattice parameter a = 5.742 Å (JCPDS No. 22-0663) [9]. The crystal structure of $Pb(Zr_{1/2}Ti_{1/2})O_3$ at room temperature is tetragonal P4mm with a lattice parameter a = 4.031 Å and c = 4.145 Å (JCPDS No. 70-4057) [10]. Therefore, crystal symmetry should change from tetragonal to rhombohedral due to the effects of the increased PZN fraction. In these patterns, the crystal structure of the specimens are revealed by the claimed (002) and (200) peak are change to (202) peak. The perovskite structure appears to change from tetragonal to rhombohedral across the MPB with the increasing amount of PZN content around 0.3 mol%.

Fig.1b., XRD peak profiles of the (200) and (002) peaks at x = 0.1 and 0.2 were shown tetragonal phase. At the x = 0.3 composition, (202) peak is observed, indicating the co-existence of the rhombohedral and tetragonal phase. The (202) peak in compositions x = 0.4 and 0.5 was clearly observed, indicating that the crystal transformed into rhombohedral phase.

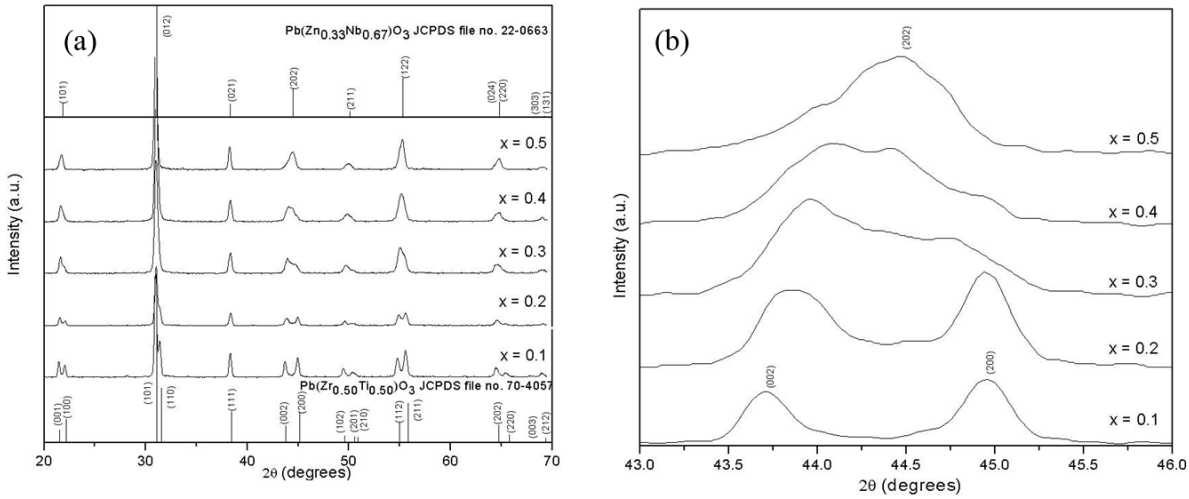

Fig.1. (a) XRD diffraction patterns of sintered *x*PZN-(1 − *x*)PZT ceramics.
(b) selected region of the diffraction patterns.

Density, dielectric constant (ε_r), electromechanical coupling factor (k_p), mechanical quality factor and piezoelectric constant (d_{33}) were plotted as a function of the amount of PZN content in Fig 2. The density was increased with the increase of PZN contents approximately from 7.7 to 7.9 g/cm3. Therefore, the improved piezoelectric and dielectric properties, which were observed, might be due to the increased density. In addition, this softening effect that could be confirmed by the increasing of ε_r , k_p and d_{33} value and decreasing of Q_m as shown in Fig 2.

Conclusions

In this study, ceramics in the $xPb(Zn_{1/3}Nb_{2/3})O_3$–$(1 - x)Pb(Zr_{1/2}Ti_{1/2})O_3$ system (when x = 0.1, 0.2, 0.3, 0.4 and 0.5) were successfully prepared by a solid-state mixed-oxide technique. PZT ceramic was identified by XRD as a single-phase material with a perovskite structure having tetragonal symmetry, while the mixed compositions showed a gradual change from tetragonal to rhombohedral symmetry, with a possible morphotropic phase boundary (MPB) between the two phases near the 0.3PZN–0.7PZT composition. Most importantly, this study showed that the addition of PZN could improve the dielectric, piezoelectric and ferroelectric behavior in PZT ceramics.

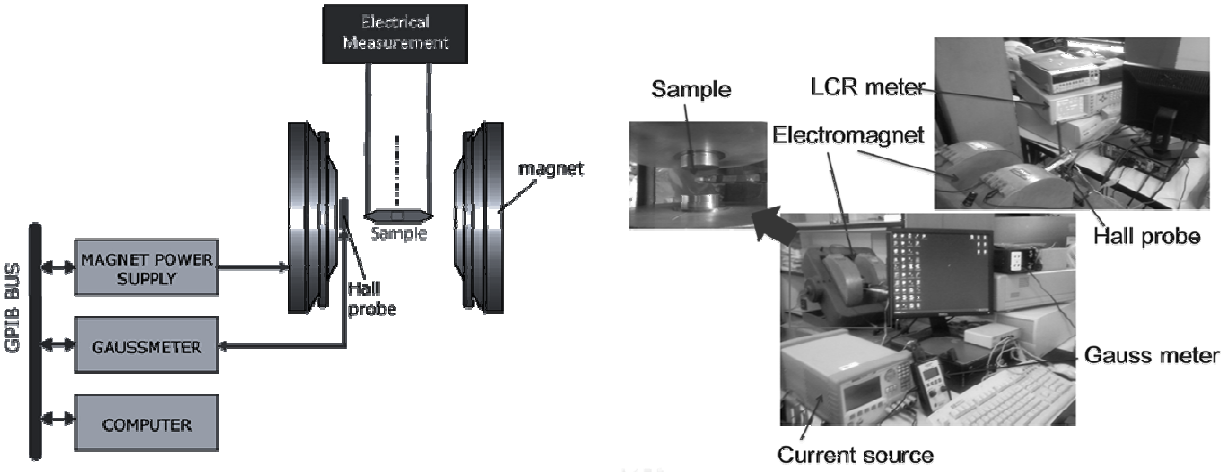
Abstract: This work involves the fabrication of high purity $Pb(Zr,Ti)O_3$ ferroelectric based in ceramic forms, and a study of the correlation between their compositions and electrical properties. In order to enhance multiferroic characteristics of $Pb(Zr,Ti)O_3$ ferroelectric based ceramics compound ferrites additives were added and the dielectric property as a function of magnetic field strength. Those are expected to explain multiferroic characteristics (ferroelectric-ferromagnetic coupling interaction) by quantitative evaluation which is the key to understand physical mechanism in coupling interaction to enhance multiferroic characteristics in materials.

Introduction

Multiferroics are materials in which magnetic and electric orders are strongly coupled, and have attracted increasing attention. Recent experimental research on multiferroics has shown that ferroelectricity and magnetism not only coexist in the same material but also couple so strongly that the magnetic degree of freedom can be manipulated by an electric field and the electric degree of freedom can be manipulated by a magnetic field. This property promises important technological applications in the future. Multiferroic magnetoelectric (ME) materials not only exhibit ferroelectricity and ferromagnetism simultaneously, but also the magnetoelectric coupling effect, which is defined as induced electric polarization under applied external magnetic field or induced magnetization by the external electric field [1,2]. Recently, multiferroic magnetoelectric materials have stimulated increasing interest due to the extensive and potential applications in sensors, memories, actuators and transducers [3]. The room-temperature single-phase multiferroic compounds are very scarce due to the fact that the ferroelectricity and ferromagnetism are incompatible.[1,4,5] However, the multiferroic magnetoelectric materials consisting of the alternating ferroelectric and ferromagnetic phases were proposed in the form of bulk or film. Recently, due to the incorporation into microelectronic technical applications, nanocomposite films on substrates have stimulated increasing interest.

Thus, in this study $Pb(Zr_{1/2}Ti_{1/2})O_3$ based ceramics were prepared and the influences of compound ferrites, such as Fe_2O_3 , $CoFe_2O_4$ and $Pb(Fe_{1/2}Nb_{1/2})O_3$ (PFN), addition on structure and dielectric properties of the ceramics were investigated, which are especially important from the viewpoint of the development of practical magnetoelectric materials.

Experimental Procedure



Raw materials of PbO, ZrO_2, TiO_2, ZnO, Nb_2O_5, Fe_2O_3 and CoO with >99% purity were used to prepare samples by a conventional mixed oxide process. The starting powders were mixed by zirconia ball media with isopropanal as a medium in a polyethylene jar for 30 min via vibro-milling technique. The mixed slurry was dried and calcined at 900 ^oC for 2 h. The calcined powders were vibro -milled again with additives and consolidated into disks of 12.5 mm diameter using uniaxial pressing about 150 MPa. PbO-rich atmosphere sintering of the ceramics was performed in a high-

purity alumina crucible at 1200 °C for 2 h. The crystal structure and symmetry of the sintered bodies were examined by X-ray diffraction Rigaku model Miniflex II.

For electrical properties characterizations, silver electrode was printed on the lapped surfaces. The electrode was fired at 600 ^{o}C for 30 min. The dielectric properties of the sintered ceramics were studied as functions of both magnetic field strength and frequency with an automated dielectric measurement system. The computer-controlled dielectric measurement system consisted of a high precision LCR-meter (Tonghui, model TH2819A), and a computer system. The capacitance and the dielectric loss tangent were determined with the frequency ranging from 100 Hz to 100 kHz as shown as Figure 1 (a-b).

The specimens studies were fabricated according to the formula:

- $Pb(Zr_{1/2}Ti_{1/2})O_3$-$Pb(Zn_{1/3}Nb_{2/3})O_3$ (PZNZT) + 0.5 wt% Fe_2O_3 (composite route)
- $Pb(Zr_{1/2}Ti_{1/2})O_3$-$Pb(Zn_{1/3}Nb_{2/3})O_3$ (PZNZT) + 0.5 wt% $CoFe_2O_4$ (composite route)
- $Pb(Zr_{1/2}Ti_{1/2})O_3$- $Pb(Fe_{1/2}Nb_{1/2})O_3$ ceramics (conventional mixed oxide route)

Results and Discussion

Figure 2 shows the XRD patterns of all sintered samples. PZNZT ceramics with Fe_2O_3 and $CoFe_2O_4$ had rhombodral crystal structure with pure perovskite phase When the PFN addition on PZT (0.5PZT-0.5PFN), the main phase is tetragonal where peak splitting of crystal planes in the same crystal family can be seen. When 70% PFN by molar fraction was added, the main phase was tetragonal where peak splitting were decreasing. When 50% PFN by molar fraction was added, the main phase was rhombohedral. Some major peaks (e.g. 20-45° and 58°) appear to be broader than that of pure PFN, which results from the overlapping between PFN and PZT peaks. It is interesting to note from XRD pattern that the phase present at 30% PZT by molar fraction addition are both rhombohedral and tetragonal and this composition is generally called morphotropic phase boundary(MPB).

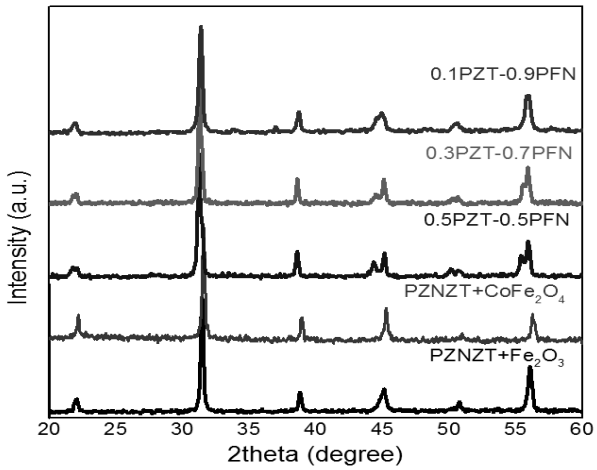

Figure 2 XRD diffraction patterns of modified PZT based ceramics.

Figure 3-7 shows the relationship between dielectric constant, dielectric loss and frequency. All of samples were shown clearly decreasing of dielectric constant with increasing applied magnetic field at low frequency. Again, it can be seen that different sample phase (i.e. rhombohedral versus tetragonal) results in different dielectric behavior. In the ceramics containing rhombohedral phase, dielectric constant slightly linear gradually decreased behavior. Tetragonal phase ceramics did not exhibit the transition; dielectric constant continually decreased like decay behavior.

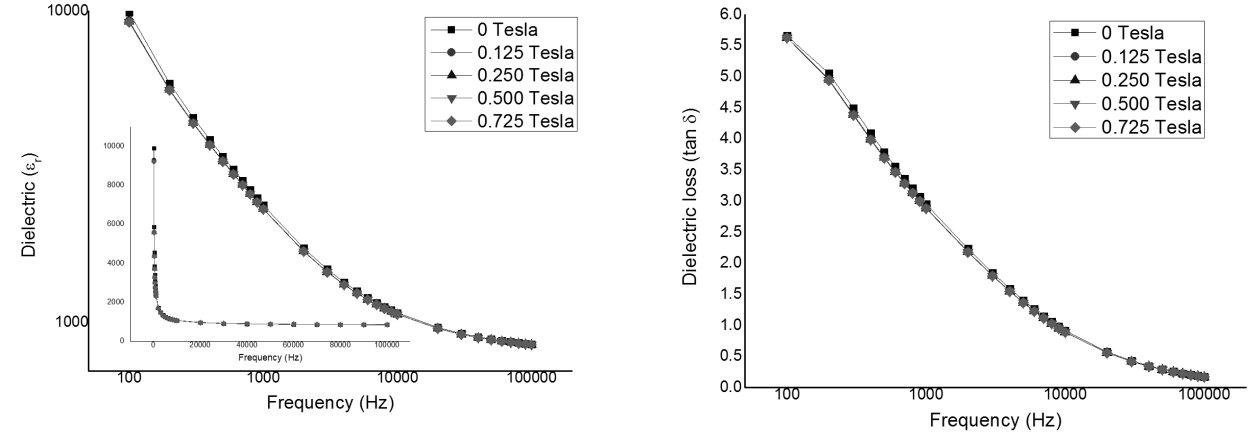

Figure 6. Frequency dependence of the dielectric constant of the 0.3PZT-0.7PFN ceramic

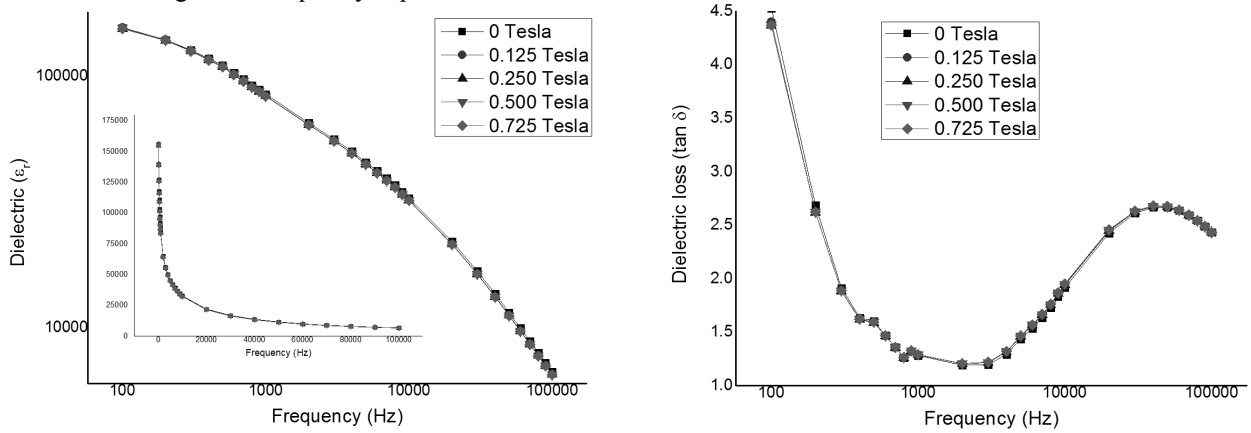

Figure 7. Frequency dependence of the dielectric constant of the 0.1PZT-0.9PFN ceramic

Conclusions

The magnetic-field-dependent dielectric properties were successfully investigated for modifed PZT by compound ferrites additives. The structural properties were found to have a significant effect on the magnetic, dielectric and magneto-dielectric properties of the composite samples. Changes in the positions of the transitional-metal ions in the magnetic phases led to variations in the magnetic properties. The decrease in dielectric constant with increasing applied magnetic field was attributed to a relaxation of the ferroelectric phase due contractive deformations occurring in the magnetic phase of the investigated particulate composite due to an magnetostriction of the magnetic phase in the presence of an external magnetic field that it was shown structure –property relation in this research.

Keywords: Ferroelectric; Optical interferometry, Piezoelectric, Electrostrictive

Abstract: Michelson interferometric technique was modified in the setup and used to measure very small changes in optical path length for electric field induced-strain phenomena. Induced-strain is established in the sample when the beam of light propagating through the sample surface undergoes a shift in phase, which in turn leads to a change in the intensity of the interference pattern formed where the reference and probing beams recombine. In this work the electric field induced-strain was measured as a function of electric field (s-E loop) and polarization (s-P loop) of $PbMg_{1/3}Nb_{2/3}O_3$ (PMN) and $0.7PbMg_{1/3}Nb_{2/3}O_3$-$0.3PbZr_{0.52}Ti_{0.48}O_3$ (0.7PMN-0.3PZT) ceramics, which showed electrostrictive (quadratic shape curve) and piezoelectric (butterfly shape curve) behavior at various frequency (0.01-1Hz).

Introduction

The piezoelectric or electrostrictive materials are the most used functional materials as sensors and actuators. Piezoelectric/electrostrictive sensor converts a mechanical variable into a measurable electrical quantity. Alternately, the actuator converts an electrical signal into a mechanical strain the s-E loop. The polarization is related to the strain the s-P loop can provide a means of investigating displacement or strain behavior because it can be used to drive the induced-strain with a nonlinear field to give a linear displacement. The solid state theory that describes the deformation of piezoelectric/electrostrictive ceramic is subjected to an electrical field is shown in Equations (1) and (2);

$$x_{ij} = d_{mij}E_m + M_{ijmn}E_mE_n \quad (1)$$

$$x_{ij} = g_{mij}P_m + Q_{ijmn}P_mP_n \quad (2)$$

where x_{ij} is the component of elastic strain, E_m and E_n are the components of electric field, P_m and P_n are the components of polarization, d_{mij} and g_{mij} are the piezoelectric tensor components, and M_{ijmn} and Q_{ijmn} are the electrostriction tensor components [1-3].

Induced-strain properties of piezoelectric and electrostrictive materials can be investigated by various experimental techniques. Four methods that have been used generally are fibre optic probe, linear variable differential transformers (LVDT), capacitance probe and strain gauges and laser interferometry. The highest resolution method for investigate of electric-field induced strain is the laser interferometry which is based on the Michelson interferometer. The Michelson interferometer technique is a simple and low cost measurement of the electric field-induced displacement. When two laser beams of the same wavelength (λ) interfere, the light intensity varies periodically (λ/2 period) corresponding to the change of optical path length between the two beams.

The intensity of the point of detection changes relative to the displacement can be written as Equation (3);

$$I = I_p + I_r + 2(I_p I_r)^{1/2}\cos(\frac{4\pi\Delta d}{\lambda}) \quad (3)$$

where I_p is the light intensity of the probing beam, I_r is the light intensity of the reference beam and Δd is optical path difference [1].

Experimental

In this research, the modified Michelson interferometric technique was used to measure strain in PMN and 0.7PMN-0.3PZT ceramics as a function of various electric field strengths to obtain a full understanding of the field induced-strain with various frequency of piezoelectric/electrostrictive materials. Preliminary characterization of dielectric behavior was carried out by measuring dielectric constant of the samples at the frequency of 1-100 kHz and the temperatures between 25 and 250^{o}C using LCR meter. A schematic diagram of the system is shown in Figure 1. A modified Michelson interferometer was constructed. It was the system with rigid optical component mounted on a vibration freed optical table to reduce the noise signal of ambient vibrations. The sample under investigation was placed in spring load sample holder which was subjected to an electric high extension field and a polarized beam from a Helium-Neon laser (monochromatic source, λ = 632.8 nm). The frequency used in this work was in the range of 0.01-1 Hz. When the sample was subjected to the applied electric field, the reflected laser beam from the sample (M_2) underwent interference with the reflected laser beam from the reference mirror (M_1) as shown in Figure 1. The resultant interfering intensity variations were detected by a photodiode. Then the amplified signal was captured on a digital oscilloscope along with P-E hysteresis loop measured by a modified Sawyer-Tower circuit which had all interfaces with PC.

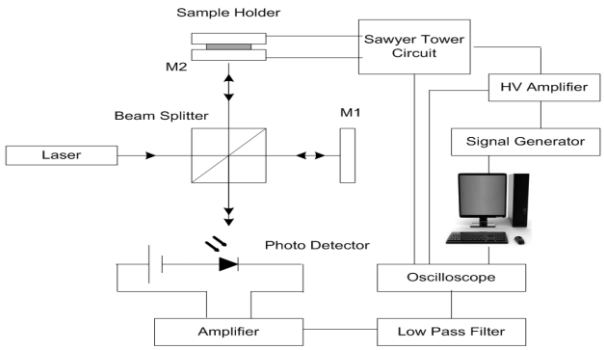

Figure 1. Modified Michelson interferometer

Results and Discussion

Figure 2 shows dielectric constant of PMN and 0.7PMN-0.3PZT as a function of temperature. It can be seen that dielectric property of the two samples is completely different where PMN was paraelectric and 0.7PMN-0.3PZT was ferroelectric (and piezoelectric) which was agreed with the previous result [4]. It should be noted that the difference in dielectric behavior would also result in the difference in response to electric field (i.e. electrostrictive strain and polarization) as discussed further in the next paragraphs.

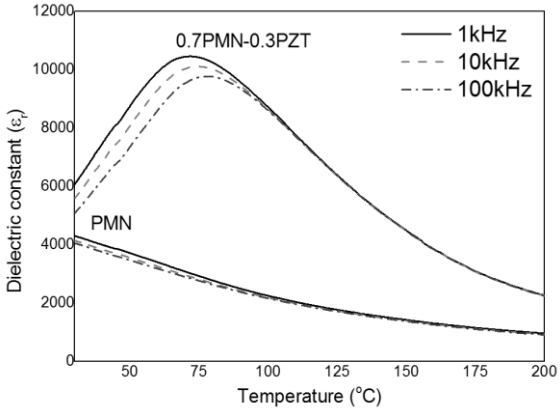

Figure 2. The temperature dependences of the dielectric constant (ε_r) of PMN and 0.7PMN-0.3PZT

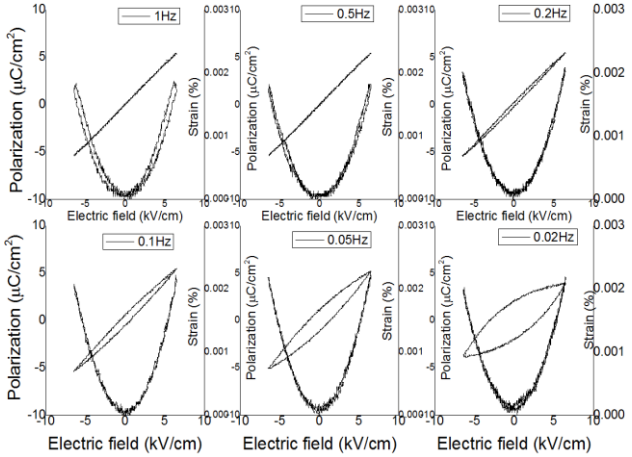

Figure 3. The s-P-E loop curve of PMN, strain proportional to the square of the electric field

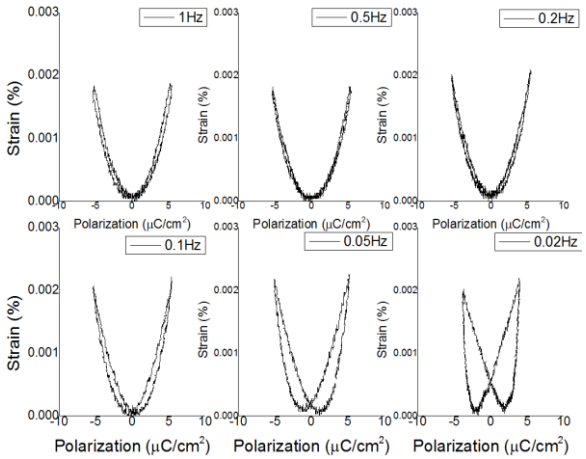

Figure 4. The s-P curve of PMN at various frequencies

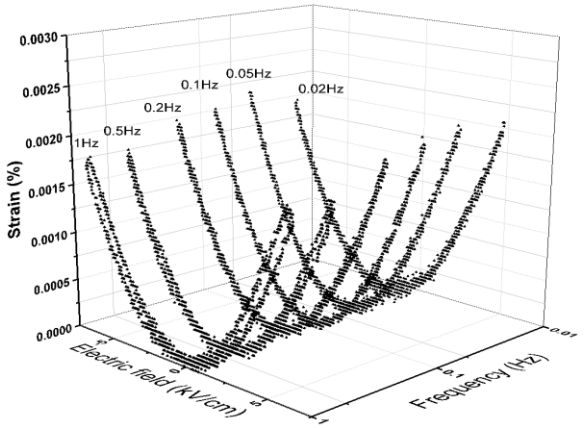

Figure 5. The field induced-strain (s-E) of PMN at various frequencies

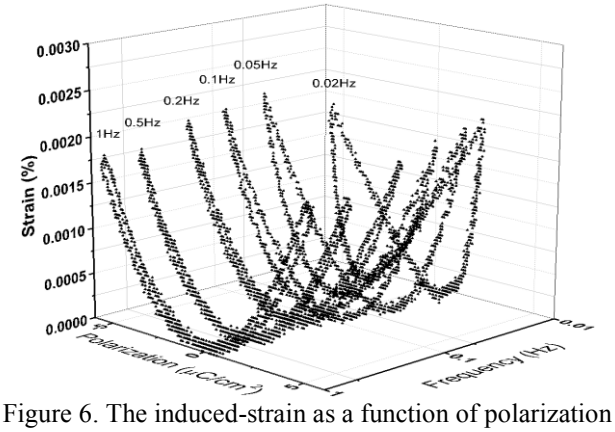

Figure 6. The induced-strain as a function of polarization (s-P) curve of PMN at various frequencies

In Figure 3 and 4, the results of optical interferometry are summarized in these two Figures to further explain the dielectric properties of PMN. Considering the s-P-E graph in Figure 3, the hysteresis polarization occurred at low frequency (clearly seen at 0.05 and 0.02 Hz). The strain behavior was quadratic in relation to electric field and proportional to the square of polarization at high frequency (≥ 0.2 Hz) as shown in Figure 4. When the frequency was less than 0.2 Hz, the response of strain to polarization was no longer quadratic where the characteristic strain loop can be seen. Figure 5 and 6 conclude the induced strain behavior at various frequencies. It can be seen clearly that frequency affected the change in the strain behavior in terms of the change of polarization.

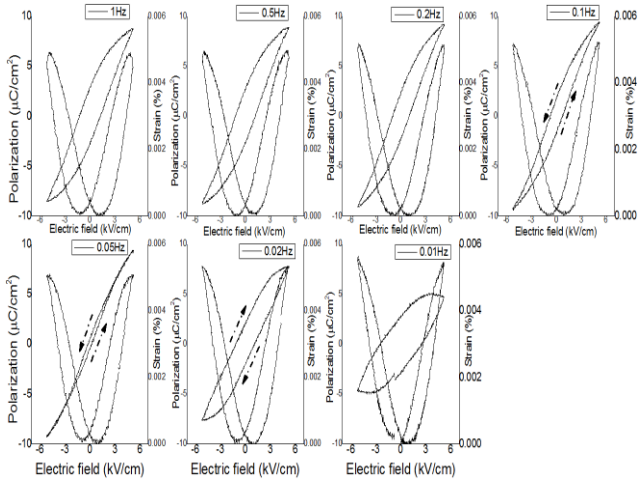

Figure 7. The s-P-E loop curve of 0.7PMN-0.3PZT, induced-strain exhibiting a butterfly loop

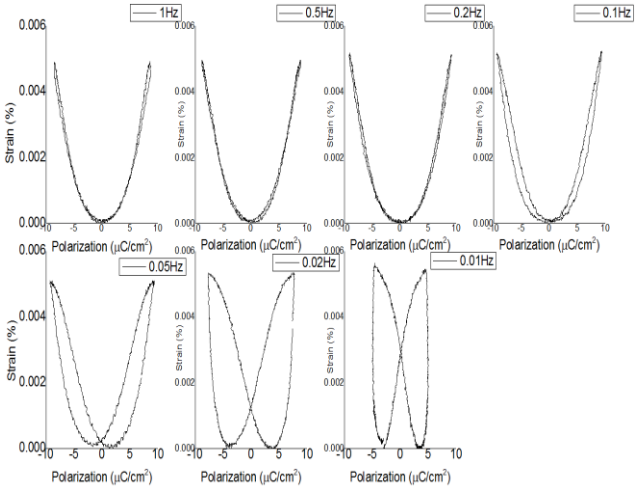

Figure 8. The s-P curve of 0.7PMN-0.3PZT at various frequencies

In Figures 7 and 8, the results of optical interferometry are summarized in these two Figures to further explain the dielectric properties of 0.7PMN-0.3PZT. Considering the s-P-E graph in Figure 7, graph had butterfly shape curve with electric field at all frequency. The strain behavior was proportional to the square of polarization at high frequency (≥ 0.2 Hz), which demonstrated 90^{o} rotation dominant as shown in Figure 8 [3]. When the frequency was less than 0.2 Hz, the response of strain to polarization was no longer quadratic where the characteristic strain loop can be seen and polarization changed from anti clockwise (0.1 Hz) to absence (0.05 Hz) and anti-clockwise (0.02 Hz) hysteresis [5]. Figures 9 and 10 conclude the increasing of strain with decreased frequencies. It can be seen clearly that frequency affected the change in the strain behavior in terms of the change of polarization.

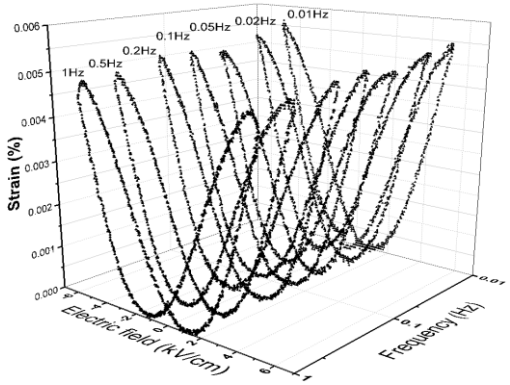

Figure 9. The field induced-strain (s-E) of 0.7PMN-0.3PZT at varies frequency

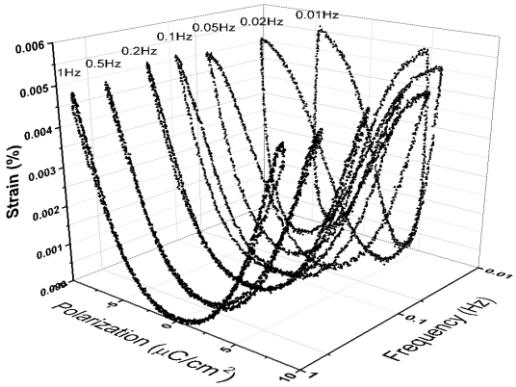

Figure 10. The induced-strain as a function of polarization (s-P) curve of 0.7PMN-0.3PZT at varies frequency

Conclusion

The dielectric characteristic of the two samples was completely different where PMN was paraelectric and 0.7PMN-0.3PZT was ferroelectric (and piezoelectric). The strain and polarization of both samples showed frequency dependence. Induced-strain of PMN was proportional to square of electric field at all frequency and showed electrical loss when the frequency was less than 0.2 Hz. For 0.7PMN-0.3PZT, butterfly shape curve of s-E was observed at all frequency, but showed quadratic shape curve with polarization at 0.2-1 Hz that related to 90^{o} domain rotation and when the frequency was lower than 0.1 Hz, polarization changed from anti clockwise to anti-clockwise hysteresis. The induced strain of 0.7PMN-0.3PZT increased with decreasing frequency.

Keywords: Elastic Strain Behavior, PLZT, Ferroelectric, Dielectric

Abstract. In this paper the effect of lanthanum addition on the phase formation, dielectric and ferroelectric characteristics of x/65/35 PLZT. This ceramics were prepared using mixed-oxide synthetic route via a rapid vibro-milling method. All samples were sintered at 1200°C for 12 h. X-ray diffraction was used to observe the crystal structure. It was found that when increasing lanthanum content, the structure remained rhombohedral. It can be seen that the change of behavior to ferroelectric relaxor with the increasing of lanthanum content resulted in the change of elastic strain

Introduction

Lanthanum modified lead zirconate titanate (PLZT) ferroelectric materials have many excellent functional properties, such as piezoelectricity, dielectricity, pyroelectricity and electroopticity. Therefore, they have been widely used in various electronic devices such as sound element, memory and light modification [1] the phase diagram of PLZT system at room temperature, the actual solubility of La in the solid solution depends on the ratio of the two compounds ($PbZrO_3$ and $PbTiO_3$). At 65/35 ratio of $PbZrO_3$ to $PbTiO_3$, a concentration of 9 mol% lanthanum (La) or PLZT 9/65/35 is sufficient to reduce the temperature of the stable ferroelectric rhombohedral phase (FE_{Rh}) to below room temperature [2] varying the amount of La in this region (65/35) could result in the change of crystal structure (from ferroelectric rhombohedral phase (FE_{Rh}) to paraelectric cubic phase (PE) passing through morphotropic phase boundary (MPB) or the boundary region between ferroelectric tetragonal phase (FE_{Tet}) and ferroelectric rhombohedral phase (FE_{Rh}) and also dielectric behaviour (from normal ferroelectric to relaxor ferroelectric) [2, 3].

Research work by Zhang et. Al. [4] revealed that the amount of La added to PZT 40/60 affected the microstructure, ferroelectric and dielectric properties significantly. They pointed out that the particular reason is the change of tetragonality in samples. There has been development of x/65/35 PLZT ceramics with different amount of La (x) ranging from 5 mol% up to the limit of solubility.

This work would serve as a revision to summarize the effect of La content to the electrical properties of x/65/35 PLZT ceramics. In this work x/65/35 PLZT ceramics (where x = 6, 8, 9, 10 and 12 mol% La) was fabricated and the relationship between composition and electrical properties was investigated.

Experimental Procedure

Stoichiometric amount of starting oxides La_2O_3 (Sigma-Aldrich), PbO (Fluka), ZrO_2 (Riedel-de Haën) and TiO_2 (Sigma-Aldrich) was calculated to fabricated x/65/35 PLZT where x is the amount of lanthanum (x = 6, 8, 9, 10 and 12 mol%) . All powders were weighed, mixed and further milled

by vibro milling (McCrone Micronizing Mill) for 30 minutes with a corundum cylindrical media in ethanol. After drying at 120°C for 24 h, the mixture of oxides was calcined at 900°C for 3 h in air. Green pellets of 12.5 mm diameter were prepared using uniaxial-pressure of 200 MPa. The pellets were then placed in a high purity alumina crucible in air and sintered at 1200°C for 12 h.

XRD patterns at room temperature were recorded with X-ray diffraction (Rigaku model MiniFlex II). The CuKα radiation was used as X-ray source. The relative amounts of perovskite phases and were determined from XRD patterns of the samples by measuring the major peak intensities. The sintered samples were polished, cleaned and screen printed with silver electrodes. The dielectric properties of the sintered ceramics were studied as functions of both temperature and frequency with an automated dielectric measurement system. The computer-controlled dielectric measurement system consisted of a high precision LCR-meter, a temperature chamber and a computer system. The capacitance and the dielectric loss tangent were determined over the temperature range of 30-250°C with the frequency of 1-100 kHz. Induced-strain measurements in the terms of strain were made using a modified Michelson interferometric technique as a function of various electric field strengths at the frequency of 0.2 Hz.

Results and Discussion

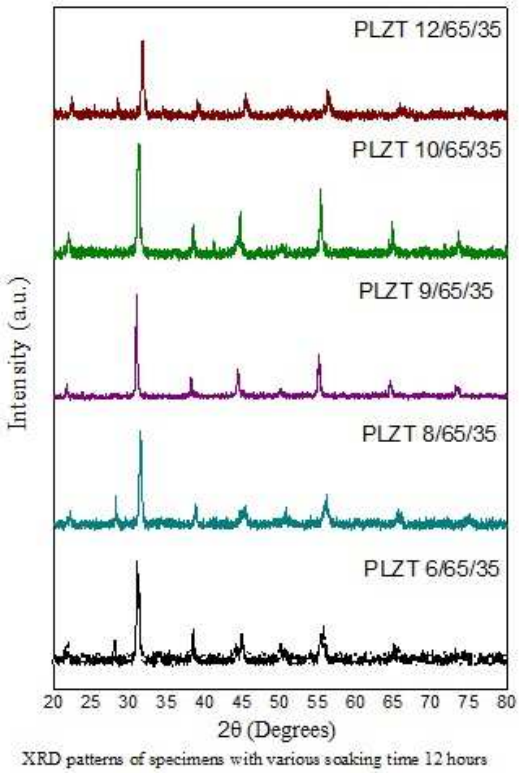

Fig. 1 XRD Patterns of x/65/35 PLZT

Fig.1 shows the XRD patterns of PLZT with different amount of lanthanum sintered at 1200°C for 12 h. It can be seen that all PLZT ceramic samples exhibit perovskite with rhombohedral crystal structure. There was no presence of ZrO_2 in the samples, which was different from the previous study that reported XRD patterns with the peaks of ZrO_2 from either incomplete calcination or PbO evaporation during sintering [5, 6].

The graphs in Fig. 2 show that dielectric behavior of x/65/35 PLZT ceramics changes toward relaxor ferroelectric behavior when the amount of La is increased. It can also be seen that the temperature of maximum dielectric constant is significantly decreased from 219°C in 6/65/35 PLZT

to 34°C in 12/65/35 PLZT. The values of T_m and dielectric properties (at T_m) are summarized in Table 1.

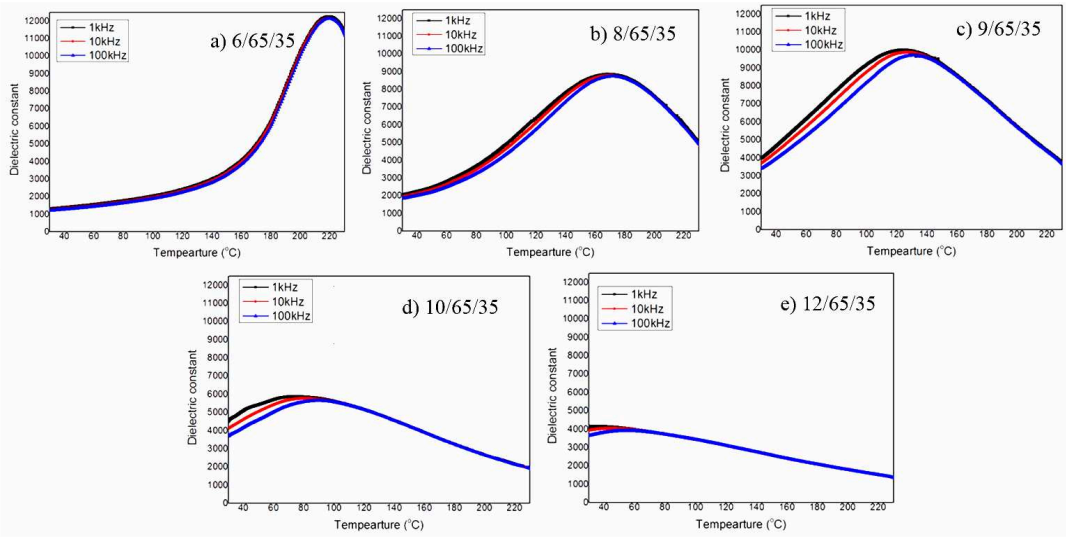

Fig. 2 Dielectric Constant of x/65/35 PLZT

The graphs of strain versus electric field (Fig. 3) imply the relationship between dielectric properties and ability to switch domain during polarization when an electric field is applied. At the content of 6 and 8 mol% La, the resulting strian from the applied field shows a bigger loop when the electric field was increased. The strain behaviour is in the region of "memory" when the La content was increased, the ferroelectric behavior of x/65/35 PLZT ceramics was changed to slimmer hysteresis loop or relaxor ferroelectric [7] hence the remanant polarization was greatly decreased, resulting in a slimmer butterfly loop with less strain at zero electric field (Fig. 3(d)). Moreover, the saturated electric field increased, resulting in an increase in maximum strain (Table 1). When the La content is 12 mol% (Fig. 3(e)), the strain behavior is changed from "quadratic" to a less degree where the S-E curve appears to be flatter (lower maximum strain) [8] .

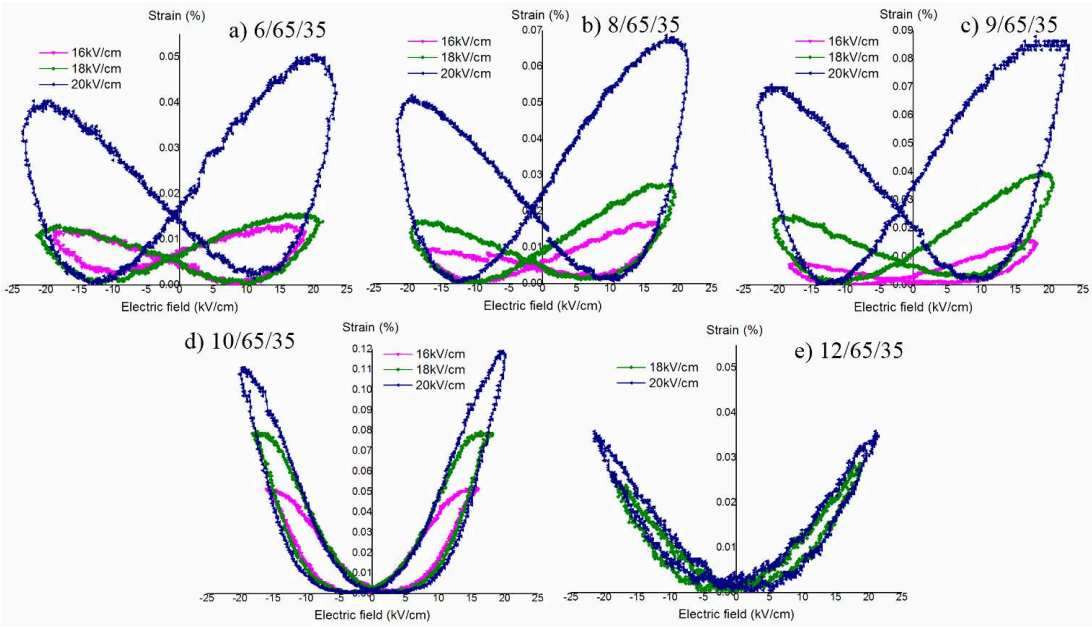

Fig. 3 S-E Characteristics of x/65/35 PLZT Based Ceramic

TABLE 1 FERROELECTRIC PROPERTIES OF X/65/35 PLZT

La content x/65/35	T_m (°C) @ 1kHz	Dielectric properties (at T_m)		Strain % @ 20 kV/cm
		ε_r	tanδ	
x =6 (6/65/35)	219.1	12277	0.0070	0.05
x =8 (8/65/35)	162.5	10443	0.0274	0.07
x =9 (9/65/35)	124.4	10024	0.0080	0.07
x =10 (10/65/35)	76.6	8004	0.0002	0.12
x =12 (12/65/35)	33.6	4175	0.0190	0.035

Conclusion

It can be concluded from the resulted that elastic strain behavior was directly associated with dielectric properties. The amout of La significantly affected the electrical behaviors. When the La content was increased, x/65/35 PLZT ceramics were ferroelectric relaxors and the strain behavior tended to be quadratic. However, there was no change of crystal structure (i.e. rhombohedral) when the La content varied.

Keywords: Tetragonality, PLZT, Ferroelectric, Dielectric

Abstract. This paper describes the relationship between sintering time conditons, tetragonality from phase formation, dielectric and ferroelectric characteristics of tetragonal PLZT (lanthanum modified lead zirconate titanate) ceramics with the pressureless sintering conditions. Ferroelectric compounds of $Pb_{0.92}La_{0.08}(Zr_{0.4},Ti_{0.6})_{0.98})O_3$, PLZT 8/40/60, were prepared using mixed-oxide synthetic route via a rapid vibro-milling method. X-ray diffraction, is used to observe the tetragonality characteristic and the presence of pyrochlore. When sintering time was increased (≥ 8 hours), pyrochlore was developed. It can be observed that with the increased sintering time, it were changed the structure and ferroelectric behavior of the PLZT ceramics.

Introduction

PLZT ferroelectric materials have many excellent functional properties, such as piezoelectricity, dielectricity, pyroelectricity and electroopticity. Therefore, they have been widely used in various electronic devices such as sound element, memory and light modification [1]. The PLZT ferroelectric system has been studied intensively for technological applications. These compound crystallize in the ABO_3 perovskite structure type, where the A and B sites are occupied by Pb^{2+} and (Zr^{4+}, Ti^{4+}) ions, respectively [2].

Lanthanum modified lead zirconate titanate (PLZT) ceramics, with variable dopant concentration and ratio of Zr/Ti, have shown to exhibit a variety of phases such as ferroelectric (FE), antiferroelectric (AFE) and paraelectric (PE) phases. Due to these advantages, PLZT ceramics have received much attention for the researcher all over the world [3-5]. The tetragonal ferroelectric phase of PLZT 8/40/60 shows a change of lattice parameter a and c indicated by the change of XRD peak. The ratio of c/a is called tetragonality which relates to the change of unit cell dimension and can be seen from x-ray diffraction from XRD patterns.

PLZT powders were traditionally prepared by a solid state reaction process using oxides as the starting materials [6-7]. Many wet chemistry based routes were also developed to prepare ultra-fine powders for PLZT ceramics, which include chemical co-precipitation, sol-gel process and hydrothermal reaction [3,8-9]. Every method has its own advantages and disadvantages. For example, the conventional solid state reaction method requires a calcination, which will lead to formation of PLZT powders.

Microstructure, phase transition from x-ray pattern of PLZT 8/40/60 ceramics were studied recently. And there is no such research involving lattice parameter that indicate the tetragonality of PLZT in the tetragonal phase of formula 8/40/60 ceramics. The purpose of this study is to investigate the tetragonality from various sintering time on properties of PLZT ceramics were investigated in lattice parameter from tetragonal phase formation.

Experimental procedure

Stoichiometric amounts of starting oxides La_2O_3 (Sigma-Aldrich), PbO (Fluka), ZrO_2 (Riedel-de Haën) and TiO_2 (Sigma-Aldrich) of PLZT ceramics having composition $Pb_{0.92}La_{0.08}(Zr_{0.4}Ti_{0.6})O_3$ were weighed, mixed and further milled by vibro milling (McCrone Micronizing Mill) for 30 minutes with a corundum cylindrical media in ethanol. After drying at 120°C for 24 hours, the mixture of oxides was calcined at 900°C for 4 hours in air. Green pellets of 6 mm diameter and 15 mm length were prepared using isostatic-pressure of 150 MPa. The pellets were then placed in a high purity alumina crucible in air. The pellets were then sintered at 1200°C various of sintering time from 2-12 hours.

XRD pattern at room temperature was recorded with X-ray diffraction (Philips PW 1729 diffractometer). The CuKα radiation was used as X-ray source. The relative amounts of perovskite phases and were determined from XRD patterns of the samples by measuring the major peak intensities tetragonality.

The sintered samples were polished, cleaned and screen printed with silver electrodes. The dielectric properties of the sintered ceramics were studied as functions of both temperature and frequency with an automated dielectric measurement system. The computer-controlled dielectric measurement system consisted of a precision LCR-meter, a temperature chamber and a computer system. The capacitance and the dielectric loss tangent were determined over the temperature range of 50-450°C with the frequency ranging between 1-100 kHz. Ferroelectric switching measurements were made using a modified Sawyer-Tower circuit.

Results and discussion

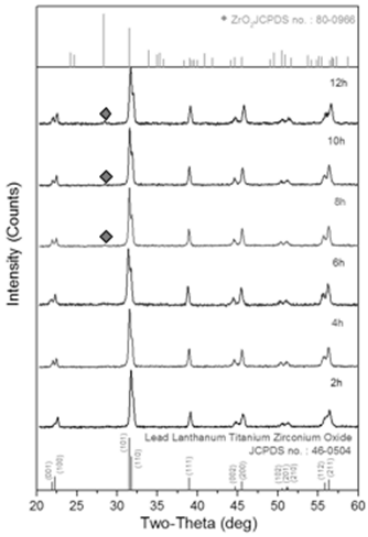

Fig. 1 XRD patterns of $Pb_{0.92}La_{0.08}(Zr_{0.4}Ti_{0.6})_{0.98}O_3$ ceramics

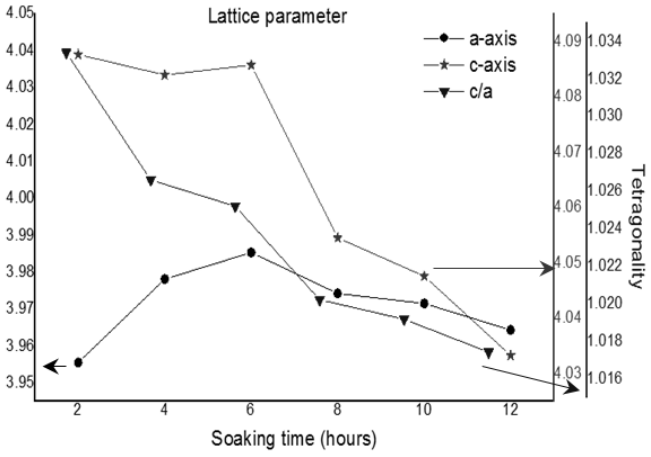

Fig. 2 Lattice parameter and tetragonality of $Pb_{0.92}La_{0.08}(Zr_{0.4}Ti_{0.6})_{0.98}O_3$ ceramics

Fig.1 shows the XRD patterns of $Pb_{0.92}La_{0.08}(Zr_{0.4}Ti_{0.6})_{0.98}O_3$ ceramics sintered at 1200°C with various sintering time of 2, 4, 6, 8, 10 and 12 h. In these patterns pure perovskite tetragonal phase transition of the samples at soaking times of 2-6 hours, as revealed by the evolution of (101) and (110), which could be matched with JCPDF no. 46-0504, confirmed the tetragonal phase of all samples. In general, only a perovskite phase was observed at a low soaking time of PLZT 8/40/60, in which is agreement with other workers [7]. The perovskite stucture of appear a small pyrochlore dovelopment with soaking time of 8-12 hours with a further increase in soaking times. the peak of the diffraction pattern where 2θ is 28.13 degrees, which could be matched with JCPDF no. 80-0966 in Fig.1. Pyrochlore phase generally affects the electrical property. Pyrochlore phase at higher sinter temperature of PLZT is shown, which resulted in a decrease of the dielectric constant.

Fig.2 the tetragonal lattice parameter of a and c were determined at various of soaking times. The results given in Fig. 2 revealed that the tetragonal cell parameters of PLZT 8/40/60 ceramics had a change of dimensions and it can be seen that the tetragonality or c/a decreased with soaking time 2-12 h.

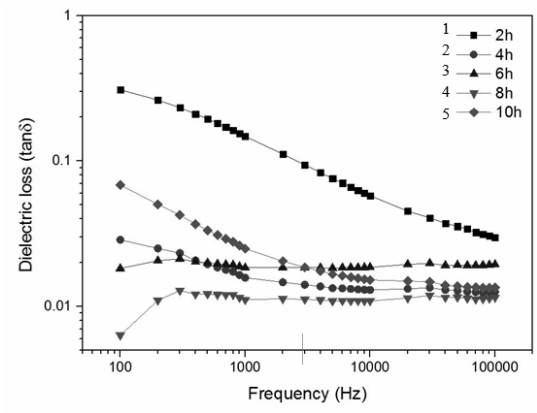

Fig. 3 Dielectric constant (ε_r) of $Pb_{0.92}La_{0.08}(Zr_{0.4}Ti_{0.6})_{0.98}O_3$ ceramics

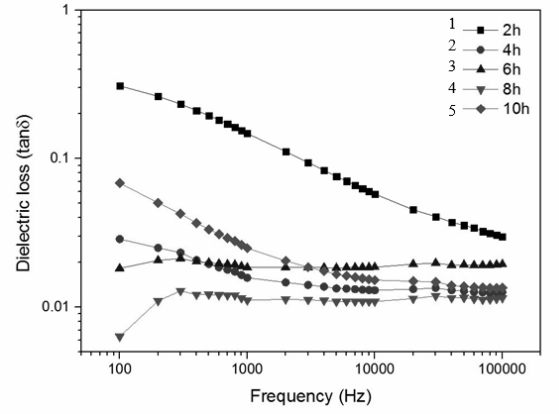

Fig. 4 Dielectric loss (tanδ) of $Pb_{0.92}La_{0.08}(Zr_{0.4}Ti_{0.6})_{0.98}O_3$ ceramics

As shown in Figs. 3-4, the dielectric constant (ε_r) and loss (tanδ) as a function of frequency are plotted. Curves 1-5 represent different soaking time of the function, (1) 1200-2h; (2) 1200-4h; (3) 1200-6h; (4) 1200-8h; (5) 1200-10h. The dielectric constant in soaking time is 12 h was not measured because of the development of pyrochlore phase. The dielectric constant and loss is decreased with the increasing of frequency.

The temperature dependences of the dielectric constant in Fig. 5 at 1 kHz for PLZT 8/40/60 PLZT ceramics. The change of the dielectric peaks may be caused from the different of soaking time at sintered temperature. The Curie temperature (T_c) as a function of all condition is displayed, which was constant at 251°C. Maximum dielectric constant at a lower soaking time of 2-6 h is 2851, 4829 and 7539. When increasing soaking times from 8 to 10 h, the dielectric constant decreased. It decreased from 6687 to 5980 which could be due to the development of pyrochlore phase at higher soaking time of 8 and 10 h. The dielectric properties at T_c, which are report in Table 1 are comparable with other results reported in literature for ceramic 8/40/60 PLZT with ferroelectric tetragonal phase [7].

The polarization-field (P-E) hysteresis loop of PLZT 8/40/60 ceramics is shown in Fig. 6 with variation of sintering time from 2-12 hours. The well developed ferroelectric characteristics in PLZT 8/40/60 ceramics, the ferroelectric parameters, i.e. P_r, P_s and E_c, have been extracted from the experimental data and given in Table 1. The PLZT 8/40/60 exhibits a memory polarization hysteresis loop, which is a switching characteristic of restrained ferroelectric domains. However,

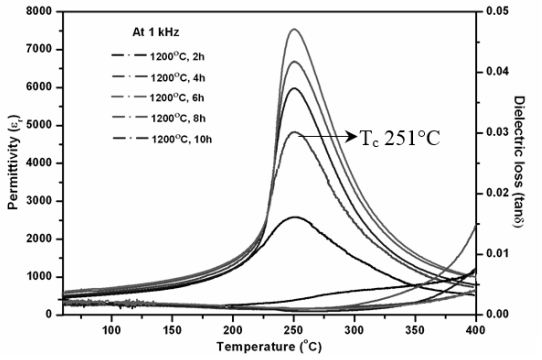

Fig. 5 Temperature dependences of the dielectric constant (ε_r) at 1 kHz

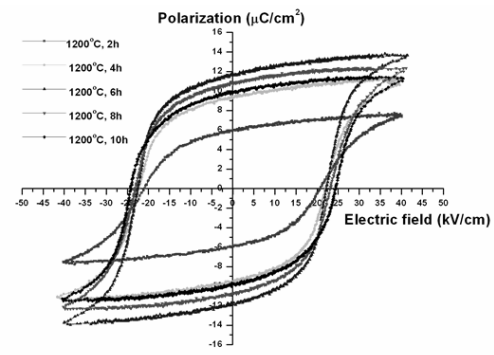

Fig. 6 P-E hysteresis loops of PLZT 8/40/60 with variation of soaking times

the polarization curve of all sintering time was increased from 2-6 h, values of remnanent polarization (P_r) increased. However, when the soaking time was 8-10 h, it was decreased in remnanent polarization (P_r). The observation of the electrical properties of PLZT 8/40/60 could be

attributed to the tetragonal ferroelectric phase when the sintering time increases, which could be matched with x-ray diffraction pattern as shown in Fig. 1.

Table 1 Dielectric and ferroelectric properties of $[Pb_{0.92}, La_{0.08}][Zr_{0.4}Ti_{0.6}]_{0.98}O_3$ ceramics (at 1 kHz)

Sintering (°C) /time (h)	Dielectric properties (at T_c)		Ferroelectric properties		
	ε_r	tanδ	P_r ($\mu C/cm^2$)	P_s ($\mu C/cm^2$)	E_c (kV/cm)
1200°C, 2h	2851	0.0234	5.9	6.2	20.4
1200°C, 4h	4829	0.0097	9.4	9.7	21.7
1200°C, 6h	7539	0.0103	11.7	12.0	22.3
1200°C, 8h	6687	0.0109	10.8	11.1	23.4
1200°C, 10h	5980	0.0061	9.9	10.0	24.4

Conclusion

Lanthanum modified lead zirconate titanate ceramics were obtained by employing mixed-oxide synthetic route sintered at 1200°C with variation of soaking times from 2-12 hours. XRD analysis indicated a small amount of pyrochlore at 8-12 hours, which made a decreasing not only dielectric constant but also remnanent polarization. The tetragonality was decreased when the pyrochlore phase is developed. The structures of tetragonal PLZT 8/40/60 ceramics was realated with the electrical properties such as dielectric constant and ferroelectric from hysteresis loop. It can be concluded that a lattice parameter (a and c) existed in PLZT (8/40/60) system, the tetragonality (c/a) increased with the soaking time increasing and associated with the structure and electrical properties

Keywords: Indium oxide; Microtubes; Electrospinning; UV light sensing

Abstract: Ultrathin indium oxide (In_2O_3) microtubes were successfully fabricated by electrospinning, magnetron sputtering and followed calcination. The hollow In_2O_3 tubes were characterized by scanning electron microscopy (SEM), X-ray diffraction (XRD) and UV-visible spectroscopy. Outer diameter of the microtubes was in the range of 700-900 nm, and inner diameter was about 400-600 nm. Optoelectronic properties of the In_2O_3 tubes were investigated by irradiation of UV light with different wavelengths (254, 308 and 365 nm). It was found that the In_2O_3 microtubes had a fast and strong response to UV irradiation.

Introduction

Electrospinning has been recognized as a convenient and efficient technique to produce ultrathin fibers. A wide variety of materials including bio-macromolecules, organic polymers, semiconductor ceramics and even metals have been fabricated by electrospinning [1-2]. Besides polymer fibers, electrospinning can also be used to fabricate inorganic oxide nanofibers from polymer solution containing inorganic/organic composite ingredients [3]. Hollow nanofibers have a broad application prospect in many fields such as gas storage, drug sustained release and sensing devices [4-6]. Up to date, many methods have been reported to produce various kinds of fibers with hollow structure [7,8].

In_2O_3 is known to be a representative n-type semiconductor material. It has exhibited promising applications in microelectronic fields, such as semiconductor sensors, flat panel display and solar energy conversion [9]. Studies have demonstrated that In_2O_3 semiconductor device has an excellent sensitivity in detecting low concentration of gas such as gasoline, alcohol, ammonia, butane gas and so on. Meanwhile, In_2O_3 also has a very high sensitivity for UV detection, which can be used to protect human body from ultraviolet irradiation. In_2O_3 nanofibers can improve sensitivity and decrease response time due to their higher surface-to-volume ratio.

In this work, In_2O_3 microtubes have been successfully prepared by a new method combining electrospinning, magnetron sputtering and calcination. The In_2O_3 microtubes fabricated by this approach have a smaller outer diameter (700-900 nm) and a thinner wall thickness (50-200 nm). Particularly, the In_2O_3 microtubes show fast and strong response to UV irradiation.

Experimental details

Firstly, poly(vinylidene fluoride) (PVDF) precursor solution was prepared for electrospinning. 2.0 g PVDF was added into 8.0 g of the mixed solvent, containing N,N-dimethyl formamide and acetone with the weight ratio of 1:1 and stirred for 3 h at 60 ^oC in water bath. The solution was loaded into a 5 ml plastic syringe with stainless steel needle connected to a high-voltage power supply (Tianjin Dongwen, China). By electrospinning with a voltage of 13 kV and distance of 10 cm, the PVDF nanofibers were deposited on the collector.

Taking advantage of FJL-560 Ultrahigh Vacuum Magnetron Sputtering Deposition System, a thin layer of In_2O_3 was deposited on the electrospun PVDF nanofibers, which acted as a hard template. The sputtering parameters were controlled as following: In_2O_3 target, sputtering power (90 W), distance between target and substrate (10 cm), sputtering time (1 h), volume ratio of Ar and O_2 (10 : 0.1), room temperature and 1 atm.

In order to get hollow tube structure, the In_2O_3/PVDF composite fibers have been calcined for 2 h under 600 ^oC in a muffle furnace to remove the PVDF fiber template. Then, the furnace was naturally cooled down to room temperature.

The tubes were characterized by a scanning electron microscope (SEM, FEI DB235 Dual-Beam System), an X-ray diffraction (XRD, Rigaku D/max-2400) diffractometer, and a TU-1901 Dual-beam UV-visible Spectrophotometer. The UV photo-detection property of In_2O_3 microtubes was tested by three kinds of UV lamps: PLS-LAM365 (365 nm UV light), PLS-LAM300 (308 nm UV light), PLS-LAM254 (254 nm UV light). The photo-response measurements of the device were carried out under following conditions: applied bias voltage 5 V; room temperature and in air.

Results and discussion

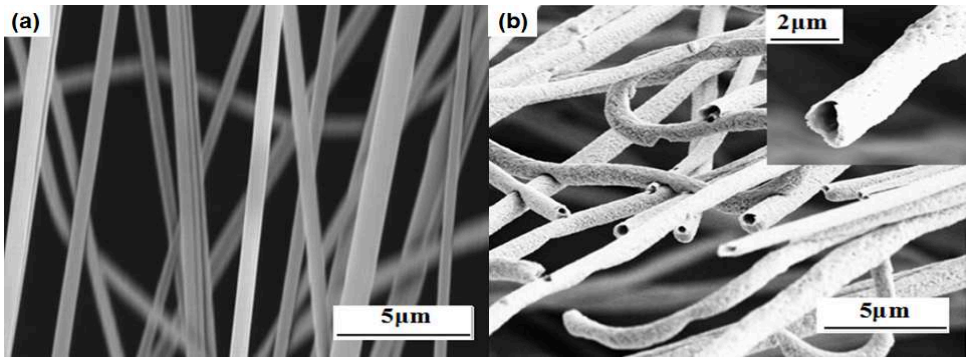

Fig. 1 SEM images of the In_2O_3 microtubes.

Fig. 1 shows the SEM images of the In_2O_3 hollow nanofibers. It is obvious that the pure PVDF nanofibers are very smooth as shown in Fig. 1a. From Fig. 1b, we can see that the PVDF fiber template has been burned out and In_2O_3 microtubes have been formed after calcination under 600^oC. Outer diameter of the tubes is broadly distributed in the range of 700-900 nm, and inner diameter is 400-600 nm. The wall thickness of the microtubes is approximately 50-200 nm. After calcining, the deposited In_2O_3 particles become more compacted.

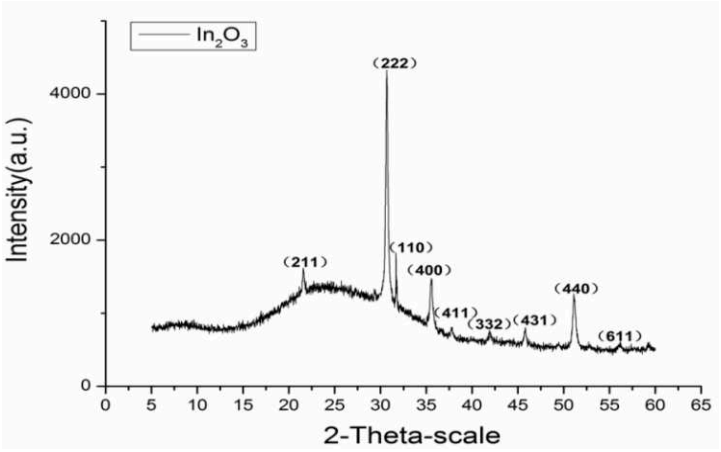

Fig. 2 XRD patterns of the In_2O_3 microtubes.

The crystal structure of the In_2O_3 microtubes after calcining at 600°C was examined by XRD. The XRD patterns prove that the In_2O_3 microtubes have cubic structure with diffraction peaks of (222), (400) and (440). All the diffraction peaks of the sample in Fig. 2 could be indexed to In_2O_3 (JCPDS No. 06-0416). There are no impurity peaks obviously in the XRD patterns, so the sample is In_2O_3 of cubic structure in high purity.

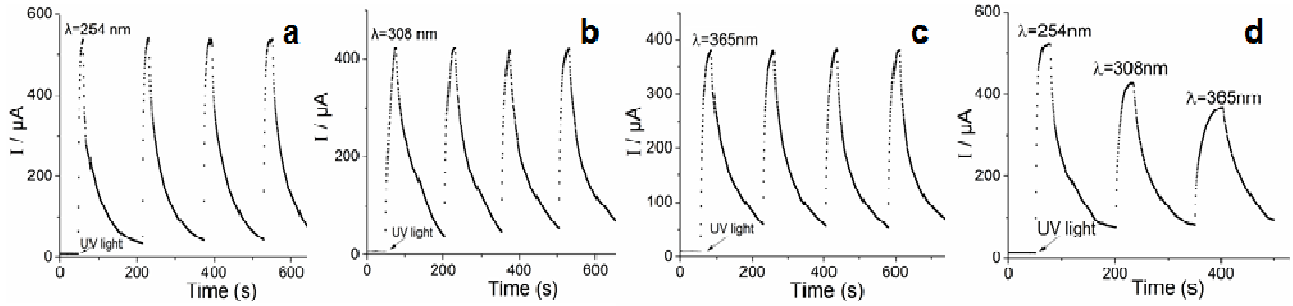

Fig. 3 Photoresponse of the In_2O_3 microtubes under UV illumination with different wavelengths of 254 nm, 308 nm, and 365 nm.

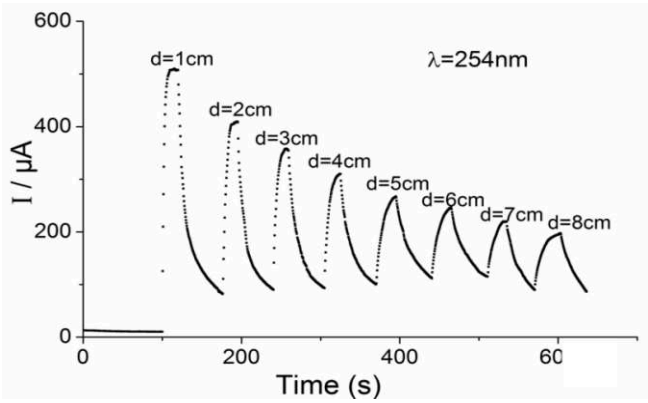

Fig. 4 Photoresponse of the microtubes at different distances from the UV lamp to In_2O_3 tubes.

Figs. 3a-c show the time-dependent photocurrent curves. When the UV light was turned on and turned off periodically and a total of four cycles of data were recorded under UV illumination with different wavelengths when the distance is 1.0 cm. The conductance of the sample was observed to increase rapidly when the UV light was turned on, and it decreased gradually when the UV light was turned off. The sensitivity defined as I_{max}/I_0 is as high as 10^2 and the response time was obtained to be less than 10 s. Fig. 3d shows the photoresponse and *I-V* characteristic curves of the

microtubes exposed to sequential UV illumination with different wavelengths of 254, 308 and 365 nm. The photocurrents increase from initial current (background current under bias of 5.0 V) 5.2 μA to 523 μA, 427 μA and 367 μA under UV illumination with wavelengths of 254 nm, 308 nm and 365 nm, respectively.

Fig. 4 shows the response of the In_2O_3 microtubes at different distances from the UV lamp to electrode under the same UV light of 254 nm. From this figure, we can observe that the sensitivity is decreased with the distance increasing. Furthermore, the decrease trend slows down with increasing distance. While the distance was 1.0 cm, the current could be brought to 508 μA from background current of 5.2 μA. But while the distance was 8 cm, the current only could be brought to 196 μA with the reason that the number of photon which can excite electrons directly from the valence band to the conduction band is less, leading to the lower sensitivity. But compared with the initial current without UV irradiation, the photocurrent has increased greatly.

Conclusion

In_2O_3 microtubes were successfully synthesized by a new method combined electrospinning with magnetron sputtering and calcination. From the SEM images, we could observe the hollow structures clearly. We have investigated photoresponse of the In_2O_3 tubes under UV illumination with different wavelengths and found that the In_2O_3 microtube device could enhance the conduction significantly when exposed to UV light. We also studied the relationship between the distance and sensitivity. Further study on gas sensing property of these electrospun In_2O_3 microtubes is now in progress.

Keywords: One-dimensional hexagonal piezoelectric quasicrystals, Crack, Elliptical hole, SIFs, EDIFs, Complex variable function method, Conformal mapping

Abstract. Using the complex variable function method and the technique of conformal mapping, the fracture mechanics of two symmetric collinear cracks originating from an elliptical hole in a one-dimensional (1D) hexagonal piezoelectric quasicrystals (QCs) are investigated under anti-plane sh-ear loading and electric loading. The crack is assumed to be either electrical impermeable or perme-able. The exact solutions in closed-form of the stress intensity factors (SIFs) of the phonon field andthe phason field, and the electric displacement intensity factors (EDIFs) are obtained. In the limiting cases, the new results such as Griffith crack, a circular hole with equal two edge cracks and cross crack can be obtained from the present solutions. In the absence of the phason field, the obtainable results in this paper match with the classical results.

Introduction

Piezoelectric materials generate an electric field when subjected to strain fields and undergo deformation when an electric field is applied. This inherent electromechanical coupling is widely exploited in the design of many devices like transducers, sensors and actuators[1,2].

D.Shechtman was awarded the Nobel Prize of Chemistry 2011 due to the discovery of QCs in 1984, which has aroused the great interest on the structure and material again[3]. The theoretical frame of QCs comes from physical research which has been done by some researchers[4]. Experim-ents have shown that QCs are quite brittle[5] and the defects of quasicrystalline materials have been observed[6]. It is well known that the presence of defects such as holes and cracks, greatly affects the physical and mechanical properties of solid materials including QCs. Therefore, the study of crack problem of quasicrystalline materials is meaningful both in theoretical and practical applications. Fan[7] presented the mathematical theory of quasicrystalline elasticity. Using this theory, a straight dislocation and a moving screw dislocation in (1D) hexagonal QCs were addressed by Li and his coauthors[8,9]. It is well known that the complex variable method initially developed by Muskh elishvili is an effective method for solving elasticity and defect problems[10]. Therefore, some workers developed the complex variable method to solve defect problems of quasicrystals. For 1D hexagonal QCs many efforts have been made in the fields of the mechanic involving the elasticity and defects by the complex variable method[11-15]. The collinear periodic cracks and/or rigid line inclusions of antiplane mode in 1D hexagonal QCs have been studied[16].

But the paper mentioned before discussed various elasticity and defect problems of QCs. To our knowledge, the study of QCs functional aspects is very little, especially the study of QCs piezo-electric properties. Therefore, the present paper is devoted to investigating the elastic problem

of an elliptical hole with two symmetric collinear cracks in a 1D hexagonal piezoelectric QCs by means of complex variable function method with conformal mapping. Two kinds of crack surface conditions, i.e. electrical impermeable and electrical permeable are adopted. The exact solutions of SIFs for the phonon field and the phason field, and the EDIFs are obtained respectively, which are useful in practice.

Basic Theory

The generalized Hooke's law of 1D hexagonal piezoelectric quasicrystal, whose period plane is the (x_1, x_2) -plane and whose quasiperiodic direction is the x_3 -axis, is given by[13]

$$\begin{aligned}
&\sigma_{11} = C_{11}\varepsilon_{11} + C_{12}\varepsilon_{22} + C_{13}\varepsilon_{33} + R_1\omega_3 - e_{31}^1 E_3,\\
&\sigma_{22} = C_{12}\varepsilon_{11} + C_{22}\varepsilon_{22} + C_{13}\varepsilon_{33} + R_1\omega_3 - e_{31}^1 E_3,\\
&\sigma_{33} = C_{13}\varepsilon_{11} + C_{13}\varepsilon_{22} + C_{33}\varepsilon_{33} + R_2\omega_3 - e_{33}^1 E_3,\\
&\sigma_{23} = \sigma_{32} = 2C_{44}\varepsilon_{31} + R_3\omega_2 - e_{15}^1 E_2,\\
&\sigma_{13} = \sigma_{31} = 2C_{44}\varepsilon_{31} + R_3\omega_1 - e_{15}^1 E_1, \sigma_{12} = \sigma_{21} = 2C_{66}\varepsilon_{12},\\
&H_3 = R_1(\varepsilon_{11} + \varepsilon_{22}) + R_2\varepsilon_{33} + k_1\omega_3 - e_{33}^2 E_3,\\
&H_1 = 2R_3\varepsilon_{31} + k_2\omega_1 - e_{15}^2 E_1, H_2 = 2R_3\varepsilon_{32} + k_2\omega_2 - e_{15}^2 E_2,\\
&D_3 = e_{31}^1(\varepsilon_{11} + \varepsilon_{22}) + e_{33}^1\varepsilon_{33} + e_{33}^2\omega_3 + \in_{33} E_3,\\
&D_1 = 2e_{15}^1\varepsilon_{31} + e_{15}^2\omega_1 + \in_{11} E_1, D_2 = 2e_{15}^1\varepsilon_{32} + e_{15}^2\omega_2 + \in_{11} E_2.
\end{aligned} \tag{1}$$

where $\sigma_{ij}, H_j (i, j = 1,2,3)$ are the phonon and phason stress components; $E_j, D_j (j = 1,2,3)$ are the electric fields and the electric misplacement; $\varepsilon_{ij}, \omega_j (i, j = 1,2,3)$ are the phonon and phason strains; k_1, k_2 are two elastic constants in the phason field; $R_i (i = 1,2,3)$ are three phonon-phason coupling elastic constants; $C_{11}, C_{12}, C_{13}, C_{33}, C_{44}, C_{66}$ are six elastic constants in the phonon field and $C_{66} = \dfrac{C_{11} - C_{12}}{2}$; $e_{ij}^1, e_{ij}^2 (i = 1,3,\ j = 1,3,5)$ are piezoelectric coefficients; $\in_{11}, \in_{33}$ are two dielectric coefficients.

The strain–displacement and electric field–electric potential relations are given by

$$\varepsilon_{ij} = \frac{1}{2}(\partial_j u_i + \partial_i u_j), \omega_j = \partial_j \omega, E_j = -\partial_j \phi, (i, j = 1,2,3) \tag{2}$$

Where $u_i (i = 1,2,3)$ are phonon displacement components, ω_3 is the phason displacement, ϕ is the electric potential. we have used the tensor notation and $\partial_j u_i = \dfrac{\partial u_i}{\partial u_j}$, the same hereafter.

In the absence of body force and electric charge density, the equilibrium equations are

$$\begin{aligned}
&\partial_1\sigma_{11} + \partial_2\sigma_{12} + \partial_3\sigma_{13} = 0, \partial_1\sigma_{21} + \partial_2\sigma_{22} + \partial_3\sigma_{23} = 0,\\
&\partial_1\sigma_{31} + \partial_2\sigma_{32} + \partial_3\sigma_{33} = 0, \partial_1 H_1 + \partial_2 H_2 + \partial_3 H_3 = 0,\\
&\partial_1 D_1 + \partial_2 D_2 + \partial_3 D_3 = 0.
\end{aligned} \tag{3}$$

For the anti-plane shear problem in which all field variables are independent of x_3. In this case, we have the following deformation geometrical equations

$$\partial_3 u_i = 0, \partial_3 \omega = 0, \partial_3 \sigma_{ij} = 0, \partial_3 H_i = 0, \partial_3 D_i = 0. \tag{4}$$

Substitution of Eq. (4) into Eqs. (1)-(3) leads to one is a plane elasticity problem of general crystals, which can be solved by the route of linear elastic theory[10]. We do not discuss it here. And the other is an anti-plane phonon-phason coupling elasticity problem as follows

$$\begin{aligned}
&\sigma_{23} = \sigma_{32} = 2C_{44}\varepsilon_{31} + R_3\omega_2 - e_{15}^1 E_2, \sigma_{13} = \sigma_{31} = 2C_{44}\varepsilon_{31} + R_3\omega_1 - e_{15}^1 E_1,\\
&H_1 = 2R_3\varepsilon_{31} + k_2\omega_1 - e_{15}^2 E_1, H_2 = 2R_3\varepsilon_{32} + k_2\omega_2 - e_{15}^2 E_2,\\
&D_1 = 2e_{15}^1\varepsilon_{31} + e_{15}^2\omega_1 + \in_{11} E_1, D_2 = 2e_{15}^1\varepsilon_{32} + e_{15}^2\omega_2 + \in_{11} E_2,\\
&\partial_1\sigma_{31} + \partial_2\sigma_{32} = 0, \partial_1 H_1 + \partial_2 H_2 = 0, \partial_1 D_1 + \partial_2 D_2 = 0,\\
&\varepsilon_{3j} = \varepsilon_{j3} = \frac{1}{2}\partial_j u_3, \omega_j = \partial_j\omega, E_j = -\partial_j\phi. (j = 1,2)
\end{aligned} \tag{5}$$

From Eq. (5), one obtains

$$\begin{aligned}
&C_{44}\nabla^2 u_3 + R_3\nabla^2\omega + e_{15}^1\nabla^2\phi = 0, R_3\nabla^2 u_3 + K_2\nabla^2\omega + e_{15}^2\nabla^2\phi = 0,\\
&e_{15}^1\nabla^2 u_3 + e_{15}^2\nabla^2\omega - \in_{11}\nabla^2\phi = 0.
\end{aligned} \tag{6}$$

where $\nabla^2 = \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2}$ is the two dimensional Laplace operator, under the condition of $\begin{vmatrix} C_{44} & R_3 & e_{15}^1 \\ R_3 & K_2 & e_{15}^2 \\ e_{15}^1 & e_{15}^2 & -\in_{11} \end{vmatrix} \neq 0$, Eq. (6) can be written as

$$\nabla^2 u_3 = 0, \nabla^2\omega = 0, \nabla^2\phi = 0. \tag{7}$$

According to the theory of complex variable function, u_3, ω and ϕ can be represented as the real part and the imaginary part of one analytic function, respectively. We assume that

$$u_3 = \mathrm{Re}\,\varphi_1(z), \omega = \mathrm{Re}\,\varphi_2(z), \phi = \mathrm{Re}\,\varphi_3(z). \tag{8}$$

where $z = x_1 + ix_2, i = \sqrt{-1}$, $\varphi_i(z)(i = 1,2,3)$ are arbitrary analytic functions.

Solution of Elastic Field

Considering a problem about an elliptical hole with two symmetric cracks in a 1D hexagonal piezoelectric QCs. It is assumed that the quasi-periodic direction of 1D hexagonal piezoelectric QCs is along the positive direction of x_3 axis. a and b are the long semi-axes and short semi-axes respectively, $c - a$ is crack length. The solid is subjected to uniform remote anti-plane shear loadings of the phonon field and the phason field, and electric loading at infinity as shown in Fig. 1.

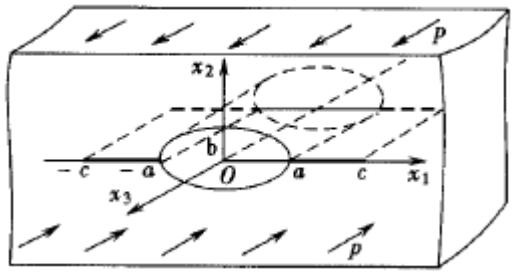

Fig. 1. An elliptical hole with two cracks embedded in 1D hexagonal piezoelectric QCs

Electric Impermeable Problem

By the linear elastic theory, the above problem is equivalent to the surface of cracks is subjected to the shear stress and electric displacement $\sigma_{32} = -p, H_2 = -q, D_2 = -T$, the problem of the electric impermeable boundary condition can be expressed as

$$\begin{aligned}
&\sqrt{x+y} \to \infty : \sigma_{32} = 0, H_2 = 0, D_2 = 0,\\
&(x,y) \in L : \sigma_{32} = -p, H_2 = -q, D_2 = -T.
\end{aligned} \tag{9}$$

where L denotes the boundary of the elliptical hole with four straight cracks.

For electric impermeable problem, we solve the boundary value problems (7) and (9) by using the complex variable function method .

By Eqs. (5) and (8), the stresses and the electric displacements can be written as

$$\begin{aligned}
\sigma_{23} &= \sigma_{32} = -\frac{1}{2i}\Big[C_{44}(\varphi_1' - \overline{\varphi_1'}) + R_3(\varphi_2' - \overline{\varphi_2'}) + e_{15}^1(\varphi_3' - \overline{\varphi_3'})\Big],\\
H_2 &= -\frac{1}{2i}\Big[R_3(\varphi_1' - \overline{\varphi_1'}) + k_2(\varphi_2' - \overline{\varphi_2'}) + e_{15}^2(\varphi_3' - \overline{\varphi_3'})\Big],\\
D_2 &= -\frac{1}{2i}\Big[e_{15}^1(\varphi_1' - \overline{\varphi_1'}) + e_{15}^2(\varphi_2' - \overline{\varphi_2'}) - \in_{11}(\varphi_3' - \overline{\varphi_3'})\Big].
\end{aligned} \tag{10}$$

Substituting Eq. (10) into Eq. (9), we obtain

$$\begin{aligned}
&C_{44}(\varphi_1' - \overline{\varphi_1'}) + R_3(\varphi_2' - \overline{\varphi_2'}) + e_{15}^1(\varphi_3' - \overline{\varphi_3'}) = 2pi,\\
&R_3(\varphi_1' - \overline{\varphi_1'}) + k_2(\varphi_2' - \overline{\varphi_2'}) + e_{15}^2(\varphi_3' - \overline{\varphi_3'}) = 2qi,\\
&e_{15}^1(\varphi_1' - \overline{\varphi_1'}) + e_{15}^2(\varphi_2' - \overline{\varphi_2'}) - \in_{11}(\varphi_3' - \overline{\varphi_3'}) = 2Ti.
\end{aligned} \tag{11}$$

We propose the following conformal mapping

$$\begin{aligned}
z = \omega(\zeta) = \frac{a+b}{2}\frac{2(d^2+1)(1+\zeta^2) + (d^2-1)\sqrt{(1+\zeta)^4 + 2k(1-\zeta^2)^2 + (1-\zeta)^4}}{8d\zeta}\\
+ \frac{a-b}{2}\frac{8d\zeta}{2(d^2+1)(1+\zeta^2) + (d^2-1)\sqrt{(1+\zeta)^4 + 2k(1-\zeta^2)^2 + (1-\zeta)^4}}
\end{aligned} \tag{12}$$

to transform the region at the z plane onto the interior of the unit circle at the ζ plane, where

$$d = \frac{c + \sqrt{c^2 - a^2 + b^2}}{a+b}, \quad k = \frac{d^4 + 6d^2 + 1}{(d^2-1)^2}.$$

Eq. (12) maps the upper edge of a onto A_2, the lower edge of a onto A_1, and $\omega^{-1}(c) \to 1$, $\omega^{-1}(-c) \to -1$, $\omega^{-1}(bi) \to i$, $\omega^{-1}(-bi) \to -i$, as shown in Fig.2.

By means of Eqs. (8) and (12), one has

$$\psi_i(\zeta) = \varphi_i(z) = \varphi_i(w(\zeta)), (i = 1,2,3),\ \varphi_i'(z) = \frac{\psi_i'(\zeta)}{w'(\zeta)}. \tag{13}$$

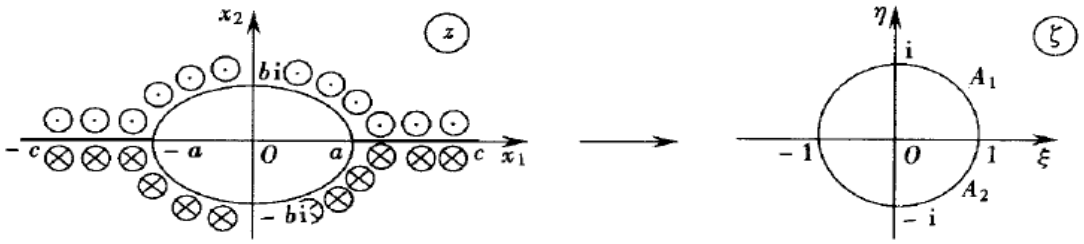

Fig. 2. Conformal mapping from exterior of an elliptical hole with two cracks onto unit disk

Substituting Eq. (13) into Eq. (11), noting that $\zeta = \sigma = e^{i\theta}$, we have

$$\begin{aligned}
&\psi_1'(\sigma) - \frac{w'(\sigma)}{\overline{w}'(\sigma)}\overline{\psi_1'}(\sigma) + \frac{R_3}{C_{44}}\left[\psi_2'(\sigma) - \frac{w'(\sigma)}{\overline{w'}(\sigma)}\overline{\psi_2'}(\sigma)\right] + \frac{e_{15}^1}{C_{44}}\left[\psi_3'(\sigma) - \frac{w'(\sigma)}{\overline{w'}(\sigma)}\overline{\psi_3'}(\sigma)\right] = \frac{2pi}{C_{44}}w'(\sigma),\\
&\frac{R_3}{k_2}\left[\psi_1'(\sigma) - \frac{w'(\sigma)}{\overline{w}'(\sigma)}\overline{\psi_1'}(\sigma)\right] + \left[\psi_2'(\sigma) - \frac{w'(\sigma)}{\overline{w'}(\sigma)}\overline{\psi_2'}(\sigma)\right] + \frac{e_{15}^2}{k_2}\left[\psi_3'(\sigma) - \frac{w'(\sigma)}{\overline{w'}(\sigma)}\overline{\psi_3'}(\sigma)\right] = \frac{2qi}{k_2}w'(\sigma),\\
&\frac{e_{15}^1}{\in_{11}}\left[\psi_1'(\sigma) - \frac{w'(\sigma)}{\overline{w'}(\sigma)}\overline{\psi_1'}(\sigma)\right] + \frac{e_{15}^2}{\in_{11}}\left[\psi_2'(\sigma) - \frac{w'(\sigma)}{\overline{w'}(\sigma)}\overline{\psi_2'}(\sigma)\right] - \left[\psi_3'(\sigma) - \frac{w'(\sigma)}{\overline{w'}(\sigma)}\overline{\psi_3'}(\sigma)\right] = \frac{2Ti}{\in_{11}}w'(\sigma).
\end{aligned} \tag{14}$$

Multiplying both sides of two equations of Eq. (14) by $\frac{1}{2\pi i}\frac{d\sigma}{\sigma - \zeta}$, where ζ is an arbitrary point in $|\zeta| < 1$, and integrating around the unit circle ℓ, we have

$$\begin{aligned}
&\frac{1}{2\pi i}\int_\ell \frac{\psi_1'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_1'}(\sigma)}{\sigma-\zeta}d\sigma+\frac{R_3}{C_{44}}\left[\frac{1}{2\pi i}\int_\ell \frac{\psi_2'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_2'}(\sigma)}{\sigma-\zeta}d\sigma\right]\\
&+\frac{e_{15}^1}{C_{44}}\left[\frac{1}{2\pi i}\int_\ell \frac{\psi_3'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_3'}(\sigma)}{\sigma-\zeta}d\sigma\right]=\frac{2pi}{C_{44}}\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\sigma-\zeta}d\sigma,\\
&\frac{R_3}{k_2}\left[\frac{1}{2\pi i}\int_\ell \frac{\psi_1'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_1'}(\sigma)}{\sigma-\zeta}d\sigma\right]+\left[\frac{1}{2\pi i}\int_\ell \frac{\psi_2'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_2'}(\sigma)}{\sigma-\zeta}d\sigma\right]\\
&+\frac{e_{15}^2}{k_2}\left[\frac{1}{2\pi i}\int_\ell \frac{\psi_3'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_3'}(\sigma)}{\sigma-\zeta}d\sigma\right]=\frac{2qi}{k_2}\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\sigma-\zeta}d\sigma,\\
&\frac{e_{15}^1}{\in_{11}}\left[\frac{1}{2\pi i}\int_\ell \frac{\psi_1'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_1'}(\sigma)}{\sigma-\zeta}d\sigma\right]+\frac{e_{15}^2}{\in_{11}}\left[\frac{1}{2\pi i}\int_\ell \frac{\psi_2'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_2'}(\sigma)}{\sigma-\zeta}d\sigma\right]\\
&-\left[\frac{1}{2\pi i}\int_\ell \frac{\psi_3'(\sigma)}{\sigma-\zeta}d\sigma-\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\frac{\overline{\psi_3'}(\sigma)}{\sigma-\zeta}d\sigma\right]=\frac{2Ti}{\in_{11}}\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\sigma-\zeta}d\sigma.
\end{aligned}\tag{15}$$

We notice that $\psi_i'(\zeta)$ are analytic in $|\zeta|<1$ and continuous in $|\zeta|\le 1$. It follows from the Cauchy's integral formula in complex functions that

$$\frac{1}{2\pi i}\int_\ell \frac{\psi_i'(\sigma)}{\sigma-\zeta}d\sigma=\psi_i'(\zeta),|\zeta|<1 \tag{16}$$

Through derivation of Eq. (12), we have

$$\begin{aligned}
\omega'(\zeta)=(1-\zeta^2)[(d^2+1)+&\frac{(d^2-1)(1+k)(1+\zeta^2)}{\sqrt{(1+\zeta)^4+2k(1-\zeta^2)^2+(1-\zeta)^4}}]\times\{-\frac{a+b}{8d\zeta^2}\\
+&\frac{8d(a-b)}{[2(d^2+1)(1+\zeta^2)+(d^2-1)\sqrt{(1+\zeta)^4+2k(1-\zeta^2)^2+(1-\zeta)^4}]^2}\}
\end{aligned}\tag{17}$$

From Eq. (17), it is not difficult to find that $\omega'(\zeta)$ is analytic in $|\zeta|>1$ and continuous in $|\zeta|\ge 1$. According to the Cauchy's integral formula of infinite region, one finds

$$\frac{1}{2\pi i}\int_\ell \frac{\omega'(\sigma)}{\sigma-\zeta}d\sigma=\omega'(\infty)=\frac{(d^2+1)(a+b)}{4d}\overset{def}{=}F(\zeta) \tag{18}$$

By Eq. (17), one has $\frac{\omega'(\sigma)}{\overline{\omega'(\sigma)}}=-\frac{1}{\sigma^2}$. Since $\psi_i'(\zeta)$ are analytic in $|\zeta|<1$, we can assume that $\psi_i'(\zeta)$ have Taylor series: $\psi_1'(\zeta)=\sum_{n=0}^{\infty}a_n\zeta^n,\psi_2'(\zeta)=\sum_{n=0}^{\infty}b_n\zeta^n,\psi_3'(\zeta)=\sum_{n=0}^{\infty}c_n\zeta^n$.

We notice that $\overline{\psi_i'(\sigma)}$ are regarded as the boundary values (the values on the unit circle ℓ) of $\overline{\psi_1'}(\frac{1}{\zeta})=\sum_{n=0}^{\infty}\overline{a_n}(\frac{1}{\zeta})^n,\overline{\psi_2'}(\frac{1}{\zeta})=\sum_{n=0}^{\infty}\overline{b_n}(\frac{1}{\zeta})^n,\overline{\psi_3'}(\frac{1}{\zeta})=\sum_{n=0}^{\infty}\overline{c_n}(\frac{1}{\zeta})^n$ respectively. Thus, $\frac{\omega'(\sigma)}{\overline{\omega'(\sigma)}}\overline{\psi_i'}(\sigma)$ in Eq. (15) areregarded as the boundary values of $-\frac{1}{\zeta^2}\overline{\psi_i'}(\frac{1}{\zeta})$, which are analytic functions in $|\zeta|>1$. According to the Cauchy's integral formula of infinite region, for $|\zeta|<1$, we have

$$\frac{1}{2\pi i}\int_\ell \frac{w'(\sigma)}{\overline{w'(\sigma)}}\cdot\frac{\overline{\psi_i'}(\sigma)}{\sigma-\zeta}d\sigma=0 \tag{19}$$

Substituting Eqs. (16) and (18)-(19) into Eq. (15), yields

$$\begin{aligned}
&\psi_1'(\zeta)+\frac{R_3}{C_{44}}\psi_2'(\zeta)+\frac{e_{15}^1}{C_{44}}\psi_3'(\zeta)=\frac{2pi}{C_{44}}F(\zeta),\\
&\frac{R_3}{k_2}\psi_1'(\zeta)+\psi_2'(\zeta)+\frac{e_{15}^2}{k_2}\psi_3'(\zeta)=\frac{2qi}{k_2}F(\zeta),\\
&\frac{e_{15}^1}{\in_{11}}\psi_1'(\zeta)+\frac{e_{15}^2}{\in_{11}}\psi_2'(\zeta)-\psi_3'(\zeta)=\frac{2Ti}{\in_{11}}F(\zeta).
\end{aligned} \tag{20}$$

From Eq. (20), one obtains

$$\begin{aligned}
\psi_1'(\zeta)=&2\mathrm{i}\frac{e_{15}^1k_2T+(e_{15}^2)^2p+\in_{11}k_2p-R_3\in_{11}q-R_3e_{15}^2T-e_{15}^1e_{15}^2q}{C_{44}(e_{15}^2)^2-2e_{15}^1e_{15}^2R_3+k_2(e_{15}^1)^2-R_3{}^2\in_{11}+C_{44}\in_{11}k_2}F(\zeta),\\
\psi_2'(\zeta)=&2\mathrm{i}\frac{(e_{15}^1)^2q+C_{44}\in_{11}q-R_3\in_{11}p+C_{44}e_{15}^2T-e_{15}^1e_{15}^2p-e_{15}^1R_3T}{C_{44}(e_{15}^2)^2-2e_{15}^1e_{15}^2R_3+k_2(e_{15}^1)^2-R_3{}^2\in_{11}+C_{44}\in_{11}k_2}F(\zeta),\\
\psi_3'(\zeta)=&2\mathrm{i}\frac{R_3{}^2T+e_{15}^1k_2p-R_3e_{15}^1q-R_3e_{15}^2p+C_{44}e_{15}^2q-C_{44}k_2T}{C_{44}(e_{15}^2)^2-2e_{15}^1e_{15}^2R_3+k_2(e_{15}^1)^2-R_3{}^2\in_{11}+C_{44}\in_{11}k_2}F(\zeta).
\end{aligned} \tag{21}$$

Substituting Eq. (21) into Eq. (13), one has

$$\begin{aligned}
\varphi_1'(z)=&2\mathrm{i}\frac{e_{15}^1k_2T+(e_{15}^2)^2p+\in_{11}k_2p-R_3\in_{11}q-R_3e_{15}^2T-e_{15}^1e_{15}^2q}{C_{44}(e_{15}^2)^2-2e_{15}^1e_{15}^2R_3+k_2(e_{15}^1)^2-R_3{}^2\in_{11}+C_{44}\in_{11}k_2}\frac{F(\zeta)}{\omega'(\zeta)},\\
\varphi_2'(z)=&2\mathrm{i}\frac{(e_{15}^1)^2q+C_{44}\in_{11}q-R_3\in_{11}p+C_{44}e_{15}^2T-e_{15}^1e_{15}^2p-e_{15}^1R_3T}{C_{44}(e_{15}^2)^2-2e_{15}^1e_{15}^2R_3+k_2(e_{15}^1)^2-R_3{}^2\in_{11}+C_{44}\in_{11}k_2}\frac{F(\zeta)}{\omega'(\zeta)},\\
\varphi_3'(z)=&2\mathrm{i}\frac{R_3{}^2T+e_{15}^1k_2p-R_3e_{15}^1q-R_3e_{15}^2p+C_{44}e_{15}^2q-C_{44}k_2T}{C_{44}(e_{15}^2)^2-2e_{15}^1e_{15}^2R_3+k_2(e_{15}^1)^2-R_3{}^2\in_{11}+C_{44}\in_{11}k_2}\frac{F(\zeta)}{\omega'(\zeta)}.
\end{aligned} \tag{22}$$

Substituting Eq. (22) into Eq. (9), we have

$$\sigma_{31}-i\sigma_{32}=2pi\frac{F(\zeta)}{\omega'(\zeta)},H_1-iH_2=2qi\frac{F(\zeta)}{\omega'(\zeta)},D_1-iD_2=2\mathrm{T}i\frac{F(\zeta)}{\omega'(\zeta)}. \tag{23}$$

From Eq. (23), the stresses fields and displacements fields can be determined, we omit them since the complexity of the expressions.

The intensity factors at the crack tip are very useful in practice, the vector of the SIFs of the phonon field and the phason field, and the EDIFs in z plane can be defined as

$$\sigma_{31}-i\sigma_{32}=-\frac{K_{III}^{II}}{\sqrt{2\pi(z-z_1)}},H_1-iH_2=-\frac{K_{III}^{\perp}}{\sqrt{2\pi(z-z_1)}},D_1-iD_2=-\frac{K_{III}^{D}}{\sqrt{2\pi(z-z_1)}}. \tag{24}$$

where $z=re^{i\theta}$, K_{III}^{II}, $K_{III}^{\perp}$ and K_{III}^{D} denote the SIFs of the phonon field and the phason field, and the EDIFs respectively.

Utilizing the conformal mapping $z=\omega(\zeta)$, from Eq. (24), the computational formulae of the SIFs and the EDIFs in ζ plane are obtained as follows

$$K_{III}^{II}=\lim_{\zeta\to1}2\sqrt{\pi}p\frac{F(\zeta)}{\sqrt{\omega''(\zeta)}},K_{III}^{\perp}=\lim_{\zeta\to1}2\sqrt{\pi}q\frac{F(\zeta)}{\sqrt{w''(\zeta)}},K_{III}^{D}=\lim_{\zeta\to1}2\sqrt{\pi}T\frac{F(\zeta)}{\sqrt{\omega''(\zeta)}}. \tag{25}$$

where $\zeta=1$ is the corresponding point of the crack tip $z=c$.

From Eqs. (17) and (18), we have

$$\frac{1}{\sqrt{\omega''(1)}}\to\frac{\sqrt{2d(d^2-1)}}{\sqrt{(d^2+1)[(d^2-1)a+(d^2+1)b]}},\zeta\to1(z\to c) \tag{26}$$

$$F(1)\to\frac{(d^2+1)(a+b)}{4d},\zeta\to1(z\to c) \tag{27}$$

Substituting Eqs. (26) and (27) into Eq. (25), we obtain the SIFs of the phonon and the phason, and the EDIFs for electric impermeable in ζ plane as following, respectively,

$$
\begin{aligned}
K_{III}^{II} &= \lim_{\zeta\to 1} 2\sqrt{\pi}p\frac{F(\zeta)}{\sqrt{\omega''(\zeta)}} = \frac{p(a+b)\sqrt{\pi(d^4-1)}}{\sqrt{2d[(d^2-1)a+(d^2+1)b]}},\\
K_{III}^{\perp} &= \lim_{\zeta\to 1} 2\sqrt{\pi}q\frac{F(\zeta)}{\sqrt{w''(\zeta)}} = \frac{q(a+b)\sqrt{\pi(d^4-1)}}{\sqrt{2d[(d^2-1)a+(d^2+1)b]}},\\
K_{III}^{D} &= \lim_{\zeta\to 1} 2\sqrt{\pi}T\frac{F(\zeta)}{\sqrt{\omega''(\zeta)}} = \frac{T(a+b)\sqrt{\pi(d^4-1)}}{\sqrt{2d[(d^2-1)a+(d^2+1)b]}}.
\end{aligned}
\tag{28}
$$

Electric Permeable Problem

the electric permeable boundary condition can be expressed as

$$
\begin{aligned}
&\sqrt{x_1+x_2}\to\infty : \sigma_{32}=0, H_2=0, D_2=0,\\
&(x_1,x_2)\in L : \sigma_{32}=-p, H_{32}=-q, \phi=\lambda(\text{const ant}).
\end{aligned}
\tag{29}
$$

Similarly, for electric permeable problem, we solve the boundary value problems (7) and (29). Substituting $\phi=\lambda$ into Eqs. (1)-(3), and through derivation, we have

$$
\begin{aligned}
\sigma_{23} &= \sigma_{32} = -\frac{1}{2i}\Big[C_{44}(\varphi_1'-\overline{\varphi_1'})+R_3(\varphi_2'-\overline{\varphi_2'})\Big],\\
H_2 &= -\frac{1}{2i}\Big[R_3(\varphi_1'-\overline{\varphi_1'})+k_2(\varphi_2'-\overline{\varphi_2'})\Big],\\
D_2 &= -\frac{1}{2i}\Big[e_{15}^1(\varphi_1'-\overline{\varphi_1'})+e_{15}^2(\varphi_2'-\overline{\varphi_2'})\Big].
\end{aligned}
\tag{30}
$$

Substituting Eq. (30) into Eq. (29), we obtain

$$
\begin{aligned}
&C_{44}(\varphi_1'-\overline{\varphi_1'})+R_3(\varphi_2'-\overline{\varphi_2'})=2pi,\\
&R_3(\varphi_1'-\overline{\varphi_1'})+k_2(\varphi_2'-\overline{\varphi_2'})=2qi,\\
&e_{15}^1(\varphi_1'-\overline{\varphi_1'})+e_{15}^2(\varphi_2'-\overline{\varphi_2'})=-\frac{(e_{15}^1k_2-e_{15}^2R_3)p+(e_{15}^2C_{44}-e_{15}^1R_3)q}{C_{44}k_2-{R_3}^2}.
\end{aligned}
\tag{31}
$$

Similar to the electric permeable derivation process, we have

$$
\psi_1'(\zeta)=2\mathrm{i}\frac{k_2p-R_3q}{C_{44}k_2-{R_3}^2}F(\zeta), \psi_2'(\zeta)=2\mathrm{i}\frac{C_{44}q-R_3p}{C_{44}k_2-{R_3}^2}F(\zeta).
\tag{32}
$$

According to Eqs. (13), (30) and (32), the expression of the SIFs and the EDIFs can be determined in z plane.

The SIFs of phonon and phason fields, and the EDIFs for electric permeable can be obtained in ζ plane as follows

$$
\begin{aligned}
K_{III}^{II} &= \lim_{\zeta\to 1} 2\sqrt{\pi}p\frac{F(\zeta)}{\sqrt{\omega''(\zeta)}} = \frac{p(a+b)\sqrt{\pi(d^4-1)}}{\sqrt{2d[(d^2-1)a+(d^2+1)b]}},\\
K_{III}^{\perp} &= \lim_{\zeta\to 1} 2\sqrt{\pi}q\frac{F(\zeta)}{\sqrt{w''(\zeta)}} = \frac{q(a+b)\sqrt{\pi(d^4-1)}}{\sqrt{2d[(d^2-1)a+(d^2+1)b]}},\\
K_{III}^{D} &= \lim_{\zeta\to 1} 2\sqrt{\pi}\frac{(e_{15}^1k_2-e_{15}^2R_3)p+(e_{15}^2C_{44}-e_{15}^1R_3)q}{C_{44}k_2-{R_3}^2}\frac{F(\zeta)}{\sqrt{\omega''(\zeta)}}\\
&= \frac{(e_{15}^1k_2-e_{15}^2R_3)p+(e_{15}^2C_{44}-e_{15}^1R_3)q}{C_{44}k_2-{R_3}^2}\frac{T(a+b)\sqrt{\pi(d^4-1)}}{\sqrt{2d[(d^2-1)a+(d^2+1)b]}}.
\end{aligned}
\tag{33}
$$

Discussion and Results

We have obtained the SIFs and the EDIFs of an elliptic hole with two straight cracks in 1D hexagonal piezoelectric QCs above. These results are discussed further as follows

If the long semi-axes b tends to zero, i.e., $b\to 0$, Eq. (28), we obtain

$$
K_{III}^{II} = p\sqrt{\pi c}, K_{III}^{\perp} = q\sqrt{\pi c}, K_{III}^{D} = T\sqrt{\pi c}.
\tag{34}
$$

These are the exact analytic solutions of the SIFs and the EDIFs at the crack tip $(c,0,0)$ of Griffith crack in a 1D hexagonal piezoelectric QCs. In the absence of the EDIFs, the obtainable results are identical to the results in Ref[7].

If the short semi-axes a tends to zero, i.e., $a \to 0$, Eq. (28) leads to

$$K_{III}^{II} = p\sqrt{\pi c}, K_{III}^{\perp} = q\sqrt{\pi c}, K_{III}^{D} = T\sqrt{\pi c}. \tag{35}$$

Eq. (35) gives the exact analytic solutions of the SIFs and the EDIFs at the crack tip $(c,0,0)$ of cross crack in a 1D hexagonal piezoelectric QCs(shown in Fig.3). The results show that if the solid is shear loading and electric loading along the quasiperiodic direction (x_3 direction) at infinity, the SIFs and the EDIFs at the crack tip of the crack parallel to x_1 axis are not affected by the crack parallel to x_2 axis. Because of its symmetry, the results are the same as the state of Griffith crack.

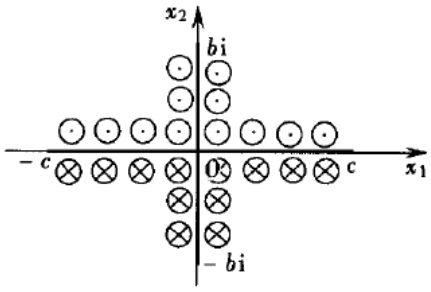

Fig. 3. Asymmetric cross crack.

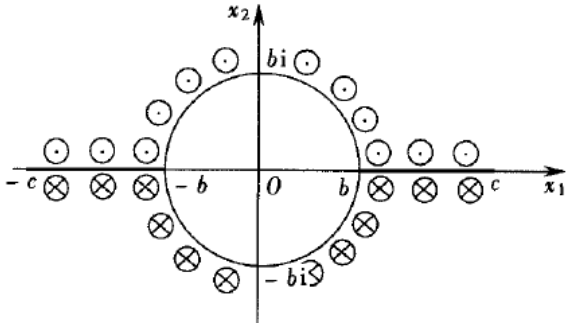

Fig. 4. Circular hole with equal two edge cracks

If $a \to b$, from Eq. (28), we have

$$K_{III}^{II} = p\sqrt{\pi c(1-\frac{b^4}{c^4})}, K_{III}^{\perp} = q\sqrt{\pi c(1-\frac{b^4}{c^4})}, K_{III}^{D} = T\sqrt{\pi c(1-\frac{b^4}{c^4})}. \tag{36}$$

These are the exact analytic solutions of the SIFs and the EDIFs of a circular hole with equal two edge cracks in a 1D hexagonal piezoelectric QCs. Seen from the result, when the circular hole with two straight cracks is the shear loading and electric loading, the SIFs and the EDIFs at the crack tip are not only related to the radius of a circle, but also the crack length.

As far as electric permeable problem, it can make similar discussions.

Conclusions

Under two kinds of the electric impermeable and electrical permeable boundary conditions, the anti-plane shear problem of an elliptical hole with two symmetric collinear cracks in 1D hexagonal pizoelectric QCs is solved by means of complex variable function method with conformal mapping in this paper. The exact solutions of the SIFs for the phonon field and the phason field, and the EDIFs are obtained in closed-form.These solutions are found for the first time in a 1D hexagonal piezoelectric QCs and have significance to the theory of brittle fracture of solids including QCs. As far as the phonon field and the phason field are concerned, these analytic solutions match with the result given in Ref[17]. About the effect of electric load on defect, there are the following two aspects: about the electric impermeable problem, from Eq. (28), it can seen the SIFs and the EDIFs does not occur coupling, and they are affected by crack size, and they have singularity at the crack tip. Electric load did not change the stress field of QCs, the EDIFs is only related to the size of the electrical load, but for strain field, it will change; about the electric permeable problem, from Eq. (33), it can seen the effect of stress and crack size on the SIFs and the EDIFs. The SIFs for the phonon field and the phason field has nothing to do with the material itself. But the EDIFs not only depends on shear loadings of the phonon field and the phason field, but also depends on the properties of the materials, and has no singularity at the crack tip. So, influence of the electric load on defects cannot be ignored, electric load has played an accelerating role in materials fracture. Therefore, this research is necessary.

With the variation of the hole-size and the crack lengths, the present results can be applied to sti-mulate many new crack configurations in practice, such as Griffith crack, cross crack, and circular hole with equal two edge cracks, which are new and useful to theoretical researchers, in particular for the study of QCs. As far as the phonon field is concerned, the special cases of the present results such as Griffith crack and a circular hole with two edge cracks agree well with the classical results[18–19]. In the absence of the phason field, the obtainable results in this paper match with the classical ones[20-21]. By using the conformal mapping technique developed in this paper and the complex variable function method, the complicated defect problem is solved electively, which can analyse similar fracture problems of this kind.

Keywords: CdS, potentiometric electrode, bentonite, sulfide ion, fixed interference method

Abstract: CdS-bentonite was prepared by an *in situ* solid-solid reaction and used as a sulfide ion potentiometric sensor. The electrode responded constant potential in the pH range of 5-10. Selectivity of the electrode was primarily estimated in terms of Nernstian slope. It was found that the electrode could be used to measure sulfide ion in water samples without interfering from Co^{2+}, Mn^{2+}, Zn^{2+}, Hg^{2+}, Cl^{-}, F^{-} or PO_4^{3-}ions. A selectivity coefficient of sulfate over sulfide was determined by using mixed solution method (fixed interference method) which indicated that SO_4^{2-} would be an interfering ion while measuring S^{2-}**,** but could be prevented by conventional precipitation method.

Introduction

Bentonite is a commercial name of a clay mineral which consists of montmorillonite as main composition. Montmorillonite is a layered silicate clay mineral in which an alumina octahedral arrangement situated between two tetrahedral of silica sheet. Substitutions of Al^{3+} within the lattice structure of Si^{4+} in tetrahedral sheet and Mg^{2+} for Al^{3+} in octahedral sheet resulted unbalanced charge in the structural units of bentonite. The charge imbalanced is compensated by exchangeable cation such as Na^{+}, Ca^{2+} and Mg^{2+} in the interlayer spaces. Bentonite has several advantages such as ion exchange property, adsorptive property, swelling behavior and large surface area. [1]

CdS is a bright yellow, sparingly soluble precipitate with a solubility product constant (K_{sp}) about $1x10^{-29}$. It exists in nature in three different crystal forms, hexagonal wurtzite, cubic zinc blend and high pressure rock-salt phase. There are many applications of cadmium sulfide, for examples; semiconductor, solar cell, photodetectors, field effect transistors and electrically driven lasers [2].

A number of bentonite-modified electrodes and electrochemical sensors have been reported [3-7]. In this work, we studied the effect of pH to the activity of CdS- bentonite electrode as well as its selectivity.

Experimental

Chemicals and apparatus

Ca-bentonite from Lopburi province, central Thailand, was provided by Klong Yang Co. Ltd. All other chemicals were analytical grade. Carboxymethyl cellulose (CMC, 3%), polytetrafluoroethylene (PTFE, 60%, DuPont), artificial graphite (Thai carbon and graphite), sodium sulfide flakes (ion free extra pure, Na_2S, loba chemie) cadmium chloride ($CdCl_2$, Univar), hydrochloric acid (6M HCl, Carlo Erba), silver nitrate ($AgNO_3$, Carlo Erba), mercuric nitrate, ($Hg(NO_3)_2.H_2O$ Carlo Erba), cobalt chloride, ($CoCl_2.6H_2O$, Univar) manganese chloride, ($MnCl_2.4H_2O$, Univar), zinc sulphate, ($ZnSO_4.7H_2O$, Univar), potassium fluoride, (KF, Unilab), potassium chloride, (KCl, Univar). Ion meter (ORION, 420A) was used to measure potential of the solution. Silver-silver chloride electrode was used as a reference electrode. The amount of Ca(II) and Cd(II) in bentonite was determined by atomic absorption spectrometer (Perkin Elmer, Analyst 800). Preparation of CdS- bentonite and construction of CdS- bentonite potentiometric electrode have been reported in our previous article [8].

The study of pH effect to the activity of CdS-bentonite potentiometric sensor

In order to investigate the appropriate pH range for CdS-bentonite potentiometric sensor, sulfide solutions of 0.001 and 0.01 M were prepared and adjusted to pH 2-12 with HNO_3 and NaOH (0.001-1 M). Potential of each sulfide solution was measured by using CdS-bentonite electrode. Then, the measured potentials of each sulfide solution *vs* pH were plotted.

Selectivity of CdS-bentonite potentiometric sensor

Selectivity of the sensor was verified by means of Nernstian slope and a selectivity coefficient was determined by using the mixed solution method or fixed interference method[16]. Selectivity coefficient was determined by the use of Nicolsky equation:

$$E_{AB} = k_A + \frac{S}{Z_A}\log\left(a_A + K_{AB}a_B^{Z_A/Z_B}\right) \quad (1)$$

Where K_{AB} is the selectivity coefficient of the electrode for B over A, k_A is a constant coresponds to that in Nernst Equation for primary ion A, a_B is the fixed concentration of interfering ion B added to each solution of A, S is slope of the calibration curve of primary ion, z_A and z_B are charges of ions A and B, a_A is the activity of the primary ion (used in terms of concentration) at which the electrode responded equally to both ions, which can be estimated by the point at the intercept of extrapolation of linear portion of calibration curve as in Fig.1.

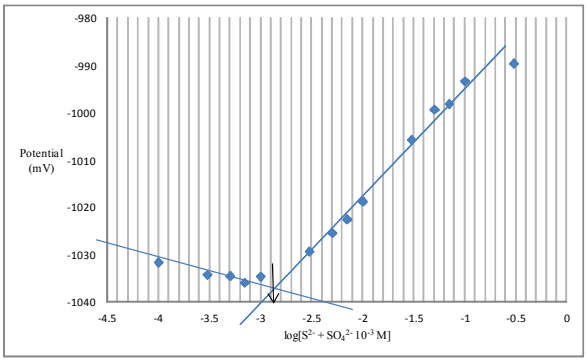

Fig.1 Potential and log $[S^{2-}]$ in the presence of fixed $[SO_4^{2-}]$, showing a_A at the intercept

At the intercept, each ion contributes equally to the potential, then in equation (1), $a_A = K_{AB}.(a_B^{z_A/z_B})$.The selectivity coefficient of the electrode for B over A, is calculated by equation (2):

$$K_{AB} = \frac{a_A}{a_B^{Z_A/Z_B}} \quad (2)$$

Results and discussion

Effect of pH to the activity of CdS-Bentonite potentiometric sensor.

At two sulfide ion concentrations (0.001 and 0.01 M), it was found that, the potential were constant at pH range 5–10, beyond which a potential change was observed as shown in Fig.2. This pH range can be taken as the appropriate working pH of the sensor.

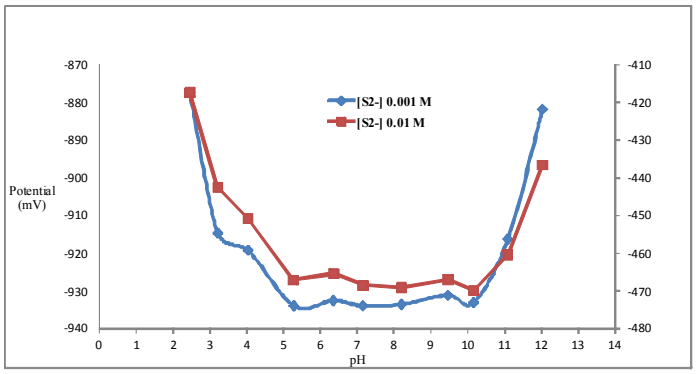

Fig.2. Plot of potential of sulfide ion at different pH

Selectivity of CdS-bentonite potentiometric sensor

When the electrode was used to measure potential of several ions such as Co^{2+}, Mn^{2+}, Zn^{2+}, Cl^{-}, F^{-} PO_4^{3-} and S^{2-}, the electrode gave best response to S^{2-}, in terms of Nernstian slope, as shown in Table 1. Calibration curve of S^{2-} gave good straight line with slope 29.3, closed to theoretical value. While slope of other ions did not fit to Nernstian slope. However, in solutions of Hg^{2+} and $SO_4^{2-}$the slopes were 28.17 and 30.65, respectively.These were only 4.5% and 3.84% far from theoretical value, which indicated that, Hg^{2+} and SO_4^{2-} could be interfering ions when the electrode is used to measure sulfide ion in real water samples.

TABLE 1. SLOPE OF S^{2-} COMPARED WITH OTHER IONS

Ion	S^{2-}	Co^{2+}	Mn^{2+}	Hg^{2+}	Zn^{2+}	Cl^{-}	F^{-}	SO_4^{2-}	PO_4^{3-}
Slope	*29.3*	21.09	20.48	*28.17*	22.17	31.82	30.07	30.65	13.14
Theoretical	29.5	29.5	29.5	29.5	29.5	59	59	29.5	19.65

To verify the interference of Hg^{2+} and SO_4^{2-}over S^{2-}, the selectivity coefficient of electrode was performed by using the mixed solution method (fixed interference method) described above. However, it was found that, the selectivity coefficient of Hg^{2+} over S^{2-} ($K_{S^{2-}Hg^{2+}}$) could not be determined by this method, the solubility of HgS is very low (Solubility Product Constant , K_{sp} = $1.6x10^{-54}$), even at low concentration of Hg^{2+} (about $1x10^{-5}$M) added to S^{2-} solution, precipitate of HgS was formed. The selectivity coefficient of SO_4^{2-}over S^{2-}($K_{AB,}$ A= S^{2-}, B= SO_4^{2-}) was calculated by using equation (2) where a_A at the intercept was $1.26x10^{-3}$M (Fig.1) and the SO_4^{2-} concentration added to S^{2-} (a_B) was $1x10^{-3}$M, and $z_A = z_B = 2$, the calculated K_{AB} was 1.26. In other word, the selectivity coefficient of S^{2-}over SO_4^{2-} (K_{BA}) would be about 0.79. This indicated that SO_4^{2-} ion will interfere the measurement of S^{2-} when the electrode is used to measure S^{2-} ion in real water samples. The selectivity coefficient of SO_4^{2-} is consistent with the measured slope in Table 1. When the electrode is used to measure S^{2-} ion in water samples, interference of SO_4^{2-} ion could be simply prevented by adding $BaCl_2$ to the solution to form white precipitate, $BaSO_4$.

CONCLUSIONS

CdS-bentonite was used to construct a potentiometric electrode to measure S^{2-} in solution. The concentration of response linear range was around $1x\ 10^{-4}$ - 0.3 M of sulfide ion. The appropriate working pH of the electrode was 5-10. Selectivity studies from Nernstian slope

indicated that Co^{2+}, Mn^{2+}, Zn^{2+}, Cl^{-}, F^{-} and PO_4^{3-} would not interfere the measurement of S^{2-}, while Hg^{2+} and SO_4^{2-}could be an interfering ions in terms of Nernstian slope. Nevertheless, since the solubility product constant (K_{sp}) of HgS is very low, in solution containing Hg^{2+} and S^{2-}, the HgS precipitae will be observed and can be filtered off, before performing S^{2-} measurement. The selectivity coefficient of SO_4^{2-}over S^{2-} was 1.26, agreed well with the slope of SO_4^{2-} in the calibration graph of SO_4^{2-} solution which was found closed to that of S^{2-}, which indicates that SO_4^{2-} ion will be an interference while measuring S^{2-} ion in water sample, however this could be simply prevented by adding $BaCl_2$ to precipitate $BaSO_4$ prior to S^{2-} measurement.

Keywords: Shape memory polyurethane, Annealing, Shape memory effect

Abstract: The relationship of annealing and shape memory effect of uniaxially oriented shape memory polyurethane was studied; meanwhile a new method of adjusting shape recovery ratio by annealing was proposed for further consideration. Experiments were designed to compare the influence on length change from annealing and shape memory effect with shape memory polyurethane film at 65°C. We found that for shape memory polyurethane which had residual strain from material processing procedure, annealing and shape memory effect have the same effect on its length change if they are both carried out at the same temperature. It is because annealing and shape memory effect have the same mechanism, which is the change of state from low conformational entropy states to the recovery of a stable high entropy state in the polymer. Moreover, it is proved by experiment that shape recovery ratio of shape memory polyurethane can be adjusted by annealing.

Introduction

Shape memory polymers (SMPs) are polymers with the ability to store and recover strains on the order of several hundred percent when subjected to a particular thermomechanical cycle [1]. Polyurethane (PU) is one of the most important materials in the SMP family. Shape recovery is one of the indexes that people are concerned about for evaluating shape memory effect. In general, SMPs are considered to consist of 'netpoints' and molecular switches. Netpoints are hard segments acting as a fixed phase under a certain thermomechanical cycle, which are assumed as crystalline, glassy domains, chain entanglements or chemical cross-links. The soft segments work as a reversible phase, which actively move as the thermal energy is inputted [2].

Meanwhile, annealing of polymer is a kind of second process wherein the polymer is brought to a certain temperature, kept for a certain time and then cooled to room temperature [3]. Annealing is also one of the ways to modify the material properties of thin films to the preferred properties [4, 5]. For example, the crystallinity of the polymer can be adjusted from annealing, as degree of crystallinity is determined by structural regularity of the polymer. Annealing can decrease the regularity if the polymer has a regular structure, which is obtained from external forces. In contrast, it also could increase the regularity if the initial structure is disordered. There are also some other researchers doing investigation on effects of annealing and thin film thickness [6] or effects of annealing with morphology change [3]. Thus, annealing treatment of shape memory polyurethane (SMPU) and the influence of annealing on shape memory recovery are quite important.

In this study, thermal annealing experiment of SMPU film was carried out to see how annealing affects film length by time. After that, annealing and thermal cycle experiments with different time combination were conducted to discover the relationship between annealing and shape recovery effect of this film. Finally, experiments with precisely controlled annealing time and thermal recovery time from calculation were carried out in order to validate our finding.

Experiments

Uniaxially oriented SMPU film with approximately 50μm thickness was prepared. Raw materials which were thermoplastic polyurethane with glass transition temperature of 55°C (MM5520) were provided by SMP Technologies Inc. For annealing, water bath was used to control the temperature. For thermal cycle, a tensile test machine with heating system imbedded was used and a microscopy was used for recording the length change of the film as seen in Fig.1. Annealing was carried out at 60°C, 65°C and 70°C, for each temperature, 3 repetitions were done to see if the results had good repeatability. Length change of the film was recorded. Curve fitting was done.

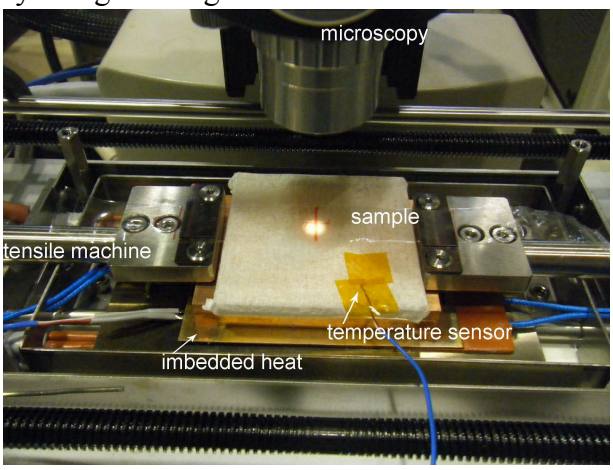

Fig.1 Device for shape memory thermal cycles. The line marked on SMPU film sample is for the ease of measuring the length change by microscopy.

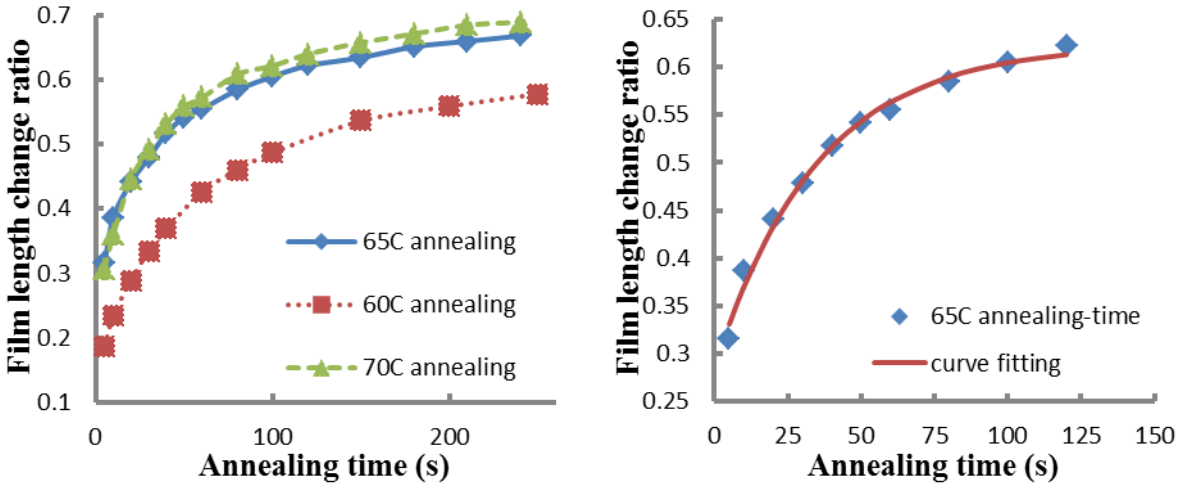

Thermal cycles were done by fixing the film in the tensile machine, followed by increasing temperature to 65°C and keeping there by the imbedded heat. After that, approx. 15(±1) % of elongation was applied to the film. Then temperature was cooled down to room temperature at 27°C within 10min. Shape recovery was carried out at 65°C water bath. 4 samples with different annealing time and shape recovery time were prepared. Table 1 shows annealing time and shape recovery time of these 4 samples. For example, sample No.2 went through a 10s of annealing followed by a thermal cycle with recovery time of 20s. This experiment was repeated three times. After that the relationship of annealing and shape recovery was revealed.

TABLE 1, ANNEALING TIME AND SHAPE RECOVERY TIME OF 4 SAMPLES

Sample number	Annealing time [s]	Elongation ratio in thermal cycle	Shape recovery time [s]
1	/	15%	30
2	10	15%	20
3	20	15%	10
4	30	15%	/

From the curving fitting equation and the relationship of annealing and shape recovery, the time which is needed for a desired length change ratio can be calculated. Annealing and thermal cycle experiments with controlled time that calculated from equation were conducted and results were analyzed.

Results and Discussion

(a) Figure of film length change ratio with respect to annealing time

(b) Curve fitting to length change ratio-annealing curve by least square

Fig. 2 (a) Relationship of film length change ratio and annealing time at 60°C, 65°C, and 70°C. (b) Least square fitting to the curve at 65°C.

Fig.2 (a) shows the relationship of length change ratio and annealing time at three different temperatures. 3 repetitions were done for each temperature. Only the intermediate curve for each temperature is shown here. From this figure, it can be seen that with the increasing of time, length change ratio caused by annealing becomes stable. It is because with the time increasing, residual strain from material manufacturing process decreases. Also it shows that length change ratio differs at different temperatures. Equation from curve fitting for 65°C is as following:

$$y = -0.3379*e^{(-0.0287*t)} + 0.6237 \quad (1)$$

where y is length change ratio, and t is annealing time.

From this equation, length change ratio at any annealing time can be calculated.

Fig.3 shows a total length change ratio of 4 samples described in Table 1. Here length change ratio is defined by the difference between lengths before annealing and after thermal cycle divided by the original length before annealing. From this figure, we can see that no matter it was pure annealing or pure shape memory thermal cycle, or different time combination of annealing and shape recovery, as long as they are the same in total time, the length change ratio is almost the same. This means, for this SMPU, length change from annealing and shape memory effect at the same temperature is the same. This can be understood as follows: annealing is a process that by heating up material, polymer chains relax from the low entropy state created by the stretch from manufacturing, follows by returning to stable high entropy state if annealing time is long enough. Meanwhile, the mechanism of shape memory effect is similar, by stretching at relatively high temperature above the glass transition temperature and cooling down, it temporarily stores energy of low conformational entropy state in molecular chains between crosslinking nodes, when heating above the glass transition temperature, stored strain recovers via an increase in the network free volume, chain rearrangement, and finally the recovery of a stable high entropy state in polymer.

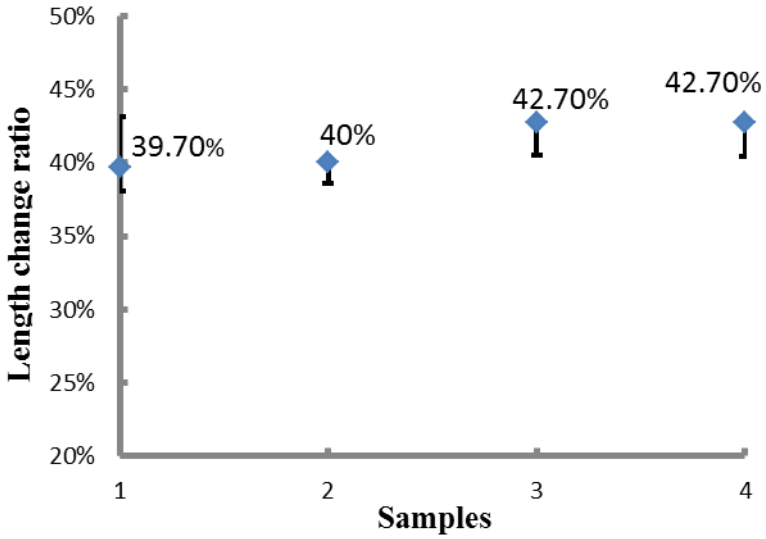

Fig.3 Total length change ratio of 4 samples. The figure shows results from 3 replications of experiment.

From these results, we can assume, it is a feasible and easy way to control the shape recovery ratio of SMP by controlling the annealing level, which is of interest in various parts of fields where SMP is used. Here is an example of controlling shape recovery ratio at 45% by annealing time. 45% shape recovery ratio is equivalent to (1-45%) / (1+15%) length change ratio by pure annealing. With the equation from curving fitting, the time which is needed to have this length change ratio by pure annealing is 41.7s. We performed experiments of 3 samples with a total processing time of 41.7s and length change during the experiments was measured. We can see all 3 samples closely reached to a length change ratio of 45%. This proves that shape recovery ratio of shape memory polyurethane can be designed by annealing.

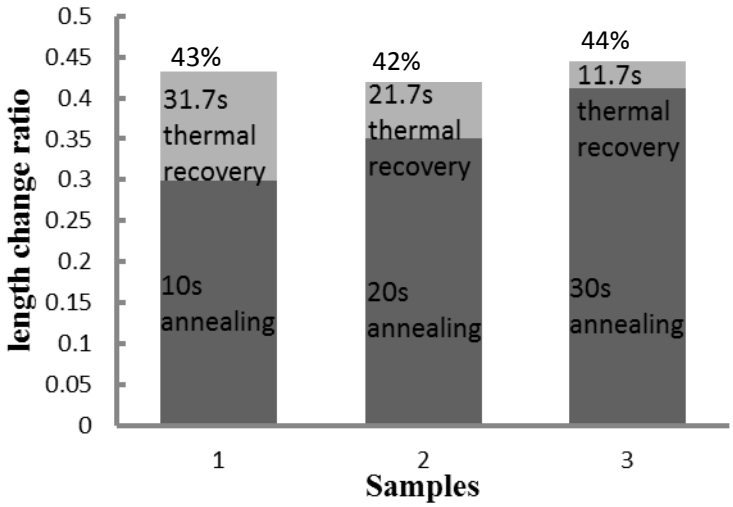

Fig. 4, All three samples with same total annealing time and thermal recovery time reach the designated shape recovery ratio.

Conclusions

(1) We studied length change of SMPU film under annealing at 3 different temperatures. From the results it can be seen that different temperatures lead to different length change ratio at same time interval.

(2) By comparing the length change ratio from annealing and thermal effect of SMPU, we concluded that annealing and shape memory effect had same effect on length change of SMPU.

(3) We also demonstrated that for obtaining a certain length change ratio of SMPU, result is same if the total processing time of annealing and thermal recovery is same as the pure annealing time which is needed for the equivalent effect. Therefore, we conclude that we can control shape recovery ratio of SMPU by adjusting annealing time.

Keywords: α-alumina, precipitation, microspheres, urea, catalyst

Abstract. Uniform α-alumina microspheres with mean partice size about 5-6 μm were prepared by the catalytic precipitation and calcination process. The spherical hydrated alumina precursor was first synthesized by the precipitation using ammonium aluminum sulfate and urea. During the reaction process, the urea can be decomposed to the mediator urease, which acts as the catalyst to influence the precipitate formation. The as-prepared α-alumina microspheres exhibit a very good shaping ability and the green body shaped by the dry-press process has a low linear shrinkage rate 5.8% at the sintering process.

Introduction

Alumina ceramics are widely used for various applications due to their excellent physical and chemical properties [1]. As spherical alumina powders have a high fluidity, low surface energy, leading a high compact density, therefore the preparative process for alumina microspheres has been demanded for technologically.

So far, there are three ways to prepare spherical alumina, such as chemical [2], physical [3,4], and physical-chemical processes [5]. Aman et al [6] employed the aerosol decomposition process at a low temperature to obtain ultrafine spherical alumina powder. Li et al. [2] developed the crystallization-precipitation process and prepared the high purity alumina. The spray-dry process [7,8] could produce spherical alumina on a large scale, but the impurities were difficult to control. In the present work, the uniform α-alumina microspheres were prepared by calcination of the precursor which was synthesized by the precipitation process using urease as the catalyst from starting reagents of ammonium aluminum sulfate and urea.

Experimental

The ammonium aluminum sulfate (AA) was provided by Zhengzhou research institute of CHALCO, and different concentrations of AA solutions (0.8, 1.1 and 1.4 $molL^{-1}$) were prepared by dissolving appropriate amount of AA salts in 800 mL deionized water, under a vigorous magnetic stirring at 75℃, with addition of about 40 g urea into the AA solution. After addition of urea, the white precipitation was observed, and continued to stir the solution for another 0.5 h. Then the suspension was separated with vacuum filtration, and the white precipitate was washed three times by deionized water. The as-prepared precursor was dried at 100℃ for 25 h in a vacuum oven. Finally, the dried precursor was calcined in an electric muffle furnace at 1230℃ for 2 h to form α-phase alumina.

The crystallinity and fraction of α-phase alumina were examined by X-ray diffraction (XRD, Rigaku D/Mmax2500PC diffractometer with Cu-Kα radiation). The particle morphology was investigated by scanning electron microscopy (SEM, JEOL, JSM-6460LV). The particle size distribution was charactized by laser particle analyser (Helos BF, German). The density was examined by powder integrated analyser (BT-1000, Dandong Bettersize Instruments, China).

Results and discussion

Catalytic precipitation

In the catalytic precipitation, there are generally three reactions (eqs(1)- (3)). By this precipitation the amorphous hydrated alumina should be formed, which is confirmed by the XRD analysis showed in Fig.1(a). Similar results were reported by Kara [9].

$$CO(NH_2)_2 + 3H_2O \rightarrow 2NH_3 \cdot H_2O + CO_2 \quad (1)$$

$$NH_3 \cdot H_2O + H_2O \rightarrow NH_4^+ + OH^- \cdot H_2O \quad (2)$$

$$Al^{+3} + 3OH^- \rightarrow Al(OH)_3 \quad (3)$$

According to the above three reactions, the precipitation process is largely influenced by the contents of AA and urease. As observed on SEM morphologies (Fig. 2) of the precursor obtained at different AA concentrations, when the AA solution concentration increasing from 0.8 to 1.1 molL^{-1} the mean particle size reduces from about 6.8 μm to 5.8 μm. With increasing AA concentration, more NH_4^+ ions and less OH^- ions in the solution, resulting in a longer time to form the precipitate. As the value of Al^{3+} and HO^- ions solubility production is possibly lower than *Ksp* at 80℃. The precipitation is a crystallization grown-controlled process. That is to say that increasing AA concentration at a constant urea content will bring about more nuclei and the precipitated particles will be much smaller.

TAB.1 INFLUENCE OF UREASE DOSAGE ON PRECIPITATION

Dosage/mg	0	0.25	0.5	0.75	1.0
Time/h	8	6	5.5	2.5	2.4

It was found out that the observed precipitation time was affacted by the content of urea, which was the resultant product of urea decomposed over 80℃. As observed in Table 1, the effect of urea dosage on the precipitation, with increasing urea concentration the time requirement for the precipitate occurring decreases. It takes about 8 h without using urea and 3.5 h with 1 mg of urea to observe the precipitate occurring respectively. Hence the mediator urease would act as the catalyst, which can in some degree control the precipitation process.

Calcination and characteristics of α-alumina microspheres

When the amorphous hydrated alumina is calcined over 1200℃, the phase can be changed from the amorphous precipitate to γ-phase and α-phase alumina, and this process consists of water removal and phase transformation [10]. To achieve a high α-phase transformation percentage, the calcination temperature is determined to at 1230℃. Fig.1 (b) showes the XRD pattern of the crystalline structure of the resultant alumina calcined at 1230℃ for 2 h. From Fig.1 (b), it can be seen that the diffraction peaks are basically indexed to the α-phase alumina (JCPDS 10-0173) and the estimated the phase transformation percentage is over 95.

Figure 3 showes the α-alumina microspheres morphologies and the corresponding particle size distributions, which are prepared by calcination of the precursors precipitated at different AA concentrations. It can be observed from Fig. 3, these microspheres are uniform, with a standard normal particles size distribution. The mean particle size is 5.6 μm for the specimen obtained at AA concentration of 0.8 molL^{-1} and 5.2 μm for another obtained at 1.1 molL^{-1}, respectively.

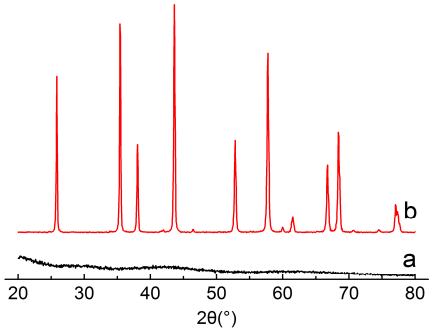

Fig.1 XRD patterns of amorphous precursor (a) and resultant α- Al_2O_3 (b) calcined at 1230℃for 2 h

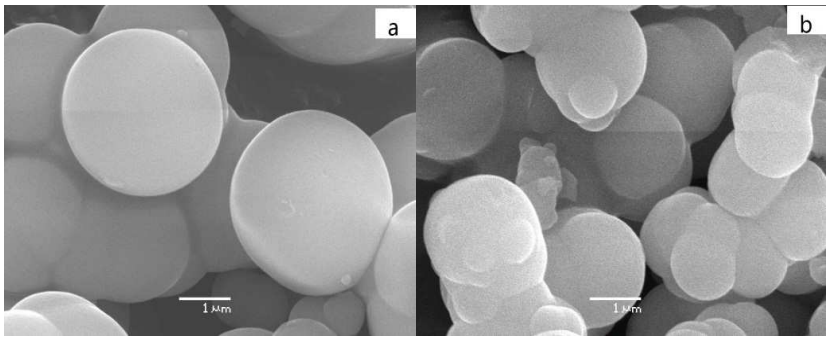

Fig.2 SEM morphologies of precursors prepared at different AA concentrations: （a）0.8 molL^{-1}（b）1.1 molL^{-1}

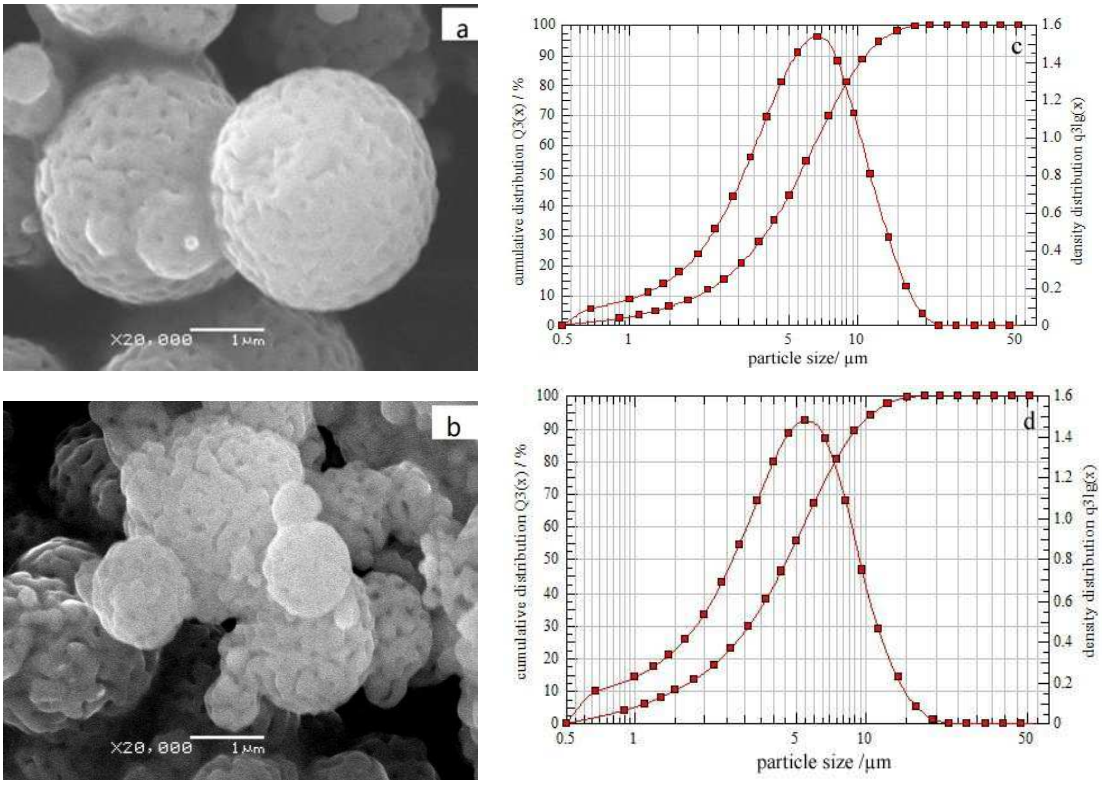

Fig.3 SEM morphologies and particle size distribution of α- Al_2O_3 microspheres by calcination of the precursor obtained at different AA concentrations:（a）and (c) 0.8 molL^{-1},（b）and (d) 1.1 molL^{-1}

In order to evaluate the as-prepared α-Al_2O_3 microspheres sintering property, the as-prepared α-Al_2O_3 microspheres is compared to the powder derived from the process using ammonium aluminum carbonate hydroxide(AACH) as the starting reagent [11]. These two kind of powders are shaped by the dry-press with 5 MPa force. It was found the powder derived from the process with AACH could not be shaped, while for the as-prepared α-Al_2O_3 microspheres the green body exhibits a high strength. Subsequenty, the green body is sintered in an electric muffle furnace at 1500℃for 2 h and the linear shrinkage rate is 5.8%, with a bulk density of 3.0 g/cm^3.

Conclusion

The uniform α-Al_2O_3 microspheres with mean particle size about 5-6 μm have been successfully prepared by calcination of the amorphous hydrated alumina precursor, which was obtained by the precipitation process using aluminum ammonium sulfate and urea as the starting reagents. The precipitation process is largely influenced by the AA concentration and the urease, which is the mediator from the decomposition of urea and act as the catalyst. The as-prepared α-Al_2O_3 microspheres have a very good shaping ability and the resultant green body shaped by the dry-press process has a lower shrinkage at the sintering process, with a ceramic bulk density of 3.0 g/cm^3.

Phase Structure and Piezoelectric Properties of $(K_{0.5}Nb_{0.5})NbO_3$ - $CaZrO_3$ Ceramics

Myoung Pyo Chun

Keywords: KNN, $CaZrO_3$, Phase transition, Lattice parameter, Piezoelectric constant.

Abstract. Lead-free piezoelectric ceramics of $(1-x)(K_{0.5}Na_{0.5})NbO_3$ - $xCaZrO_3$ (abbreviated as KNN-CZ, x = 0 ~ 0.04) were synthesized by the conventional solid state method. Their phase structures and piezoelectric properties were investigated with x-ray diffraction (XRD), Scanning Electron Microscope (SEM), d_{33} meter and Impedance Analyzer. KNN-CZ samples exhibit only pure perovskite phases with a small monoclinic distortion. It was observed that the lattice parameter b has a maximum at x = 0.02 but the monoclinic distortion angle β shows a minimum at the same composition. From the dependence of the lattice parameters (a, b, c, β) and cell volume on the content of CZ, it is considered that the intermediate phase transition exists near at x = 0.02. Piezoelectric properties show the maximum value of d33 = 121 pC/N and kp = 0.35 for the sample with x = 0.02, which seems to be due to the co-existence of the two different phases.

Introduction

A variety of piezoelectric elements are increasingly used in electronic apparatuses as electronic technology is being developed. The most widely used piezoelectric ceramics are lead-oxide-based ferroelectrics (PZT) [1-3]. However, the toxicity of lead oxide and its high vapor pressure during processing have led to a demand for alternative lead-free piezoelectric materials. The search for alternative piezoelectric materials is now focused on alkali niobates (KNN) [4-5] and modified bismuth titanates (BNT) [6-7] based on the perovskite structure. It is well known that the highest piezoelectric performances are obtained for the composition of morphotropic phase boundary (MPB). Two different phases coexisting around MPB can generate more polarization directions and make the polarization switching much easier, which contributes to the highest piezoelectric property. Therefore, searching for new MPB compositions is a promising way to develop lead-free piezoelectric ceramics with highly electrical performances. There are some previous studies on the formation of the phase boundary using various ABO_3 compounds [8-9]. In order to obtain a phase boundary in KNN ceramics, their rhombohedral to orthorhombic transition temperature should be shifted to near room temperature by substituting them with other components [10]. Even though it was reported that the addition of $CaZrO_3$ could shift the TR–O to above room temperature [11], there are few reports on the effect of $CaZrO_3$ on the phase structure and electrical properties of KNN ceramics.

In this work, lead-free piezoelectric ceramics of $(1-x)(K_{0.5}Na_{0.5})NbO_3$ - $xCaZrO_3$ (KNN-CZ, x = 0 ~ 0.04) were fabricated by the conventional solid state method, their phase structures and piezoelectric properties were investigated with X-ray diffraction (XRD), Scanning electron microscopy (SEM). In particular, the possibility of phase boundary in this composition system was studied by analyzing the lattice parameters (a, b, c) and the monoclinic angle (β) as a function of the content of $CaZrO_3$.

Experimental

$(1-x)(K_{0.5}Na_{0.5})NbO_3$ - $xCaZrO_3$ (x = 0 ~ 0.04) powders were synthesized by using the conventional solid state method. The raw materials such as K_2CO_3 (Kojundo Chemical, 99.99%), Na_2CO_3 (Wako Pure Chemical, >99.5%), TiO_2 (Wako Pure Chemical, 99.7%), Nb_2O_5 (Kojundo Chemical, 99.9%), and ZrO_2 (Kojundo Chemical, 99.99%, 99.9%) were weighed and were mixed

for 24 h in ethanol with Zirconia balls of 5φ by wet ball milling. The mixed powders were dried and then calcined at 900°C for 5 h. The calcined powders were uniaxially pressed at 800 kgf/cm^2 using 10 wt. % poly vinyl alcohol (PVA) as a binder to form discs of 10 mm in diameter and 1 mm in thickness. These discs were sintered at 1160°C for 3 h in air. Silver external electrodes were formed by screen printing a silver paste on both sides of a sample and firing at 700°C for 10 minutes. After that, the poling of samples was performed by applying a dc voltage of 2.5 kV/mm to both sides of a sample at 120°C for 30 minutes. Piezolectric constant of d_{33} was measured with d_{33} meter [Piezotest, PM100]. The crystal structures were determined by using X-ray Diffractometer [Mac Science, KFX-987228-SE] with Cu-K_α radiation and the lattice parameters were calculated from the X-ray patterns. The surfaces of the sintered samples were etched thermally and their microstructures were observed with SEM [Topcon, Sm-300]. Raman spectra of samples were measured with Micro Raman spectrophotometer [Jasco, NRS-3100].

Raw Materials	K_2CO_3, Na_2CO_3, Nb_2O_5, $CaCO_3$, ZrO_2
Mixing	Ball milling for 24h at 180 rpm, ZrO_2 ball Φ5, Solvent ethanol
Calcination	900℃x5hour
Binder Mixing	PVA (15% in D.I water) 10wt%
Forming	Disk, Thickness 1mm, Dia. 10mm, 800 kgf/cm^2
Sintering	1160℃, 2hr in air
Termination	Ag-paste, 700℃ x 10 min.
Poling	2.5kV/mm, 30min., 120°C
Aging	24h
Measurement	Microstructure (SEM), Phase Analysis (XRD) Raman Spectroscopy, Piezoelectric Properties(d33)

Result and Discussion

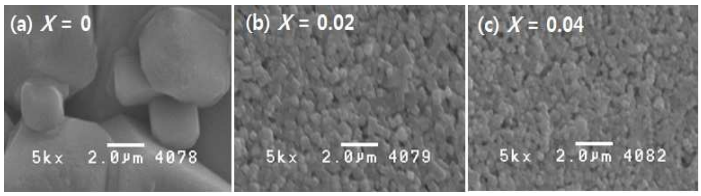

Fig.2. SEM Micrographs of (1- x)KNN - xCZ Samples
Sintered at 1160oC for 3h in Air.

Fig. 2 (a)-(c) show SEM micrographs of (1-x)KNN - xCZ (x = 0 ~ 0.04) samples sintered at 1160°C for 3h in air. Pure KNN reveals a bimodally and abnormally grown microstructure consisting of spherical shaped grains ranging from 2 up to 8um as shown in Fig. 2(a) but samples including small amount of CZ do not exhibit any grain growth except that their microstructures, consisting of uniform sub-micron grains, become more densified with increasing the content of CZ as shown in Fig. 2(b) and (C). The addition of a small of amount of CZ is very effective on inhibiting the grain growth of KNN, which is likely to be because some of CaO and/or ZrO_2 exist in the grain boundary region due to a solubility limit of KNN and hinder the grain growth of KNN. There are many studies that the dopants located near the grain boundary inhibit the grain growth of

$BaTiO_3$ [12-13] and KNN [14]. It was reported in a study of KNN-ZrO_2 ceramics that ZrO_2 inclusions of around 50 nm in size exist at the junctions of the matrix grains and Zirconia is enriched in the grain boundary region in comparison to the grain interior by TEM/EDAX.

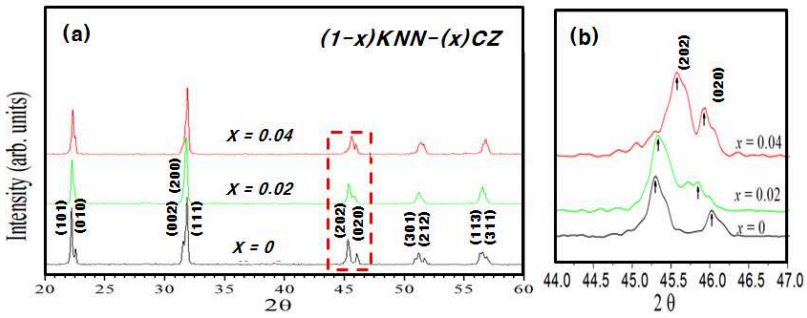

Fig. 3. X-ray Diffraction Patterns of (1-x)KNN - xCZ Samples Sintered at 1160oC in the Range of 2θ (a) from 20o to 60o and 44o to 47o.

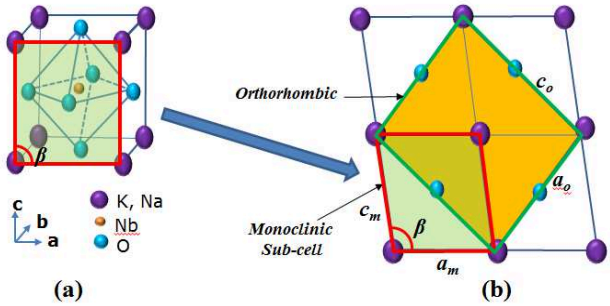

Fig. 4. Schematic Diagram of the KNN Structure at Room Temperature: (a) Perovskite ABO3 Subcell, and (b) Relationship Between the Orthorhombic (ao, co) and the Monoclinic (am, cm, β) Unit Cells.

Fig. 3 (a) and (b) show the XRD patterns of (1-*x*)KNN - *x*CZ samples sintered at 1160°C and are completely in accord with the standard card (JCPDS No. 71-2171) of orthorhombic $KNbO_3$. All the samples exhibit only pure perovskite phases, suggests that Ca^{+2} and Zr^{+4} have diffused into the KNN lattice, with Ca^{+2} entering the $(Na0.5K0.5)^{+1}$ site and Zr^{+4} occupying the B site, to form a homogeneous solid solution. Fig. 1(b) is the magnification of XRD pattern (a) in the 2θ range of 44–47°, which clearly exhibits the peak splitting of (202) and (020) diffraction lines with a separation distance between them decreased with increasing the content of CZ. The crystal structure of samples can be considered as an orthorhombic phase because the intensity of (202) diffraction line is greater than that of (020). The orthorhombic structure can be expressed with the monoclinic one according to the orientation relationship between them as shown in Fig. 4 (a) and (b). The lattice constants (a_m, b_m, c_m, β) of monoclinic unit cell can be calculated by the following equations:

Where the lattice constants a_o, b_o, c_o and β were calculated from the (101), (010), (002), (200), (111), (202), and (020) diffraction lines of Fig. 3(a) and (b).

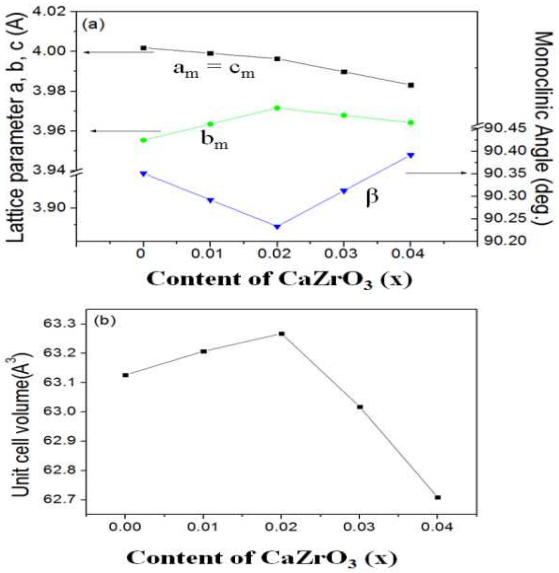

Figure 5(a) and (b) Show the Variations of the Lattice Constants (a, b, c, β) and Monoclinic Sub-cell Volume of (1-x) KNN - x CZ Samples.

Figure 5(a) shows the variations of the lattice constants a_m, b_m, c_m and the monoclinic angles β of (1-x)KNN - xCZ samples. As x increases, the lattice parameters a_m and c_m decrease monotonically but b_m increases at first and has the maximum value at x = 0.02 and then decreases again over x = 0.02. In contrast to b_m, the monoclinic angles β decreases at first and has the minimum value at x = 0.02 and then increases again over x = 0.02. In considering the ionic radius, it is likely that Ca^{+2} (1.34 A) ions incorporate A-site of the ABO_3 perovskite structure consisted of Na^+ (1.39 A) and K^+ (1.64 A) ions and contract its monoclinic sub-cell isotropically to result in a monotonic decrease of the lattice parameters b_m, while Zr^{+4} (0.72 A) ions seem to occupy B-site consisted of Nb^{+5} (0.64 A) ions and expand its sub-cell anisotropically.

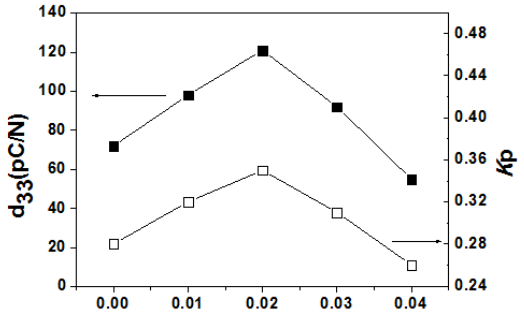

Figure 6 The Composition Dependence of d33 and kp for (1-x) KNN - x CZ Samples.

Figure 5(b) shows the variations of the monoclinic sub-cell volume. As x increases, the sub-cell volume increases at first and has the maximum value at x = 0.02 and then decreases again over x = 0.02. The combined effects between Ca^{+2} (1.34 A) ions contracting the sub-cell and Zr^{+4} (0.72 A) ions expanding its sub-cell seem to give rise to both a maximum b_m and a minium β at x = 0.02.

Fig. 6 Fig. 5 shows the piezoelectric coefficient (d_{33}) and coupling factor (k_p) of all compositions. Both d_{33} and k_p increase firstly with increasing CZ content and reach maximum at x = 0.02, but then decrease rapidly when the CZ content is larger than 0.02. The maximum d_{33} and k_p in x = 0.02 composition are 121 pC/N and 0.35, respectively. These values are comparable with other KNN-based piezoelectric ceramics. The composition dependence of d_{33} and k_p may be attributed to the existence of the intermediate phase transition region near at the composition rage of x = 0.02, which can make the polarization switch more easily and have the highest ferroelectric and piezoelectric

properties as similar results were shown in previous reports [15-16]. It is considered that this study may be contributed to the formation of the phase boundary and enhancing the piezoelectric properties of KNN-based ceramics.

Summary

Lead-free piezoelectric ceramics of (1- x)($K_{0.5}Na_{0.5}$)NbO_3 - $x$$CaZrO_3$ (KNN-CZ, x = 0 ~ 0.04) were fabricated by the conventional solid state method, their phase structures and piezoelectric properties were investigated. The introduction of a small of amount of $CaZrO_3$ is very effective on inhibiting the grain growth of KNN and enhancing its densification. The ceramic with x = 0.02 has the maximum piezoelectric constants of d33 = 121 pC/N and kp = 0.35, which seems to be attributed to the existence of the intermediate phase transition region near at this composition. Our results might be helpful for developing KNN-based piezoelectric ceramics.

Keywords: fiber reinforced ceramic; composite material; thermal conductivity; prediction model

Abstract. The prediction of fiber reinforced ceramic is one of the most important procedure when investigating the application of ceramic composite. Numerical simulations were applied and a novel model was brought out in this paper. Firstly, four different models for predicting thermal conductivities of unidirectional fiber reinforced materials were compared, which include the Rayleigh，LN，ST and TE model,. It shows that Rayleigh model and LN model have good precision only in low fiber volume content cases. There existed big differences between the experimental and numerical results if predicted the high fiber volume content with either these four models. Then a novel model based on LN model was studied with the correction of the representative volume element method. Further comparison results indicate that the error can be reduced as 55.6% with this novel model. At the same time, the longitudinal (k_{11}) and transverse (k_{22}) thermal conductivities predicted by the novel model were also analyzed. It was found that k_{11} had a linear relationship with fiber volume fraction and thermal conductivity ratio (p). But k_{22} had a nonlinear relationship with fiber volume fraction, which increased much greatly when fiber volume fraction increasing at high fiber volume fraction and p>1.

Introduction

There is always a stable need to develop new materials to fulfill requirements of different power equipments, which is more urgent for aero turbine engine because of the high operation temperature. Now the firing temperature in combustion and the inlet temperature of turbine are far beyond the melting point of current single crystal superalloy. A lot of air is extruded from compressor to cool the hot section components such as combustor, guide vane and turbine blade, which may result in distinguished power loss.

The ceramic matrix composites (CMCs) have been studied extensively since the 1960s as one of the most exciting candidate materials for structural gas turbine hot section components. They are well known for the high-temperature resistant, high specific strength and low density. Higher fuel efficiency will be achieved by replacing those metallic hot section components with CMCs due to the reduced coolant demands and increased firing temperature. In the 1980s, SNECMA made nozzles flaps using nD-Cf /SiC(n=2,3) composites named “Sepcarbinox”, which was tested on M53-2 and M88-2 engine. GE and P&W had applied SiCf /SiC composite in combustor liner which can be operating more than 10000h at 1200℃ condition. NASA Glenn Research Center also developed SiCf /SiC turbine blades to decrease the coolant by 15% to 25%. In most cases above, the CMCs were used as insulator to prevent too much heat flux transferred inside and endure the extreme high temperature. It is obvious that the performance of structures with CMCs depends on the thermophysical properties, especially the thermal conductivity. In this paper, thermal conductivity of unidirectional composite which can also be found as element in multi-dimensional composite materials will be discussed.

As for unidirectional fibers composite materials, it can be assumed that fibers are arranged in the microstructure periodically shown in figure 1. So it can be treated as periodically piled structural

unit, which is named RVE (Representative Volume Element) shown in figure 2. The primary important thermal conductivities of composite are in the two principal directions, namely in the directions parallel (k11) and normal (k22) to the fibers. Once these conductivities are known, the conductivities in other directions can be calculated using the transformation matrix [7].

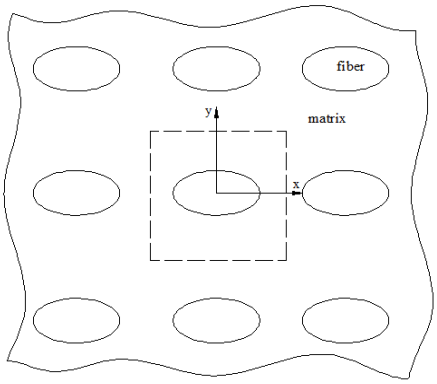

Fig.1 Fiber Arrange Structure

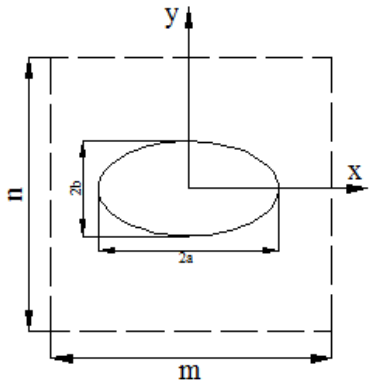

Fig.2 RVE

With reinforcing phases, CMCs form heterogeneous systems with distinct micro-structural geometries. Considering the different thermal conductivities of the constituents and various micro-structural arrangements, it makes predicting effective thermal conductivities (ETC) of composites much more complicated. The effective longitudinal thermal conductivity k11 of a 2D array follows the rule of mixtures exactly [2-4], thus k11 is not the interest of this work. From here on, the discussed effective thermal conductivity is focused on the transverse one.

A number of theoretical, empirical and semi-empirical models have been published in the literatures to describe the transverse thermal conductivity, which include those proposed by Rayleigh, Springer and Tsai [8], Behrens [9], Halpin-Tsai [10], Lewis and Nielsen [11]. The semi-theoretical model developed by Springer and Tsai assumes a square distribution of cylindrical fibers in the matrix material. The estimation of the thermal conductivity in the direction normal to the fibers is based on the analogy between the response of the composite to shear loading and heat transfer. Halpin-Tsai derived a theoretical model for the transverse thermal conductivity using the analogy between in-plane field equation and boundary conditions to the transverse transport coefficients. Lewis and Nielsen modified and adapted the Halpin-Tsai equation for elastic modulus of composite materials to thermal conductivity of particulate-filled composites, which can also be used in unidirectional fiber thermal conductivity prediction by adjusting the parameters. Zou derived analytical expressions based on the thermal-electrical analogy technique for transverse thermal conductivities of unidirectional composites[12].

In recent years more attention has been given to determine properties by using the FEM(Finite Element Method)[6-7]. Islam and Pramila [13] used FEM method to predict the effective transverse thermal conductivity of fiber reinforced composites systematically. Four different boundary conditions representing the periodicity of the temperature field were employed and ideal perfect contact between fiber and matrix was assumed. Lu[18] investigated 2D arrays using FEM, which included the square arrays of long circular/square cylinders and hexagonal arrays of long circular cylinder. Klett [33] used a finite-element model to predict the thermal conductivities of parallel and transverse to the fiber axis C/C composites.. Xia and Guo [20] also investigated the thermal conductivity of composite which had high-conductivity component with a given fraction. Some researchers also brought out some multi-scale methods including the asymptotic expansion homogenization (AEH) scheme, sub-structuring method, and multi-level homogenization scheme. Chung [34] used the AEH method to predict heat conduction in unidirectional FRP composites with temperature dependent thermal conductivity. The equations that govern the heat conductions at the macro and micro scales were solved concurrently. Rodrigo[35] developed a numerical procedure to calculate the effective conductivity of unidirectional fibrous composites with an interfacial thermal resistance between the constituent phases.

Experimental tests have also been conducted to measure the ETC (effective thermal conductivity) of fiber reinforced composites. Pilling et al. [30] measured ETC of unidirectional carbon fiber-

reinforced plastic (FRP) composites in the axial and transverse fiber directions. The tests were conducted between 80 and 270 K. The ETC of the tested composites and the thermal conductivities of the carbon and epoxy constituents are strongly dependent on temperature. Manocha [36] tested unidirectional C/C composites using high-pressure impregnation/carbonization technique with PAN.

Compared with the theoretical, empirical and semi-empirical models, more detailed and micro information can be caught with FEM method based on RVE. More accurate results will be achieved due to these information. But it requires that the microstructure of the composite material has a periodicity distribution and a detailed node description for each micro characteristic, which leads to generate mesh difficultly and a long calculate time. At the same time it is more difficult to define the size and internal geometry characteristics of RVE, especially in the real inhomogeneous composite. Although the theoretical, empirical and semi-empirical models are simple and easy to use, the low accuracy is the fatal disadvantage.

In response to these difficulties in thermal simulation, this paper compared accuracy and applied range of typical theoretical models. Correction was applied to improve accuracy and expand of semi-empirical model with the results concluded from the FEM simulations. Further comparisons were carried out and the improvement of accuracy was demonstrated. Then the novel model was used to estimate thermal conductivity of unidirectional fiber reinforced composite to study the effective thermal conductivity transformation rule with fiber volume fraction and fiber-to-matrix thermal conductivity.

Validation of Theoretical and Empirical Model

For unidirectional fiber composite materials, Prediction of the longitudinal thermal conductivity k11 can be assumed fibers and matrix in parallel and bond together well.

$$k_{11} / k_m = V_f k_f / k_m + V_m \quad . \tag{1}$$

Where k is the thermal conductivity, V is the volume fraction. Subscript f and m represent the fiber and matrix respectively.

Rayleigh equation:

$$\frac{k_{22}}{k_m} = \frac{(p+1)+(p-1)V_f}{(p+1)-(p-1)V_f} \quad . \tag{2}$$

Dimensionless parameter is defined as p=kf /km.

G. S. Springer and S. W. Tsai (ST model) [8] used parallel model method and shear loads comparable method to establish expression for predicting thermal conductivity of unidirectional fiber-reinforced composite.

$$\frac{k_{22}}{k_m} = (1-2\sqrt{V_f/\pi}) + \frac{1}{B}(\pi + \frac{4}{\sqrt{1-\left(B^2 V_f/\pi\right)}}(\tan^{-1}\frac{B\sqrt{V_f/\pi}}{\sqrt{1-B^2 V_f/\pi}} - \tan^{-1}\frac{1+B\sqrt{V_f/\pi}}{\sqrt{1-B^2 V_f/\pi}})) \quad . \tag{3}$$

Here $B = 2\left(k_m / k_f - 1\right)$.

Behrens[9] assumed composite structure is orthogonal symmetric and established the thermal conductivity formula for elliptical fiber reinforced composite in a square arrangement:

$$\frac{k_{22a}}{k_m} = 1 + (p-1)V_f - (p-1)^2 \frac{\sigma - \varepsilon^2/2}{1-\varepsilon^2} \frac{\left(1-\varepsilon^2\right)V_f - \left(\sigma - \varepsilon^2/2\right)}{(p+1)\varepsilon^2/2 - (p-1)\left(V_f - \sigma\right)} \quad . \tag{4a}$$

$$\frac{k_{22b}}{k_m} = 1 + \frac{(p-1)V_f \varepsilon^2}{(p+1)\varepsilon^2/2 - (p-1)\left(V_f - \sigma\right)} \quad . \tag{4b}$$

Here $\sigma = \sqrt{\varepsilon^4/4 + (1-\varepsilon^2)V_f^2}$, parameter ε is the ellipse eccentricity. When ε increases to be 0, the shape of fiber will become circle and the above equation will become fundamental Rayleigh equation.

Halpin-Tsai (HT model) [10] equation:

$$k_{22} = \frac{1+\zeta\eta V_f}{1-\eta V_f} \quad . \tag{5}$$

Here $\eta = (k_f/k_m - 1)/(k_f/k_m + \zeta)$ .For circular and square fiber, $\zeta = 1.0$ and the equation also becomes Rayleigh equation.

Lewis and Nielsen (LN model) [11] added correction term ψ:

$$\frac{k_{22}}{k_m} = \frac{1+ABV_f}{1-B\psi V_f} \quad . \tag{6}$$

Here $B = (k_f/k_m - 1)/(k_f/k_m + A)$, constant A is related to the materials of sharp and orientation. Correction term $\psi = 1 + \left((1-\phi_m)/\phi_m^2\right)V_f$, ϕ_m represent the largest filling fraction, for hexagonal array, quadrilateral array and random array, ϕ_m = 0.907, 0.785, 0.82 respectively.

Zou gave a thermal conductivity expression (TE model) by the thermal-electrical analogy method for elliptical fiber reinforced composite.

$$for \quad |c| > |d| \qquad \frac{k_{22}}{k_m} = 1 - \frac{1}{c} + \frac{\pi}{2d} - \frac{c}{d\sqrt{c^2-d^2}}\cos^{-1}\frac{d}{c} \quad . \tag{7a}$$

$$for \quad |c| < |d| \qquad \frac{k_{22}}{k_m} = 1 - \frac{1}{c} + \frac{\pi}{2d} - \frac{c}{d\sqrt{d^2-c^2}}\ln\left|\frac{d+\sqrt{d^2-c^2}}{c}\right| \quad . \tag{7b}$$

Here $\rho = a/b$, $c = \sqrt{\pi\rho/V_f}/2$, $d = \rho(1/p - 1)$。

In order to compare the accuracy of various theoretical models and indicate the occasion application, this paper selected unidirectional glass fiber reinforced plastic composites as a study target. We assumed that fibers were circular and were arranged in square. According the constituent material properties given in the literature 14, effective thermal conductivities were calculated at kf /km equals to 4.4 and 666 respectively. Rayleigh model, ST model, LN model, TE model and FEM simulation were compared with the experimental values in Figure 3 and figure 4. FEM simulation was performed according to the literature 1.

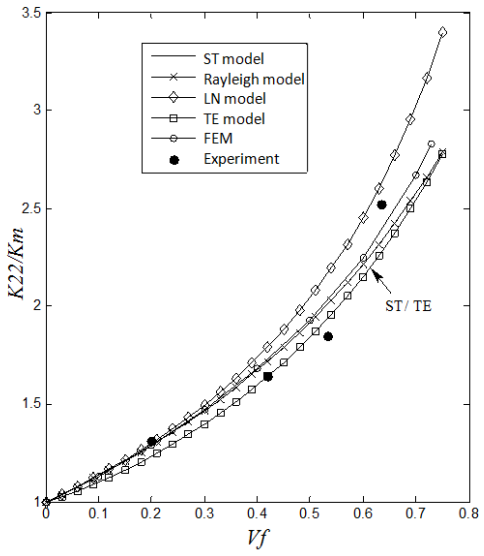

Fig.3 Relationship between Thermal Conductivity and Fiber Volume Fraction(kf /km =4.4)

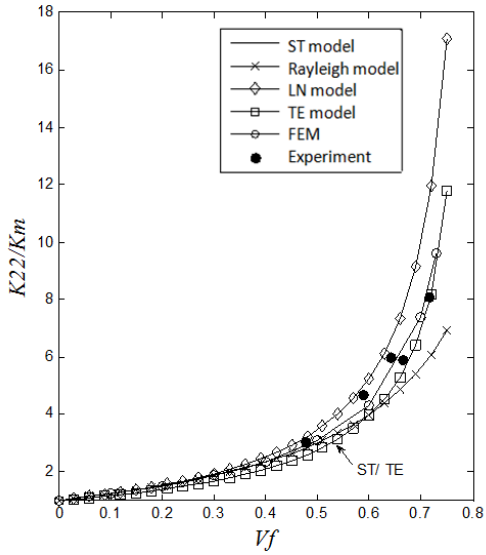

Fig.4 Relationship between Thermal Conductivity and Fiber Volume Fraction(k_f/k_m =666)

Table 1 TABLE OF ERROR

error	ST/ TE	Rayleigh	LN	FEM
kf /km =4.4	0.019	0.018	0.034	0.015
kf /km =666	0.570	1.648	2.796	0.156

The calculation results from four models are more or less in agreement with the experimental values. The effective thermal conductivity increases with the fiber volume fraction increasing, and this growth trend also accelerates when volume fraction is high. Rayleigh model nearly coincides with the NS results, and it is in good agreement with the experimental values at relatively low volume fraction (Vf <0.4). But at high volume fraction, Rayleigh model become less than NS model gradually due to the Rayleigh model ignores the interaction between the fibers. Throughout the whole range of the volume percentage, ST model and TE model thermal coefficient curve is overlapping, but the results are lower than experiment data. TE model consider heat flux flow parallel to the boundary and only calculate the thermal resistance in direction parallel to heat conduction, but in fact there is a small amount of heat flux flowed in a large angle with mainstream (showed in figure 5). It results in thermal resistance is sometimes too large and the equivalent thermal conductivity will be relatively too small. LN model based on the Kerner formula had been improved for particulate reinforced composites at low volume fraction. It also gave A and ϕ_m values to predict the thermal conductivity of unidirectional fiber composites, but from the figures it was found that the calculation results are gradually larger when the volume fraction is relatively high (Vf >0.6)。 Comparatively speaking FEM results are more accurate than the prediction model and more close to the experimental value.

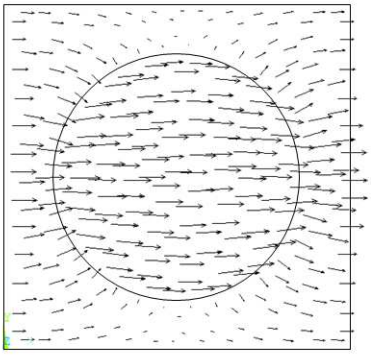

Fig.5 The direction of heat flow in the RVE

Correction Model

LN model increases the prediction accuracy at low fiber volume fraction after introducing the correction term. While at high volume fraction, the predicted data is still too large. Literature 11 proposed three boundary conditions for the correction term ψ to be met.

(1)when $V_f=0$, $\psi V_f=0$;

(2)when $V_f=0$, $\frac{d(\psi V_f)}{dV_f}=1$;

(3)when $V_f=V_m$, $\psi V_f \approx 1$。

The general formula of correction term ψ was considered like this:

$$\psi=1+\left(\frac{1-\phi_m}{\phi_m^{n+1}}\right)V_f^n \quad (8)$$

As the accuracy of numerical simulation is the best, this paper used the results of the numerical simulation at kf /km=10 to obtain the parameter n=4.38.

Besides the literature 14, this article further selected test data from literature 21 to verify accuracy of the proposed LN modified model (LNM model). Figure 6 and Figure 7 show LN model and LN modified model in comparison with the experimental values from literature 14 and 21. These experiment data was tested in one condition that the thermal conductivity of fiber kf is greater than the matrix thermal conductivity km. As it can be seen from figures and table, the revised LN model results are in better agreement with the experimental value and have a small error, the error is reduced by 55.6%.

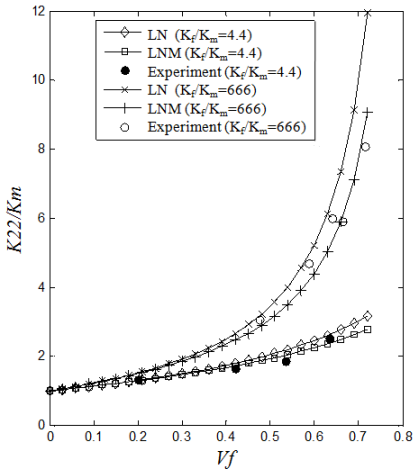

Fig.6 Comparison between LN model and LN correction model with experiment data from literature 14

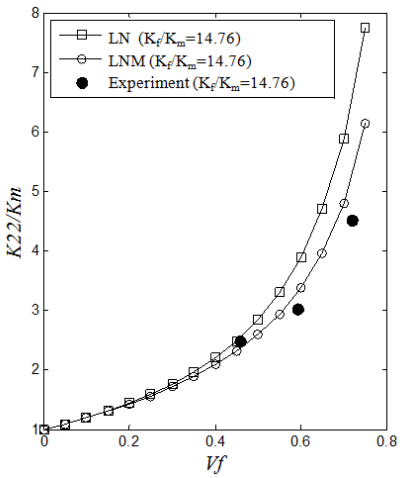

Fig.7 Comparison between LN model and LN correction model with experiment data from literature 21

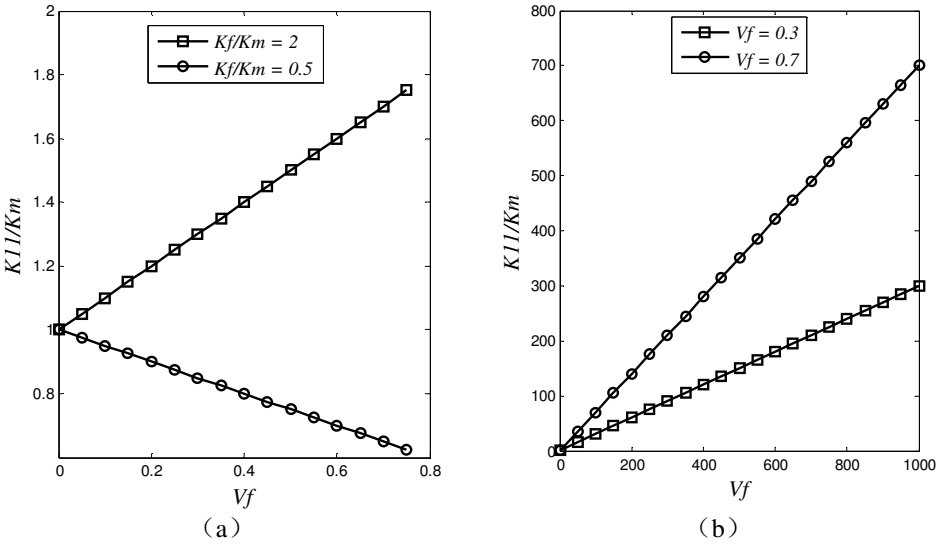
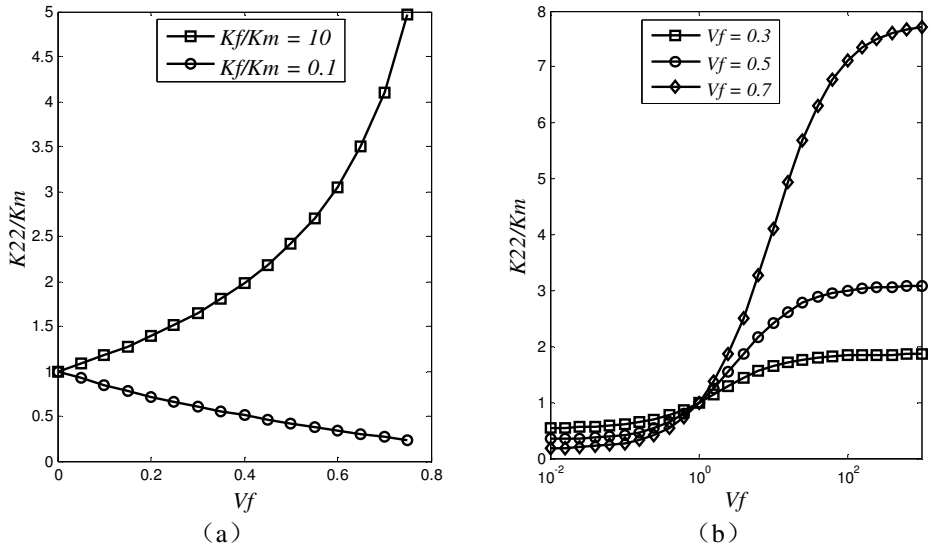
Table 2 TABLE OF ERROR



error	LN	LNM	Error reduction
kf /km =4.4	0.034	0.0151	55.6%
kf /km =666	2.796	0.230	91.7%
kf /km =14.76	1.470	0.203	86.2%

Thermal Conductivity Prediction for Unidirectional Composite

C/C and C/SiC composites are two kinds of typical unidirectional fiber reinforced ceramic matrix composites. C fibers are obviously anisotropic, fiber axis thermal conductivity is about several times or even dozens of times than radial thermal conductivity, C fiber axial thermal conductivity is about 4.7~600. Matrix material can be considered isotropic, as the C matrix microstructure have different effects on thermal properties of the material, the thermal conductivity is about 25~134. The cold isostatic SiC material thermal conductivity was determined between 0.1~0.35 using flash method by Wu QingRen.



On the basis of the LNM model was validated, we further carried out computational analysis on C fiber reinforced composite materials thermal conductivity. Figure 8 and Figure 9 show thermal conductivity variation predicted by modified LN model.

The longitudinal thermal coefficient varied with fiber volume fraction and the thermal conductivity ratio was showed in figure 8. The unidirectional fiber reinforced composite longitudinal thermal conductivity is predicted by the parallel model. From figure 8, it can be seen that the longitudinal thermal conductivity shows a linear relationship with fiber volume fraction and the thermal conductivity ratio, the slopes are kf /km -1 and Vf respectively.

（a） （b）

Fig.8 Relationship between Longitudinal Thermal Conductivity with Vf (a) and kf /km (b)

（a） （b）

Fig.9 Relationship between Transverse Thermal Conductivity with V_f (a) and k_f/k_m (b)

Figure 9 shows the transverse thermal conductivity varied with Vf and kf /km. When kf /km>1, relation curve between transverse thermal conductivity and fiber volume fraction is bullish, that is to say increasing volume fraction at high volume fraction can significantly improve the transverse thermal conductivity. When kf /km <1, transverse thermal conductivity decreases with fiber volume fraction increasing, but the slope changes are not dramatic. From figure 9(b), it can be seen that the transverse thermal conductivity is proportional to the thermal conductivity ratio. But it has limited effect on transverse thermal conductivity, when the thermal conductivity ratio increases (or decreased) to a certain extent, the effective thermal conductivity coefficient tends to be constant.

Summary

The unidirectional fiber reinforced composites transverse thermal conductivity was studied in this paper, ST model, Rayleigh model, TE model, LN model and numerical simulation results were compared with the experimental values. It is found that the calculated effective thermal conductivity from ST model and TE model which ignore smaller portions thermal process is small; LN model prediction results are fit at low volume fraction but larger than experiment data at high volume fraction; Rayleigh model agrees well with the experimental values at low volume fraction while at high volume fraction it has low accuracy.

As for low accuracy of LN model, it was amended based on the numerical simulation results. Amended LN model fits the experimental values well, the error is reduced by 55.6%.

Relationship between longitudinal thermal conductivity and the fiber volume fraction or thermal conductivity ratio was discovered by the parallel model, it is found that the linear slope is kf /km-1 and Vf respectively. Transverse thermal conductivity was predicted by LN modified model, it is shown when kf /km >1 and volume faction is relatively high, increasing the volume fraction can significantly improve the transverse thermal conductivity; the thermal conductivity ratio has limited influence on k22, when the thermal conductivity ratio increases or decreases to a certain extent, the effective thermal conductivity coefficient tends to be constant.

Keywords: mica; fluorapatite; glass-ceramic; crystallization; microstructure

Abstract: The glass system of SiO_2-Al_2O_3-MgO-MgF_2-$SrCO_3$-$CaCO_3$-CaF_2-P_2O_5 was used to prepare machinable glass-ceramics for restorative dental applications. The aim of this study was to apply various heat treatments to produce mica-based glass-ceramics. Differential Thermal Analysis (DTA) was used to determine the optimal heat treatment conditions for nucleation and growth of the crystalline phases in the quenched glass. It was found that the optimum nucleation temperatures for the first and the second crystallization temperatures (T_{p1} and T_{p2}) were 642°C and 635°C, respectively, and the optimum nucleation times were between 2 and 4 hours. X-Ray Diffraction (XRD) showed the phases developed were anorthite, calcium-mica, fluorapatite, strontium apatite, forsterite, fluorite and stishovite phases. The microstructures of glass-ceramics were observed by Scanning electron microscope (SEM), found to exhibit plate-like mica crystals with high interlocking and randomly oriented with a higher soaking temperature and prolongation of the soaking time for crystallization.

Introduction

Ceramics used for implants and for the repair and reconstruction of diseased or damaged body parts are called 'bioceramics', and are used mainly to repair hard tissue such as bones, joints or teeth. Glass-ceramics have the advantage of good control of mechanical properties by heat treatment and are widely used and accepted today in dental applications to meet the patient's need of new, durable and aesthetic materials [1].

As we know, ceramics are brittle, and the quality of the final product is very fabrication technique-sensitive, in terms of strength. Attention has focused on the development of machinable mica-based glass-ceramics because they possess many good properties necessary for restorative dental applications. Mica has excellent machinability. Consequently, mica glass-ceramics can be machined using conventional metallic tools and their machining precision is high. In addition, it is easier to process mica-based glass-ceramics into surgical parts with various complex shapes [2,3]. Fluorapatite improves the biocompatibility for both medical and dental application, since apatite is the mineral phase of tooth and bone. According to the research of Keawsupsak et al., the introduction of not more than 4 mol% fluorapatite into the glass-ceramic system increases both the strength and fracture toughness [4].

Materials and Method

Glass Preparation

The glass system of SiO_2-Al_2O_3-MgO-MgF_2-$SrCO_3$-$CaCO_3$-CaF_2-P_2O_5 was developed [4]. The reagents were mixed and melted in a high density alumina crucible in a furnace (Nabertherm, HT 16/18, Lilienthal, Germany, max. 1,800°C) at 1,400°C for 1 hour. Batch size was approximately 100 g.

The resulting melts were rapidly quenched by pouring directly into water at room temperature to prevent phase separation and crystallization. The glass frit produced was then dried in an industrial

oven (ESPEC, PH-101, Japan). They were then ground and size separated by sieving (Endecotts, England) into fine (smaller than 45μm, powder) and coarse (between 45μm and 2mm) particles. The glass powder was used in the subsequent analysis to determine the optimum nucleation temperature and time. The coarse particles were re-melted at 1400°C. The melt was poured into a carbon mould, preheated to 50°C below their glass transition temperature for 1 hour in order to decrease the stress concentration, and formed transparent glass cylinders approximately 150 mm long by 25 mm diameter. The obtained glass rods were then immediately placed in a purpose-designed furnace (Linn High Therm, LM 512, Eschenfelden, Germany, max. 1,200°C) to anneal for 1 hour and, consequently, to heat-treat for the nucleation and crystallization of the glass-ceramic which was more opaque.

Glass-ceramics Synthesis

Mica-based glass-ceramics are formed by melting and recrystallizing. The recrystallization process must be carefully controlled to create a multiphase solid with crystalline phases dispersed in a glassy matrix. Heat treatment processes were applied in order to transform either glass frit or glass rod to glass-ceramics, according to the following regime [5]: firstly, the temperature was raised from room temperature up to the optimum nucleating temperature and held for the optimum nucleating time (determined from DTA runs). The temperature was then increased to the crystallization temperature plus 20°C (T_p+20°C) and held for different length of time as 1, 3, 6 and 10 hours, respectively. The resultant glass-ceramic was then cooled in the furnace to room temperature (Fig. 1). This process was called the recrystallization process and includes two individual processes, nucleation and crystal growth.

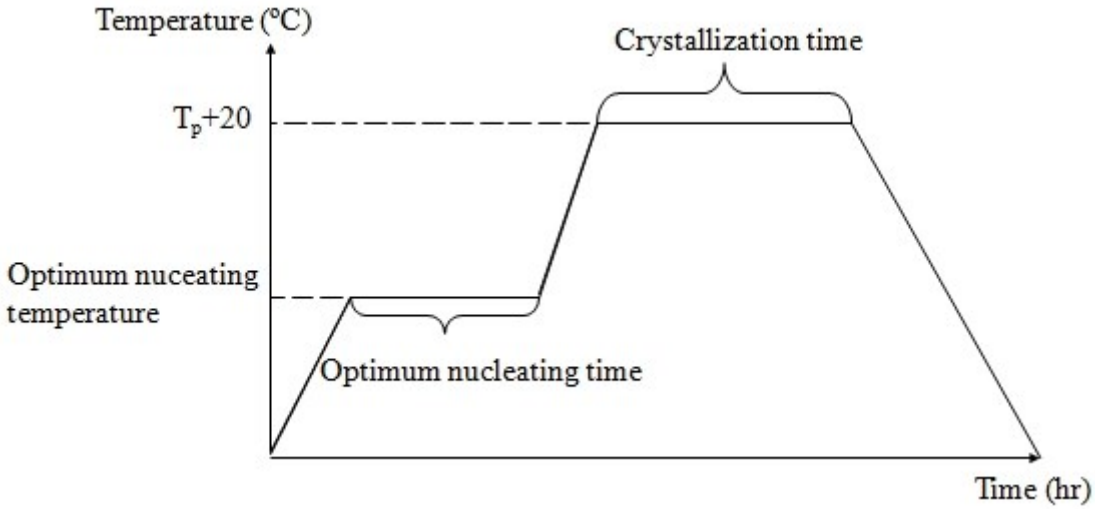

Fig. 1 Schematic of heat treatment process

Characterization Techniques

The differential thermal analysis (DTA) was performed using a Perkin Elmer TAC7/DX (Perkin Elmer, DTA7, Massachusetts, USA) with alumina as the reference material. Both alumina and our glass powder were filled in the platinum crucibles and their weight is 67mg±0.25mg. The program was performed in dry nitrogen at a heating rate of 10°C/min.

X-ray powder diffraction (XRD) analysis was used on both glass and glass-ceramic samples at room temperature. A Philips powder diffractometer (Philips, X'pert PW 3040/00, Eindhoven, The Netherlands) was used with Cu Kα X-rays between 5° and 80°.

The samples were coated by gold sputtering with a vacuum evaporation/deposition method. The microstructures were observed with a scanning electron microscope (Philips, XL30&EDX, The Netherlands).

Results and Discussion

Glass Characterization

The DTA curve of the as-quenched glass powder was 400°C to 1200°C to determine the glass transition (T_g), crystallization (T_p) and melting (T_m) temperatures, as shown in Fig.2. The optimum nucleation temperature and time were determined according to the method of Marotta A. et al. [5].

The glass transition temperature (T_g) was denoted by an endothermic peak at approximately 630℃. The two exothermic peaks, corresponding to T_{p1} and T_{p2} (representing the first crystallization and the second crystallization temperatures), were at 772°C and 878°C respectively. The endothermic peaks above 1,000°C are due to the decomposition, softening and probably melting processes of the different crystalline phases.

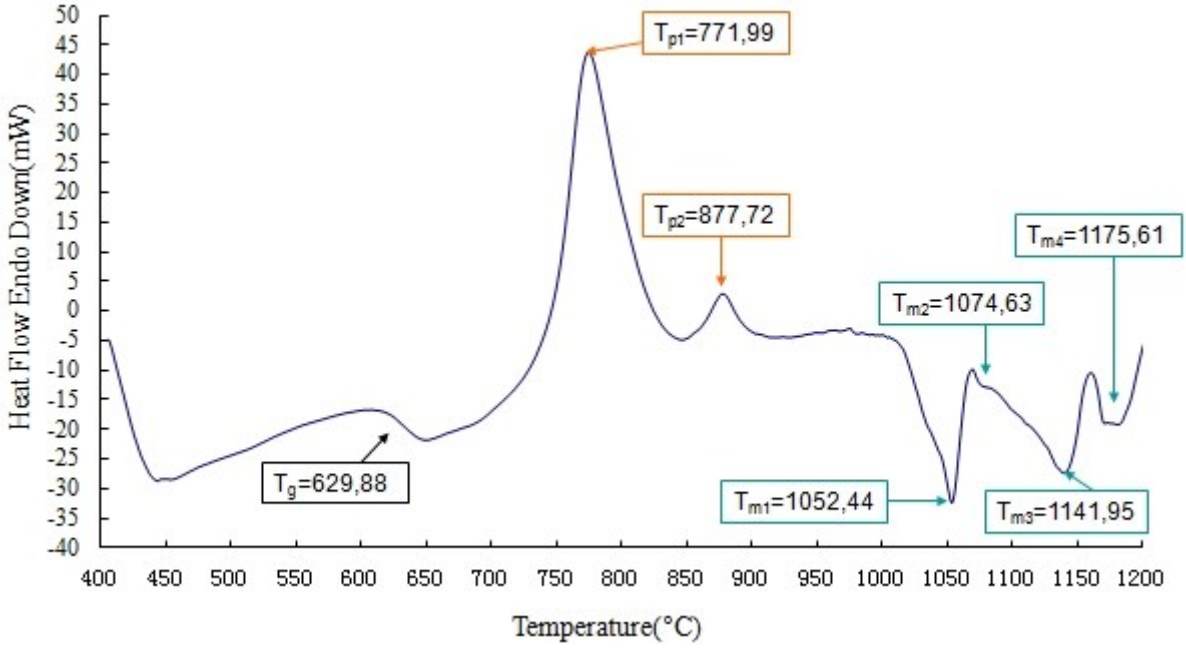

Fig. 2 DTA curve of glass powder

Determination of the optimum nucleation temperature and time of heat treatment

From DTA thermographs, the new crystallization temperatures, T_{p1}*, were determined. T_{p1}*-T_{p1} were plotted against temperatures of heat treatment, namely T_g, T_g-15°C, T_g-30°C, T_g+15°C and T_g+30°C. The point of intersection of tangent lines was 642°C, considered as the optimum nucleating temperature.

The optimum nucleating time was selected by a similar process. The samples were heated from 400°C to the optimum nucleating temperature, namely 642°C and held for 0.5, 1, 3, 4, 8 and 10 hours, respectively. T_{p1}*-T_{p1} were plotted against holding times. The optimum length of time was 2 hours.

The same method done for T_{p1} was used for T_{p2}. Accordingly, the optimum nucleating temperature and time for T_{p2} was 635°C and 2 hours, respectively.

The glass-ceramics were heat treated with different experimental conditions. Table 1 gives the glass codes, heat treatment condition and crystallization time for each sample.

Table 1 Glass codes, heat treatment conditions and crystallization time for subsequent analysis

Sample codes	Heat treatment	Nucleation [^{o}C/ h]	Crystallization [^{o}C/ h]
GCF4_1_1	T_{p1}	642/ 2	792/ 1
GCF4_1_3	T_{p1}	642/ 2	792/ 3
GCF4_1_6	T_{p1}	642/ 2	792/ 6
GCF4_1_10	T_{p1}	642/ 2	792/ 10
GCF4_2_3	T_{p2}	635/ 2	898/ 3
GCF4_2_6	T_{p2}	635/ 2	898/ 6
GCF4_2_10	T_{p2}	635/ 2	898/ 10

X-ray diffraction analysis (XRD)

Calcium-mica ($CaMg_6Al_2Si_6O_{20}F_4$), fluorapatite ($Ca_5(PO_4)_3F$), strontium apatite ($Sr_6Ca_4(PO_4)_6F_2$), forsterite (Mg_2SiO_4), anorthite ($CaAl_2Si_2O_8$), fluorite (CaF_2) and stishovite (SiO_2) phases were found in all heat-treated glass-ceramics. Fig. 3 presents a typical phase evolution for the glass-ceramic powder heat-treated at T_{p1} and held for different soaking time for crystallization. The diffraction peaks became more intensive with increasing crystallization time.

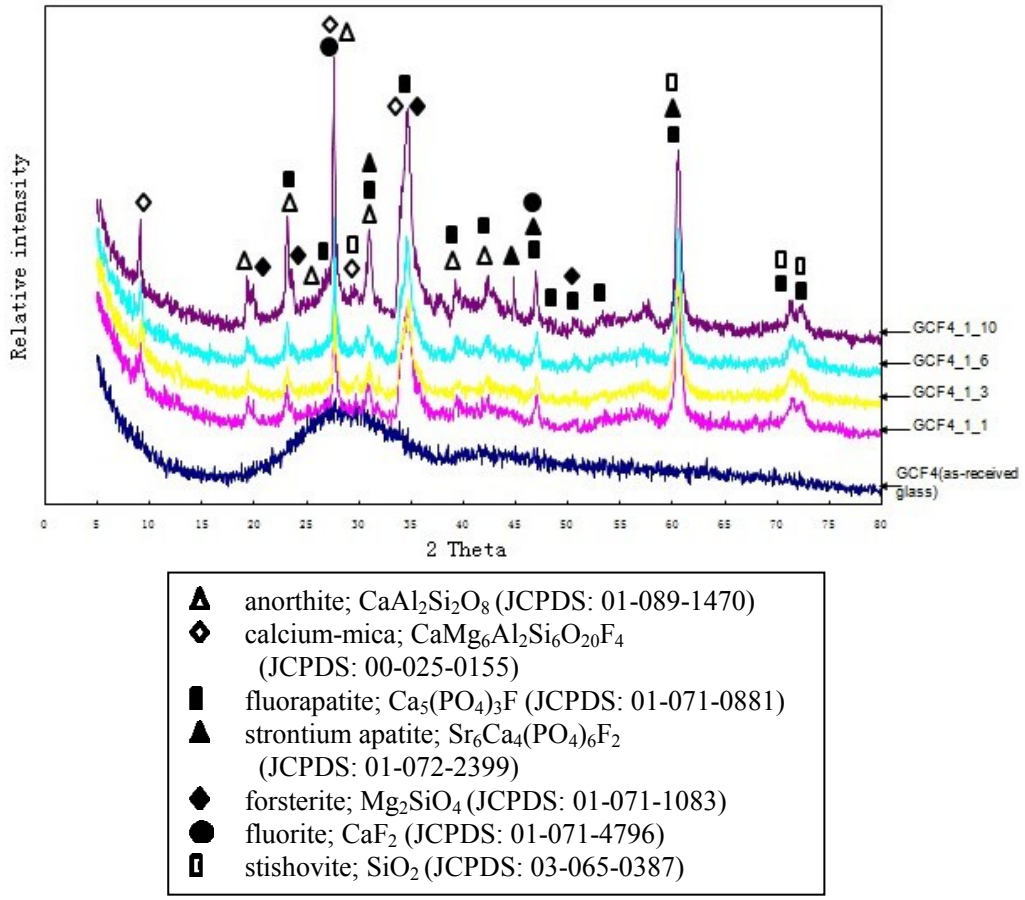

Fig. 3 XRD patterns of as-received glass and T_{p1}-heat-treated glass-ceramics with crystallization time of 1, 3, 6 and 10 hrs.

The change in peak intensity for the glass-ceramics crystallized at T_{p1}+20°C (792°C), GCF4_1_6, and T_{p2}+20°C (898°C), GCF4_2_6, both for 6 hours, are shown in Fig. 4.The main peaks of T_{p2} were more intensive than those of T_{p1} because temperature of T_{p2} was higher than that of T_{p1}. In this case, the bioactivity of glass-ceramics has been developed.

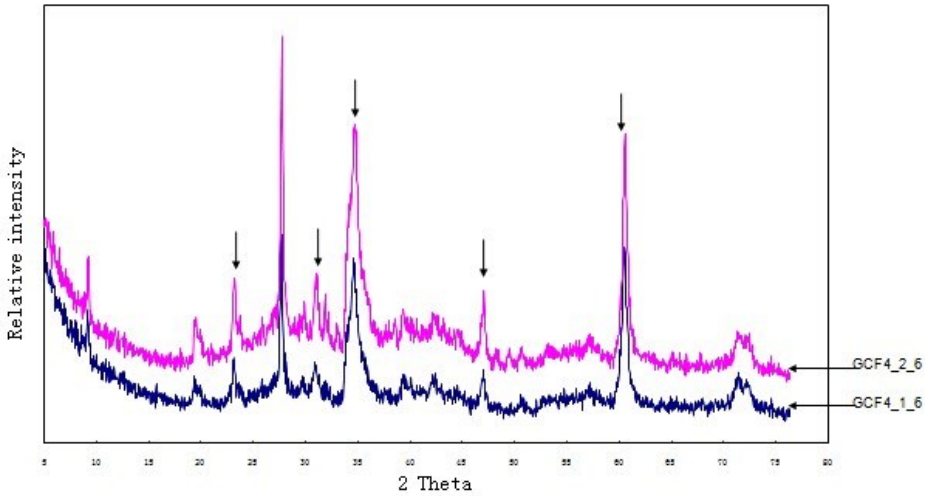

Fig. 4 XRD patterns for glass-ceramics at T_{p1} and T_{p2} for 6 hours crystallization time.

Microstructure analysis

The different heat treatments result in difference in microstructure. Fig. 5 (a) and (b) show the microstructure on fracture surfaces for the specimens heat treated at T_{p1} for 1 and 3 hours. The crystals can hardly be observed when the crystallization time is short. With prolongation of the soaking time for crystallization, the crystals occur and the equiaxed grains increased. Finally, the bulk microstructures consist of plate-like structures, as shown in Fig. 5(c) and Fig. 5(d). The plate-like morphologies indicate to be mica crystals.

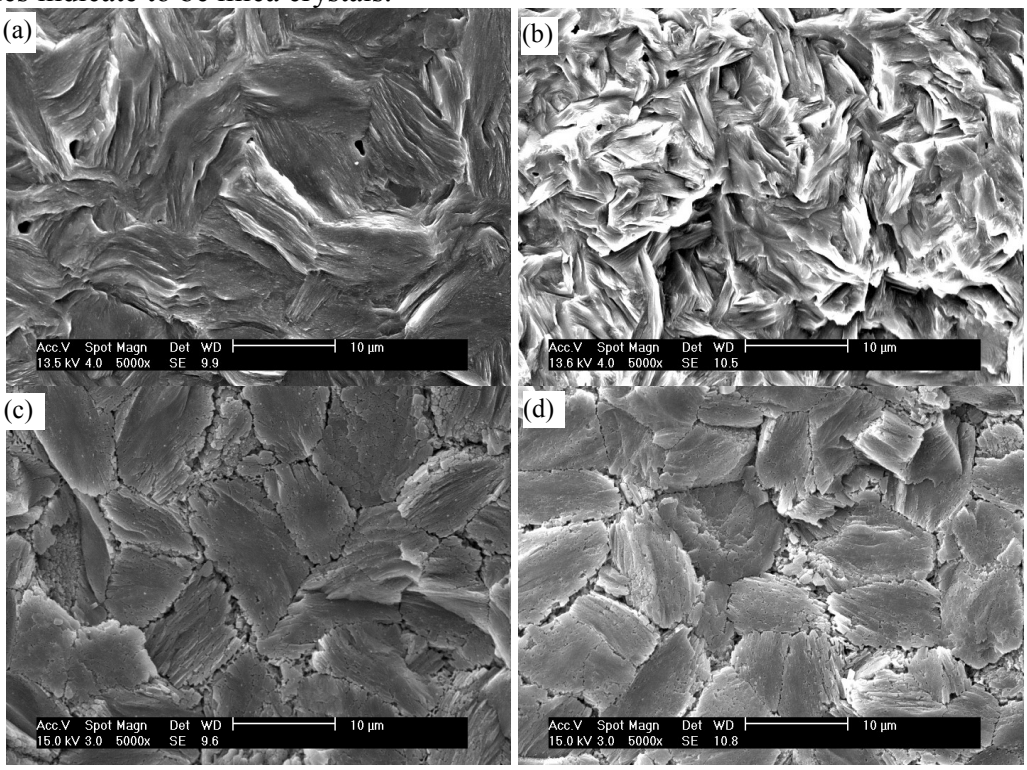

Fig. 5 SEM micrographs of fracture surface
(a) GCF4_1_1, no etching (b) GCF4_1_3, no etching
(c) GCF4_1_6, etched by HF (d) GCF4_2_6, etched by HF

The plane of the mica crystals will be the preferred direction of cleavage when the glass-ceramics are machined. The machinability of mica glass-ceramics is determined by their microstructure such as plate-like mica, which is a highly interlocked array of 2D sheet crystals embedded in a glassy matrix. A great number of interlocking mica crystals in the glass-ceramics prevents macroscopic fracture of these materials during continuous machining [6]. The machinability increases simultaneously with increasing of the crystallinity of mica [7].

Conclusion

Mica-based glass-ceramics with fluorapatite can be successfully prepared with various heat treatments conditions following recrystallization process including two individual processes, nucleation and crystal growth. The optimum nucleation temperature and time have been determined for the first crystallization temperature (T_{p1}) and the second crystallization temperature (T_{p2}).

From XRD patterns, it can be concluded that there is no significant difference in crystalline phases formed for different crystallization times for heat-treatments at either T_{p1} or T_{p2}. The crystals peaks became more intensive with prolongation of the crystallization time or with a higher crystallization temperature.

The bulk microstructure consists of plate-like structures indicate to be mica crystals, which are highly interlocked. With prolongation of the soaking time for crystallization, the grain size of interlock mica increases. Plate-like calcium-mica and fluorapatite crystal are considered as dominant crystalline phases.

Keywords: C@$ZrSiO_4$ inclusion pigment, compound colorants, non-hydrolytic sol-gel process.

Abstract: C@$ZrSiO_4$ inclusion pigment was prepared by using commercial carbon black RX8002C and phenolic resin (PF) as compound carbon source via non-hydrolytic sol-gel (NHSG) process. The RX8002C carbon could well disperse in phenolic resin solution, which developed a compound carbon source after calcination. Dense $ZrSiO_4$ layer was coated on the carbon surface as a protector. The structure and morphology of samples were characterized by X-ray diffraction (XRD) and transmission electron microscopy (TEM). The chromatic value of the pigments was measured by the CIE color system. The results show that the compound colorants can be well coated by $ZrSiO_4$ dense layer to develop a black inclusion pigment. When the compound proportion is 1:4 and the compound colorants amount is 4wt.%, the chromatic value of the C@$ZrSiO_4$ inclusion pigment is 27.54.

Introduction

The black ceramic pigment is an important decorating material in ceramic industry. Most black pigments are got from two main crystalline structures, spinel crystals and hematite, which can resist high temperature but easily be influenced by the basic glaze and firing conditions [1]. Therefore, the development of the inclusion pigment takes a great interest owing to its properties, such as good thermal and chemical stability at elevated temperature [2]. Over the past few years, kinds of methods have been used to prepare zirconium silicate based inclusion pigments, such as solid state synthesis [3], hydrothermal method [4], precipitation method [5], hydrolytic sol-gel method [6] and so on. Non-hydrolytic sol-gel process (NHSG) was firstly proposed by R Corriu *et al.* [7] in the early 1990s, which did not go through metal alkoxide hydrolysis but directly turned into gel by polycondensation of reactants. This method makes the sol homogeneous at the atomic level during the sol-gel process. In addition, the $ZrSiO_4$-based inclusion pigments still have many problems, such as low encapsulation rate, poor chromophoric performance and high synthesis temperature. The preparation of $ZrSiO_4$-based inclusion pigments with NHSG method could greatly reduce the synthesis temperature of $ZrSiO_4$ by adding appropriate mineralizer [8], which greatly resolved these above problems. Carbon black was reported as a promising colorant for black ceramic pigment application [9-10]. However, its homogenous dispersion is a great problem for the coating process. In this study, C@$ZrSiO_4$ inclusion pigment was synthesized via non-hydrolytic sol-gel process. Compound colorants, commercial carbon and in-situ carbon were used as colorants. The in-situ carbon was carbonized by phenolic resin (PF), which could disperse the commercial carbon and enhance the color value simultaneously. The morphology and structure of the pigment were investigated. The influence of the compound proportion and the addition amount of compound colorants on L* value was studied.

Experimental procedures

Tetraethoxysilane (TEOS, AR) and zirconium tetrachloride ($ZrCl_4$, CP) were selected as precursors, and LiF (AR) was used as mineralizer at the molar ratio of TEOS:$ZrCl_4$:LiF=1.2:1:0.36. All the reagents were completely dissolved in isopropyl alcohol with the $ZrSiO_4$ concentration of 1 mol/L. The precursors were continuously heated reflux at 110 ^oC for 24 h to get the $ZrSiO_4$ sol via non-hydrolytic sol-gel process. Meanwhile, the commercial carbon black (RX8002C, particle size about 28nm) and phenolic resin (PF) were added into isopropyl alcohol with constantly stirring for 24 h to get a well dispersed suspension. The obtained suspension was added into the $ZrSiO_4$ sol, and then the mixture was dried at 110 ^oC to get a xerogel. Finally, the xerogel was calcined at 1000 ^oC in N_2 atmosphere for 2 h at a heating rate of 3 ^oC min^{-1} to obtain C@$ZrSiO_4$ inclusion pigment, and then recalcined at 900 ^oC in the air at a heating rate of 5 ^oC min^{-1} to remove the uncoated carbon black.

The phase compositions of samples were characterized by using the Bruker D8 Advance X-ray diffraction with Cu Kα radiation in the angle range from 10 to 80^o with a step of 0.02 ^{o} and a scan speed of 9 ^{o} min^{-1}. Infrared spectroscopy (IR) studies were determined by Nicolet 5700 infrared spectrometer in the wavenumber range of 4000-400 cm^{-1}. Microstructures of the pigment samples were observed by using JEM-2010 transmission electron microscope. The chromatic parameters CIE-L*a*b* of samples were measured by the Automatic WSD-3C color system.

Results and Discussion

Fig. 1 shows the FT-IR spectrum of the colorants/$ZrSiO_4$ dry xerogel prepared via NHSG method. It exhibits bands at around 1610.1 and 3440.0 cm^{-1}, which is belong to the C=O [11] and -OH [12] band occluded in phenolic resin, respectively. The peak splitting appears at 1373.8 and 1461.9 cm^{-1} due to the isopropyl group in isopropyl alcohol. The 1037.5 cm^{-1} band is attributed to the vibration of Si-O-Zr band [13], which indicates that the sol is homogeneous mixed at the atomic level via the non-hydrolytic sol-gel process. This result leads to the low-temperature synthesis of $ZrSiO_4$ with mineralizer LiF, resulting in accelerating the inclusion process at lower temperature [9].

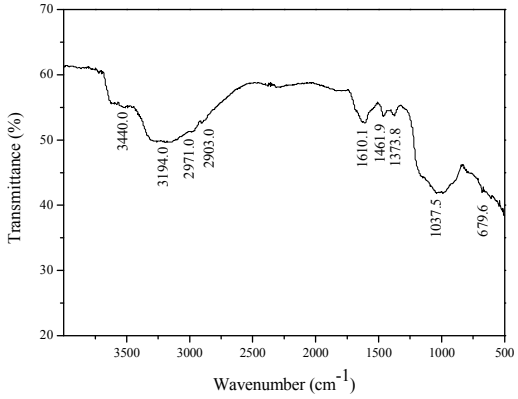

Fig. 1 FT-IR spectrum of the colorants/$ZrSiO_4$ xerogel prepared via NHSG method

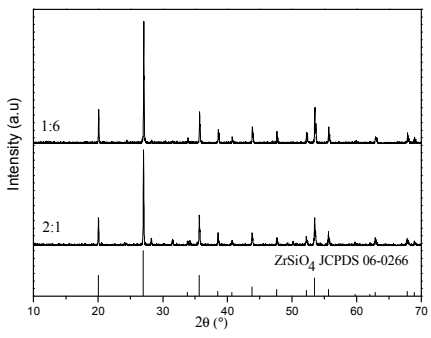

Fig. 2 XRD patterns of the C@$ZrSiO_4$ inclusion pigment with different compound proportion

Fig. 2 shows the XRD patterns of the C@$ZrSiO_4$ inclusion pigments under different compound proportions heated at 1000 ^oC for 2 h. The pure $ZrSiO_4$ phase is formed when the compound proportion of phenolic resin and carbon black is from 1:6 to 2:1, which indicates that the compound proportion has no influence on the synthesis of $ZrSiO_4$ in this range.

Fig. 3 shows the L* values of C@$ZrSiO_4$ inclusion pigments with the different weight ratios of PF to C, including 0:1, 1:6, 1:5, 1:4, 1:3, 1:2, 1:1, 2:1 and 1:0. The L* value of the C@$ZrSiO_4$ pigments firstly decreases with increasing the compound proportion and then increase. All of them exhibit better chromophoric performance than individual carbon black or phenolic resin (1:0 and 0:1). The carbon black can well disperse in phenolic resin solution, which makes the compound colorants easier to be wrapped by $ZrSiO_4$ [14]. At lower compound proportion, the phenolic resin solution is not enough to disperse carbon black, while too much phenolic resin affect the chromophoric performance due to its long polymer chain molecular structure hindering the package of carbon black. When the compound proportion is 1:4, the L* value of C@$ZrSiO_4$ inclusion pigment is 37.09.

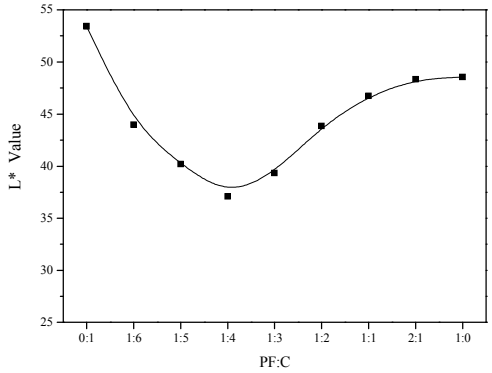

Fig. 3 L* values of the C@$ZrSiO_4$ inclusion pigment with different compound proportion

On the base of 1:4 compound proportion, Fig. 4 shows the XRD patterns of the C@$ZrSiO_4$ inclusion pigment with different addition amounts of compound colorants heated at 1000 ^oC for 2 h. When the total colorants range from 2-12 wt.%, there is no effect on the preparation of $ZrSiO_4$.

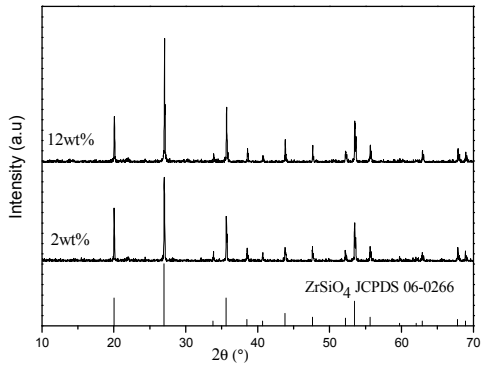

Fig. 4 XRD patterns of the C@$ZrSiO_4$ inclusion pigment with different compound colorants addition

Fig. 5 shows the L* values of C@$ZrSiO_4$ inclusion pigments with different addition amounts of compound colorants (PF:C=1:4), such as 2 wt.%, 4 wt.%, 6 wt.%, 8 wt.%, 10 wt.% and 12 wt.% for $ZrSiO_4$. The corresponding L* value was 40.28, 27.54, 37.09, 38.44, 44.72 and 49.14, respectively. The more compound colorants amounts, the better chromophoric performances are achieved. However, increasing the compound colorants amount constantly, over colorants impacted the mass transfer process during the synthesis of $ZrSiO_4$, which leads to the low encapsulation rate and high L* value.

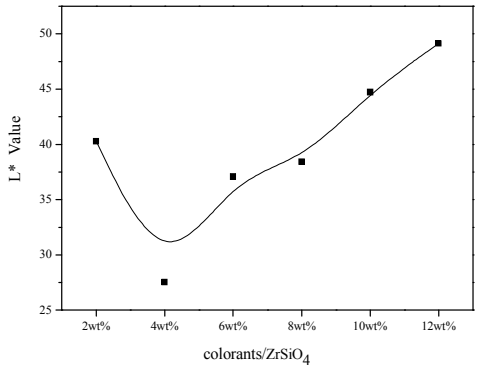

Fig. 5 L* values of the C@$ZrSiO_4$ inclusion pigment with different compound colorants addition

TEM micrographs of carbon black, in-situ carbon got from PF and @$ZrSiO_4$ inclusion pigment are shown in Fig. 6. The morphological features revealed that the size of carbon black particles is range of 25-30 nm (Fig. 6(a)), and the in-situ carbon got from PF is 10-15 nm size (Fig. 6(b)). The phenolic resin can be carbonized to in-situ carbon and coated by $ZrSiO_4$ together with carbon black at elevated temperature (Fig. 6(c)). The result indicates that C@$ZrSiO_4$ inclusion pigment can be synthesized by using PF and carbon black as compound colorants.

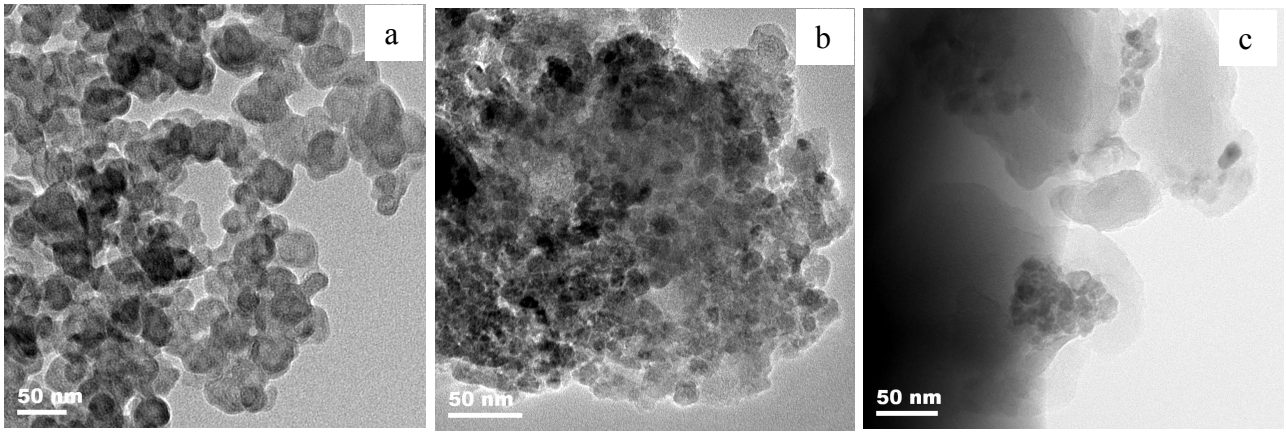

Fig. 6 TEM micrographs of RX8002C (a), in-situ carbon got from PF (b) and @$ZrSiO_4$ inclusion pigment prepared with compound colorants (c)

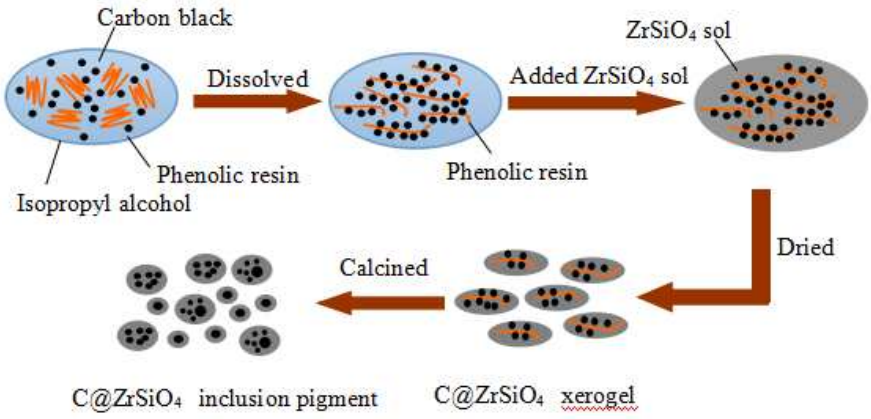

Fig. 7 Schematic of the C@$ZrSiO_4$ inclusion process

Fig. 7 shows the schematic of $ZrSiO_4$ coating carbon process. Firstly, the PF and commercial carbon black compound colorants were dissolved in the isopropyl alcohol to get a suspension due to the well dispersing effect of phenolic resin, and then the $ZrSiO_4$ gel was added into the suspension with stirring. After drying the C@$ZrSiO_4$ xerogel was obtained. Finally, the commercial carbon

black and in-situ carbon black got from PF were coated by $ZrSiO_4$ dense layer through calcined at 1000 ^oC for 2 h in N_2 atmosphere and recalcined at 900 ^oC for 1 h in the air to remove the redundant carbon black. Therefore, the $C@ZrSiO_4$ black inclusion pigment is achieved, which has excellent chromophoric performance and is a promising candidate for ceramic pigment applications.

Conclusions

The $C@ZrSiO_4$ inclusion pigment was prepared via non-hydrolytic sol-gel (NHSG) method by using phenolic resin and carbon black as compound colorants. The results indicate that the compound proportion and addition amount have no influence on the synthesis of $ZrSiO_4$. When the compound proportion is 1:4 and the compound colorants amount is 4wt.%, the best chromatic value of the $C@ZrSiO_4$ inclusion pigment is 27.54, which indicates that it is an excellent black ceramic pigment for ceramic pigment applications.

Keywords: Multi-walled carbon nanotubues, Coating, Reaction bonded silicon carbide.

Abstract: SiC-coated multi-walled carbon nanotubes (SiC-coated MWNTs) made by RF magnetron sputtering were introduced into the SiC suspensions to enhance the mechanical behaviors of reaction bonded silicon carbide ceramics. The composites were prepared by the epoxy resin curing and liquid silicon infiltration at 1550℃for 60min. The distribution, morphology, and reinforcing behaviors of MWNTs were investigated. X-ray diffraction (XRD) reveals that the MWNTs were reserved during the reaction sintering. The flexural strength and fracture toughness increase with MWNTs ranging from 0wt% to 0.5wt%, reaching the peaks value of 347MPa and 4.3MPam$^{1/2}$ respectively at the MWNTs fraction of 0.5 wt%. This improvement derives from the MWNTs pullout. The consequent decline at MWNTs fraction of 1wt% is resulted from the corrosion of agglomerated MWNTs and the increase of residual silicon.

Introduction

Reaction bonded silicon carbide (RBSC) ceramic is an attractive structural material since the development in the 1950s. In general, the RBSC is prepared by reaction sintering of SiC/C mixtures or porous carbon with liquid silicon [1, 2]. The main advantages of the RBSC are: (a) low sintering temperature as compared to pressure-less or hot pressing densification; (b) short sintering time; (c) full densification; (d) near-net shaping compared with the conventional sintered SiC. Additionally, in the view of the low coefficient of thermal expansion (CTE) and high thermal conductivity, the RBSC is believed to be a promising candidate for the large scale, complex shaped and ultra-light weight structural components [3, 4]. However, due to the presence of the residual silicon the mechanical properties, such as flexural strength, Young's modulus, fracture toughness and hardness, were lower than normal sintered SiC. To improve the mechanical property, many works have been made by fabricating RBSC composites using the starting SiC particles with an appropriate multimodal particle size distribution, boron carbide (B_4C) as an alternative source of carbon, and silicon alloy infiltration [5-7]. In summary, the current attempts have focused on the elimination of residual silicon and the particulate reinforcing.

An alternative is to add carbon nanotubes which represent a promising candidate to substitute the carbon fibers as reinforcing element in composites due to their tremendous mechanical properties. Theoretical and experimental studies have shown that CNTs with very high aspect ratios have excellent mechanical properties: the Young's modulus of MWNTs has been calculated to be up to 1.4 times that of graphite whiskers and the extraordinary flexibility under large strains and resist failure under repeated bending [8]. Thus, MWNTs can effectively toughen the ceramic matrix composites via various toughening mechanisms, such as MWNTs pull out, MWNTs bridging, MWNTs debonding and crack deflection [9-11]. However, using carbon nanotubes as reinforcing additives in the RBSC, there are two major obstacles to be overcome. Firstly, the more critical issues are MWNTs dispersion and MWNTs/SiC interaction-factors, which influence mechanical and electrical properties of the resulting composite material. Secondly, theses MWNTs will be corroded with the liquid silicon during the sintering [12, 13].

In this study, to avoid the degradation and aggregation of the MWNTs during the sintering, MWNTs was coated with SiC by RF magnetron sputtering firstly. Then, SiC-coated MWNTs were introduced into SiC/C suspension. Epoxy resin curing and liquid silicon infiltration (LSI) were combined to prepare composites. The MWNTs fraction ranged from 0 to 1.5wt%. The effects of SiC-coated MWNTs on microstructure and mechanical properties were investigated. Morphology changes of MWNTs after LSI were evaluated.

Experimental

Raw materials and fabrication

MWNTs (supplied by Shenzhen NANO tech. Port Co., Ltd., China) have dimensions of 60–100 nm in diameter and 5–15 μm in length. SiC powders (Jiechuang New Material Technology Co., Ltd, Xuzhou, China) with size of 3.5μm were chosen. Carbon black was introduced as carbon resource in LSI.

The silicon carbide and carbon black powders combined with epoxy resin and dispersant were ball-milled in n-butyl alcohol. After 24h of ball milling, a uniform SiC/C suspension was obtained. The MWNTs were first purified with nitric acid to remove the catalyst such as Fe and then coated with SiC by RF magnetron sputtering. With this treatment, the SiC-coated MWNTs were used as "raw". Before adding to the suspension, the SiC-coated MWNTs were pre-dispersed by ultrasonication and mechanical homogenization. Subsequently, the curing agent for epoxy resin and dispersed SiC-coated MWNTs were ball milled with the obtained SiC suspension for 45min. After mixing, the slurry was vacuumed and then poured into the mold to obtain the green body. The resulting green body was dried at 80℃, carbonized at 1000℃ and then sintered via LSI in vacuum at 1550 ℃ for 60 min.

Characterization

Fracture toughness and the flexural strength of the composites were measured in air at room temperature. Flexural strength measurements were performed on bar specimens (3mm×4mm×40mm) using a three-point bend fixture with a span of 30 mm. Fracture toughness was evaluated using a single edge notched beam (SENB) test in the dimension of 2mm×4mm×26 mm with a span of 20 mm , a notch of 2mm in depth and 0.02mm in width. Crystalline phases of the produced MWNT/SiC composites were characterized by X-ray diffraction (XRD, Philips X' Pert Pro MPD DY1219). Microstructure of the fracture surfaces were examined by scanning electron microscopy (SEM, FEI INSPECT-F). The densities of the samples were measured using Archimedes' method in distilled water at 20℃.

Results and discussion

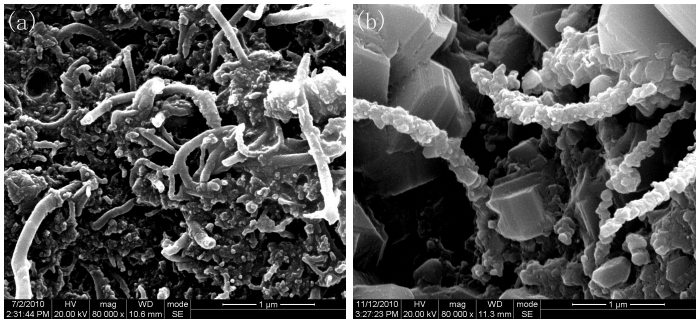

Fig. 1 SEM Images of the MWNTs: (a) Purified MWNTs, (b) SiC-coated MWNTs.

Fig. 1 shows SEM photographs of the MWNTs before (Fig. 1(a)) and after coating with SiC by RF magnetron sputtering (Fig. 1(b)). As shown in Fig. 1 (a), after the purification by nitric acid the surface of MWNTs became smooth and the randomly entangled pristine MWNTs could be separated into single tubes. After coating with SiC by RF magnetron sputtering, the surface of MWNTs became rough coated with polycrystalline SiC particles which could protect the MWNTs from siliconization during reaction sintering.

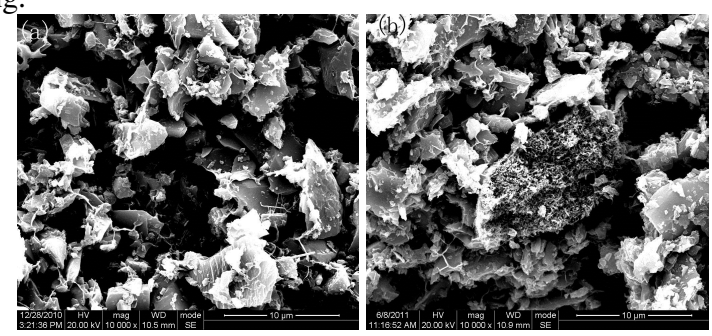

Fig. 2 SEM Images of the Fracture Surfaces of the Green Body After Carbonization with Different MWNTs Fractions: (a) 0.5wt%, (b) 1.5wt%.

Fig. 2 exhibits the microstructures of the fracture surfaces of green body after carbonization with MWNTs fraction of 0.5wt% (Fig.2 (a)) and 1.5wt% (Fig.2 (b)). From Fig.2 (a), no agglomerated SiC-coated MWNTs are observed in the image, implying the homogeneous dispersion of the SiC-coated MWNTs in the matrix. This homogeneous dispersion is ascribed to a series of treatments, including acid purification, coating with SiC, ultrasound vibration and ball milling. With the increasing of the fraction of the SiC-coated MWNTs, the agglomeration in the matrix could avoid formidably as seen in Fig.2 (b).

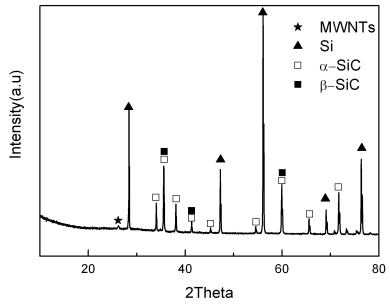

Fig. 3 XRD Pattern of Sample with the MWNTs Fraction of 0.5wt%.

Fig. 3 shows the XRD pattern of the sample with 0.5wt% SiC-coated MWNTs. The composite consist of α-SiC, β-SiC, silicon and MWNTs. The diffraction peak around 2θ=26° with lower relative intensity is attributed to the MWNTs, which indicates the MWNTs are partly preserved in the structure after the reaction sintering.

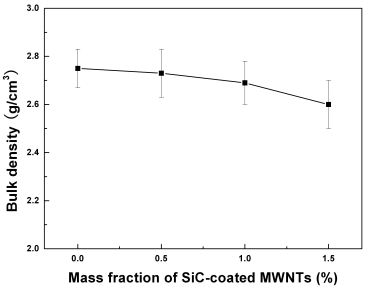

Fig. 4 Bulk Density of the SiC-coated MWNTs Reinforced RBSC Composite as a Function of MWNTs Fraction.

The bulk density as a function of SiC-coated MWNTs is illustrated in Fig. 4. Compared with the monolithic RBSC, the bulk density is decreased by the SiC-coated MWNTs, resulting from the increase of agglomeration of the MWNTs and residual silicon of low density. Due to the low residual carbon of epoxy resin and high porosity of the green body after the carbonization at 1000℃, the bulk

density of the monolithic RBSC is only 2.75g/cm^3 with high proportion of the residual silicon. From Fig. 3, the MWNTs were preserved in the composites, which indicate that the SiC coating can protect the MWNTs from silicification in high fraction of silicon. With the increasing of the fraction of MWNTs, the agglomeration of the MWNTs leads to higher porosity than the monolithic RBSC in the structure as seen in Fig. 2. At the MWNTs fraction of 1.5wt%, the bulk density declines to 2.6g/cm^3.

Variations of the flexural strength and fracture toughness are shown in Fig. 5 with the SiC-coated MWNTs fraction in the range from 0 to 1.5wt%. The flexural strength increases in the initial stage, reaching the peak value of 347MPa at the MWNTs fraction of 0.5wt%. Because of the silicification of the MWNTs and the increase of residual silicon, the flexural strength is reduced when the SiC-coated MWNTs is further increased. The fracture toughness increases from 2.7MPa·m$^{1/2}$ (monolithic RBSC) to 4.3MPa·m$^{1/2}$ (SiC-coated MWNTs fraction of 0.5 wt%). The enhancement is result from the preserved MWNTs in the composites after the infiltration. Owing to the increase of the fraction of SiC-coated MWNTs, the agglomeration which leads to the porosity and defects become form smoke into smother and the residual silicon with high brittleness increases more and more. Due to the damage of the MWNTs, the fracture toughness is degraded at a MWNTs fraction of 1.5 wt%.

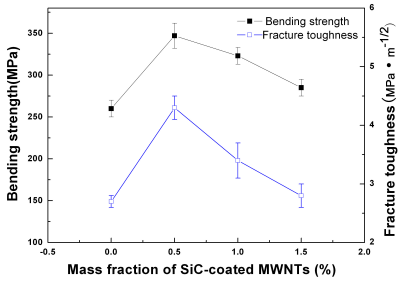

Fig. 5 Flexural Strength and Fracture Toughness as a Function of SiC-coated MWNTs Content (wt %).

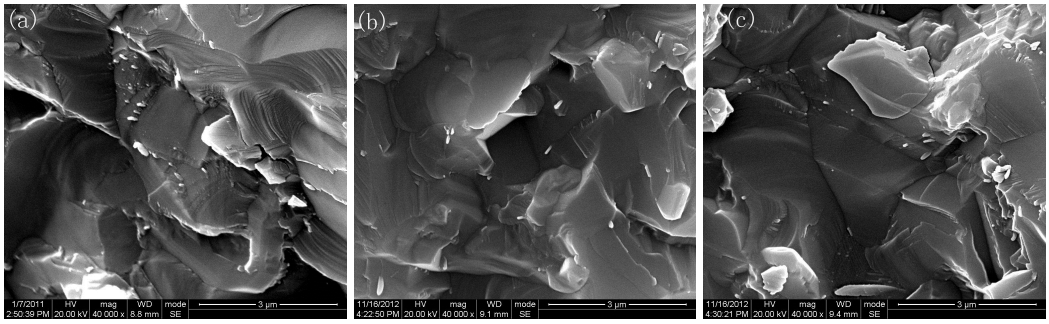

Fig. 6 SEM Images of the Fracture Surfaces of the MWNTs Reinforced RBSC with Different MWNTs Fractions: (a) 0.5wt%, (b) 1wt%, (c) 1.5wt%.

The improvement of fracture toughness derives from MWNTs pullout as seen in the fracture surfaces of the different fraction SiC-coated MWNTs reinforced RBSC of Fig. 6. Owing to the high strength and high elastic modulus of MWNTs, the MWNTs pull out is believed to consume extensive fracture energy. The maximum MWNTs pull out is at the MWNTs fraction of 0.5 wt%, which is in agreement with the variations of the flexural strength and fracture toughness. So, MWNTs pullout is considered the most effective mechanism of MWNTs toughening. No agglomeration of the MWNTs appears on fracture surface of composites, which indicates that the agglomerate MWNTs were silicified absolutely. In general, the shorter fiber pull-out, the stronger bond, the length of fiber pull-out reflects the bond strength between the fiber and matrix in the fiber reinforced composites [14]. Because of the SiC coating, the bond strength between the MWNTs and RBSC become stronger, which can be seen from the shorter and thin MWNTs pull-out compared with the purified MWNTs.

Summary

SiC-coated MWNTs reinforced RBSC composite was prepared by a combination of epoxy resin curing and reaction sintering. The MWNTs can be preserved with the SiC coating made by RF

magnetron sputtering at the MWNTs fraction of 0.5 wt%. At the MWNTs fraction of 1.5 wt%, the agglomerations of MWNTs are siliconized by the liquid silicon due to the increase of porosity and defects. Also, the bulk density declines to 2.6 g/cm^3.

Compared with the monolithic RBSC, the flexural strength and fracture toughness are improved by the MWNTs incorporation. However, the increment is small due to the silicification of MWNTs and the increase of residual silicon. The pull-out of MWNTs is great importance for the improvement of fracture toughness of the composites. To further develop the reinforcing RBSC with the MWNTs, it is necessary to reduce the agglomerations of MWNTs and residual silicon in the sintered body. So, further investigation should focus on distribution of the modified MWNTs and the porosity reduction of the green body.

Keywords: ZrO_2, Y_2O_3 doping, carbonization, phase structure, toughness strengthen

Abstract. Phase evolutions and structures of zirconium oxides with 2 percent yttrium before and after carbonization have been systemically studied with X-ray diffraction and Rietveld structural refinement. The carbonization decreases the structural stability of original ZrO_2. According to the X-ray diffraction patterns, three phases with monoclinic, tetragonal and cubic structure coexist after carbonization. With increasing carbonizing temperature, the content of tetragonal phase in ZrO_2 with 2% mol Y_2O_3 doped increases，however, the phase content of monoclinic phase decreases. The content of tetragonal phase in ZrO_2 with 3% mol Y_2O_3 doped increases greatly after carbonization. It implies that carbonization is beneficial for the formation of ZrO_2 tetragonal phase.

Introduction

As being a fundamental material, zirconia has been widely used in manufacturing due to its attractive mechanical, thermal, electrical and optical properties [1,2]. In order to keep the advanced performance of ZrO_2 in various fields and temperatures, many methods have been proposed for improving its strength and toughness, which are various in physical and chemical methods, e.g. second-phase strengthening and whisker strengthening, *etc* [3,4]. ZrO_2 has three kinds of polymorphs generally, they are corresponding to cubic, tetragonal and monoclinic structures, which are stabilized in different temperature regions, in the temperature ranges from 2953 to 2643 K for cubic, 2643 to1223 K for tetragonal, below 1223 K for monoclinic, respectively [5]. The existence of hexagonal phase is identified by slowly cooling from high temperature to room temperature under high pressure, however，the followed studies are very limited [6].

The spontaneous stress-induced martensitic transformation from the tetragonal to the monoclinic phase plays an important role on ZrO_2-toughened ceramics [5]. The phase transition induces the increase of cell volume and presses on the substrate gradually. Thereby the stress-induced compressive strain can effectively prevent the extension of cracks [7]. Usually, t-ZrO_2 could be stabilized at room temperature by doping cations such as Y^{3+}, Ce^{2+}*etc* [8]. The cost is lower than that of other methods such as nano-crystalline stabilized ZrO_2 at intermediate temperature under ambient conditions [9-14]. Based on the previous reports on the phase transformation mechanism and stability for ZrO_2, the Y_2O_3 doping in Zirconia, which has formed fully stabilized ZrO_2 (FSZ) or partially stabilized ZrO_2(PSZ) or other multiphase case, exhibit excellent performance in strength and fracture toughness caused by the stress-induced martensitic transformation from t→m [15]. In this study, the carbonization technology was used to synthesize the ZrO_2 with 2% and 3% molY_2O_3 for investigating the effects of carbonation temperature on the content of tetragonal phase. The phase structure of samples was checked by X-ray diffraction and their crystal structures were determined using Rietveld refinement technology. It reveals that the content of tetragonal phase in

ZrO_2 with 2% mol Y_2O_3 is going up with increasing the carbonization temperature. The carbonization causes the formation of the t-ZrO2 for the samples with 3% mol Y_2O_3 doping in ZrO_2.

Experiment

The starting materials ZrO_2 with 2% - 3% mol Y_2O_3 were mixed, ground and pelletized with diameter of Φ 20 mm and thickness of 4- 6 mm, followed by sintering in SX-8-16-type silicon molybdenum rod resistance furnace at 1600 ℃ for 4h under an atmosphere of oxygen.

The sintered samples were carburized in a ceramic crucible buried with graphite powder in various temperatures and periods. In order to enhance the activity of the carbon, the graphite powder was mixed uniformly with a small amount of $BaCo_3$ powder, and the crucible was sealed with cement for preventing oxidation.

The phases in samples were checked using a Rigaku diffractometer with rotating anode and an 18-kW X-ray generator $CuK_{\alpha 1}$ radiation (λ = 1.54056 Å), and a graphic monochromator for diffracted beams were used. A step-scanning mode was adopted with a scanning step of 0.02° / *s* (2θ) for determining structure with a Rietveld method. .

Analysis and Discussion

The diffraction data were analyzed by using Rietveld's powder diffraction profile-fitting [16]. For the carburized samples with 2% mol Y_2O_3, the XRD patterns exhibit that the monoclinic, tetragonal and cubic phases coexist in all samples under various sintering temperatures and periods, as shown in Fig 1. It is significant that the content of tetragonal phase is going up with increasing carbonizing temperature. The lattice parameters and unit cell volumes for the monoclinic phase are listed in Table 1.

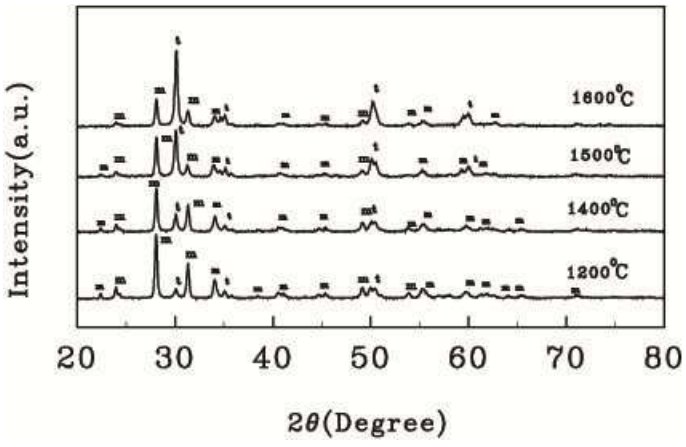

Fig 1. XRD patterns of carbonized zirconia with 2% mol Y_2O_3 under various temperatures

Table 1. Analysis of monoclinic phase in carbon doped zirconia with 2% mol Y_2O_3

Monoclinic phase: S.G.: $P2_1/c$; Z=4				
Carbonization temperature (℃)	1200	1400	1500	1600
Parameters a (Å)	5.169（7）	5.169（6）	5.164（8）	5.166（5）
b (Å)	5.220（9）	5.221（6）	5.223（7）	5.213（6）
c (Å)	5.325（1）	5.325（6）	5.325（9）	5.330（4）
β (°)	99.24	99.26	99.18	98.97
Cell volume V ($Å^3$)	141.8（6）	141.8（8）	141.8（5）	141.8（2）

For these carburized samples with 3% mol Y_2O_3, XRD analysis shows that the tetragonal phase is obtained, and small amount of cubic and monoclinic phase exist as impurity. The space group of tetragonal phase is also $P4_2/nmc$, Z = 2. The refined lattice parameters are a = 3.609(1) Å, and c = 5.184(3)Å. The experimental and calculated XRD patterns of multiphase are given in Fig 2. The residual factor is R*p* = 3.19%, the weighted residual factor is R*wp* = 4.22% and the good fit factor s = 2.08, which indicate that the refinement can be accepted. The lattice parameters and unit cell volume of tetragonal phase are listed in Table 2. The refined structural parameters and ionic positions of multiphase are listed in Table 3. The nearest bond lengths and neighbors of the ions and the O-Zr bond angles in tetragonal phase have been listed in Table 4. The refined results reveal that carbon prefers to occupy Zr position, i.e. 2b crystal position.

Based on the structural refinement, the contents of multiphase can be determined by the reported formula [17]:

$$w_i = \frac{Z_i M_i V_i S_i}{\sum (Z_i M_i V_i S_i)} \tag{1}$$

Where Z_i, M_i, V_i, S_i are presented the numbers of the molecular in a unit cell, the relative molecular mass, the *i*th cell volume, and the scale factor, respectively. The calculated weight percent of tetragonal, cubic and monoclinic phases are 91.14%, 3.73% and 5.13%, respectively. It is noted that the content of dopant of carbon is very lower than that in ZrO_2 – WC composites, where the dopant of WC is as high as 30 vol.% reported by Ref [18] . The more content of dopant is, the more stress induced by doping secondary phase is. It implies that the carbonization technology is beneficial for strengthen toughness by stabilizing more tetragonal zirconia since its content of 3.5 wt%.

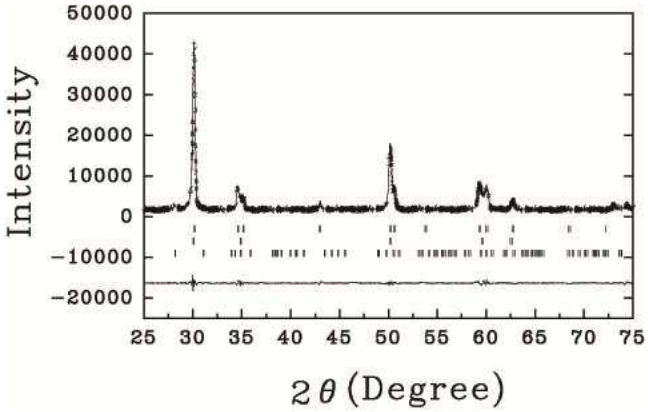

Fig 2. The refined XRD pattern of carbon doped zirconia with 3% mol Y_2O_3

The relationship among the three polymorphs of zirconia in crystallography has been discussed in Ref [1], the reconstructive transformation could be used to explain the transition from tetragonal to monoclinic, *i.e.* two unit cells with tetragonal symmetry combine to one monoclinic cell resulting in volume changes. The oxygen vacancies tend to increase with increasing the doping content of Y_2O_3 [9]. And the structural stability of tetragonal ZrO_2 phase is attributed to the small crystallite size and great oxygen deficiency in phase-pure tetragonal ZrO_2. Y^{3+} substitution for Zr^{4+} cause the increase of ionic radius ratio between the cation and nation (r_+/r_-) since the ionic radius of Y^{3+} is larger that that of Zr^{4+}, which is beneficial for the stability of the tetragonal structure.

Summary

The crystal structures and structural phase transitions of carbon doped ZrO_2 have been investigated by means of the X-ray powder diffraction and Rietveld refinement technique. The carbonization is beneficial for the stability of tetragonal phase, which is identified in 3% mol Y_2O_3 doped ZrO_2 after carbonization. The space group of tetragonal phase is $P4_2/nmc$, with Z=2. The content of tetragonal phase in 2% mol Y_2O_3 doped ZrO_2 is going up with increasing carbonization temperature. Large ionic radius ratio (r_+/r_-) is beneficial for the stability of the tetragonal structure.

Keywords: Thermoplastic slurry; Formation process; Solidification; Viscous–plastic state; Solid–plastic state

Abstract: Simulation results of the formation process of the ceramic fabrications by a hot molding method are presented. Mathematical model describes motion and heat exchange of the liquid thermoplastic slurry of beryllia including the aggregate state change. Velocity and temperature fields during the formation process in the bushings with flat cavity are obtained. Heat flow distribution at the wall of the form-building cavity is demonstrated. The increase of the slurry density during the transition from the liquid state into the viscous–plastic and solid–plastic states is defined.

Introduction

The method of hot molding includes motion and heat exchange of the slurry in the liquid state, as a solid–liquid mixture and as a solid–plastic mixture [1,2]. At stages of filling the form-building cavity and holding under pressure, it is very important to ensure a most structure destruction for obtaining the homogeneous slurry [2]. It is achieved by ultrasonic (US) exposure [2,3]. Minimal friction upon walls of the form-building cavity and maximal plasticity must be reached during the solidification process, to avoid the destruction of the newly formed structure of the molding.

Hydrodynamics of thermoplastic slurry during molding relates to the class of the physical processes of flow and deformation. Slurry flow maintains its configuration after leaving the feeder. It was found during experiments, that for considered molding velocities, the flow of the thermoplastic slurry in the casting mould is laminar [2]. The slurry arrives in the mold at the temperature of $75℃$ and cools down up to $45℃$, at which the molding can be extracted from the mold without buckling [2].

Development and realization of the hot molding method mainly have an empirical nature [5,6], and carrying out of the detailed analysis of the motion and heat exchange will allow to more soundly study the ceramics formation process. Below, the modeling of the ceramics formation process of beryllia by hot molding method is presented.

Rheological Model of the Thermoplastic Slurry

Thermoplastic slurry (high-viscous suspension) is a two phase dispersed system, where solid mineral phase is beryllia powder, and liquid phase is an organic binder. Organic binder consists of 3 components: paraffin, beeswax and oleic acid in the ratio of $0.82: 0.15: 0.03$.

Thermoplastic slurry with thixotropic nature of flow can be related to viscous–plastic fluids of Shvedov–Bingham within the range of shear rate of $0.005 - 1200s^{-1}$ [2,4]:

$$\tau = \tau_0 + \mu \frac{\partial u}{\partial y} \tag{1}$$

where τ is the shear stress; τ_0 is yield point; μ is plastic viscosity coefficient, $\partial u/\partial y$ is the change of the longitudinal velocity along y coordinate.

Ultrasonic exposure influences on the rheological properties of the slurry. Plastic viscosity coefficient, μ, and yield point, τ_0, of the slurry depend on temperature, T, and mass fraction of the binder, ω. The experimental data of μ and τ_0 before ultrasonic exposure for the binder mass fraction $\omega = 0.117$ are described by empirical dependences according to the experimental data of [2,5,6]:

$$\mu(T) = 293.6259 \cdot exp(-0.05816 \cdot T) \quad (2)$$

$$\tau_0(T) = 11.4 + 11.41 \cdot exp\left(-\frac{T-70.05}{5.47}\right) \quad (3)$$

and after ultrasonic exposure:

$$\mu(T) = 629.544 \cdot exp(-0.0709 \cdot T) \quad (4)$$

$$\tau_0(T) = 18.1 + 8.3 \cdot exp\left(-\frac{T-69}{4.8}\right) \quad (5)$$

The temperature is defined in Celsius's ºC in empirical dependences (Eqs. (2)–(5)).

Density of the thermoplastic slurry is defined by the concentration of the binder and densities of the beryllia powder and the binder:

$$\rho = \frac{\rho_{ber} \cdot \rho_{bin}}{(1-\omega)\rho_{bin} + \omega\rho_{ber}} \quad (6)$$

where ρ_{ber} is the density of the beryllia, ρ_{bin} is the density of the binder, ω is relative mass content of the binder normalized to unity.

Density of the binder depends on the temperature and is determined from empirical equation according the experimental data [6]:

$$\rho_{bin}(T) = 0.852 + 0.0725 \cdot cos[\pi(0.01786 \cdot T - 5.3274)] \quad (7)$$

The density of the beryllia is $\rho_{ber} = 3.02\ g/cm^3$. The density of the binder ρ_{bin} in the range of temperature between 75 ºC and 45 ºC is changed within $0.7840\ g/cm^3$ and $0.8845\ g/cm^3$ and the density of the thermoplastic slurry during solidification increases from $2.2643\ g/cm^3$ to $2.3548\ g/cm^3$.

As it was determined experimentally in [1,4,5], ultrasonic exposure has almost no influence on either thermal conductivity or thermal capacity. Both the thermal conductivity, λ, and thermal capacity, c_p, depend on the temperature in accordance with (8) and (9):

$$\lambda(T) = 1.6 + 4.8 \cdot exp(-0.017 \cdot T) \quad (8)$$

$$c_p(T) = 70 + 1070 \cdot exp(0.0027 \cdot T) \quad (9)$$

Thus, rheological properties of the beryllia thermoplastic slurry are functions of temperature, and an aggregate transformation of liquid suspension into solid–plastic state during the forming process is occurred.

Mathematical Model

A flow and a heat exchange of thermoplastic slurry in a bushing are considered. The bushing has a form-building flat cavity (Fig.1). Heat exchange with the coolant occurs on the outer surface of the bushing.

The flat cavity has a thickness of $2y_1 = 0.0015\ m$, a width of $B = 0.03\ m$ and a length of $L = 0.071\ m$. The cooling contour of the bushing is divided into 3 parts. Temperature of the cooling water in the first part is $\theta_1 = 73$℃, in the second part is $\theta_2 = 59$ ℃, in the third part is $\theta_3 = 45$℃.

The liquid slurry flows in the cavity with the initial temperature of $\theta_0 = 75$ ℃. The mass of slurry is cooled and solidified during the movement. At the exit of the cavity, it becomes a structural form. Motion of the thermoplastic slurry is a laminar flow. The feature of the beryllia slurry is its high thermal conductivity: however Prandtl number $Pr = \mu c_p/\lambda$ is much higher than unity due to high viscosity of the thermoplastic slurry. Density of the slurry is variable and increases with solidification.

The problem is studied in Cartesian axes of z and y. OZ axis coincides with the cavity axis direction, and OY axis is radially directed to the cavity axis. Molding velocity is directed vertically downward along the axis OZ. Radial component of the velocity along the axis OY originates from the cooling of the liquid slurry on the side of the wall. An intensive circulation of water occurs in the cooling contours. Therefore wall temperature of each part of the cavity is believed to be equal to the temperature of the cooling fluid.

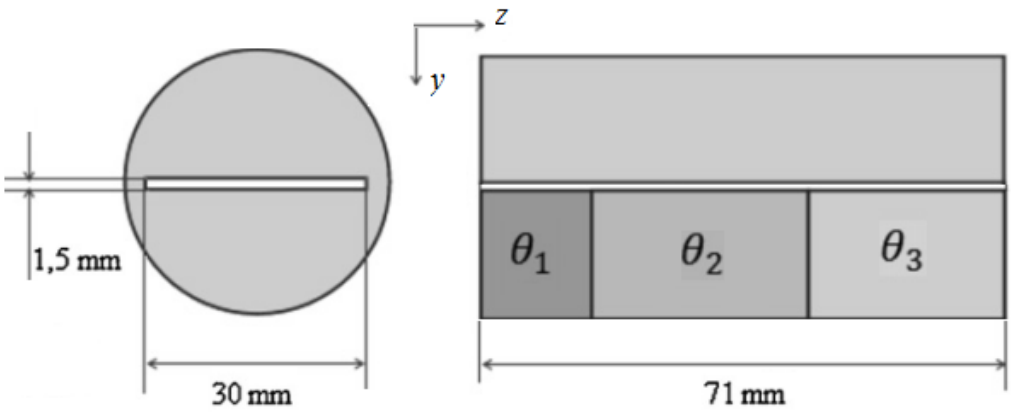

Fig. 1. Bushing diagram of a flat cavity

Rheological properties of the liquid slurry are changed as a result of solidification, and the heat of phase transition is released on the surface of the aggregate transition. Cooling of the slurry may lead to the irregularity of the temperature profile and rheological properties of the pressed out slurry. Solidification begins on the side of the wall, while the slurry may be in liquid state in the center of the cavity. As a result, replenishment by the liquid slurry for the compensation of internal volume shrinkage in the cooling zone of the cavity may occur.

The motion of the slurry is considered to be steady-state along the direction of the molding velocity and for is investigation a set of motion equations of non-Newtonian fluids involving the Shvedov-Bingham model for expression of τ according to Eq. (1) is used [9,10]:

$$\rho u\frac{\partial u}{\partial z}+\rho v\frac{\partial u}{\partial y}=-\frac{dp}{dz}+\frac{\partial}{\partial y}\left(\mu\frac{\partial u}{\partial y}\right)+\frac{\partial \tau_0}{\partial y}+\rho g \tag{10}$$

$$\frac{\partial \rho u}{\partial z}+\frac{\partial \rho v}{\partial y}=0 \tag{11}$$

$$\rho u c_p\frac{\partial T}{\partial z}+\rho v c_p\frac{\partial T}{\partial y}=\frac{\partial}{\partial y}\left(\lambda\frac{\partial T}{\partial y}\right)+H_k\left(u\frac{\partial \rho}{\partial z}+v\frac{\partial \rho}{\partial y}\right)+\mu\left(\frac{\partial u}{\partial y}\right)^2 \tag{12}$$

The following notations are here used: z, y – axial and radial coordinates; u, v –components of the velocity vector; $p, \rho, T, \tau_0,\ c_p,\ \mu,\ \lambda$ –pressure, density, temperature, shear stress, coefficients of thermal capacity, viscosity and heat conductivity of the slurry, respectively.

The heat of aggregate transition of the beryllia slurry is found by experimental data and is equal to $H_k = 7800\, J/kg$ [4]. Rheological properties of the slurry are expressed according to the previously mentioned empiric equations $(2)-(9)$.

Condition of conservation of the mass flow rate permits to define a pressure gradient for pressing out thermoplastic slurry from the molding mold [9]:

$$\int_S \rho u\, dS = \rho_0\, u_0 S \tag{13}$$

where S is cross-section area of the cavity.

Both velocity and temperature distributions at the inlet are considered to be constant along the cross-section of the cavity and all the thermo-physical properties of the slurry are constant:

$$\text{if } z=0: \quad u=u_0,\quad v=0,\quad T=\theta_0 \tag{14}$$

Symmetry conditions are assumed at the cavity axis:

$$\text{if } z>0,\ y=0: \quad \frac{\partial u}{\partial y}=\frac{\partial T}{\partial y}=v=0 \tag{15}$$

For the longitudinal velocity, the conditions of sticking and sliding are set at the wall, depending on the aggregate state of the slurry. It is assumed that the temperature of the cavity wall at each zone is maintained to be constant and equal to the temperature of the cooling fluid. Marking the water temperature in the first, second and third contours as $\theta_1, \theta_2, \theta_3$, respectively, the boundary conditions for the temperature at the wall are achieved [12]:

$$T = \theta_1,\ \mathrm{u} = 0 \tag{16}$$

if $0 \le z < l_1,\ y = y_1$.

$$T = \theta_2, -\frac{\mathrm{dp}}{\mathrm{dz}} = \frac{1}{\mathrm{y_1}}\left[\tau_{0\mathrm{w}} + \left(\mu\frac{\partial \mathrm{u}}{\partial \mathrm{y}}\right)_{\mathrm{w}}\right] \tag{17}$$

if $l_1 \le z < l_2,\ y = y_1$.

$$T = \theta_3, -\frac{\mathrm{dp}}{\mathrm{dz}} = \frac{1}{\mathrm{y_1}}\left[\tau_{0\mathrm{w}} + \left(\mu\frac{\partial \mathrm{u}}{\partial \mathrm{y}}\right)_{\mathrm{w}}\right] \tag{18}$$

if $l_2 \le z < l_3,\ y = y_1$.

Eqs. (10)–(18) can be presented in the dimensionless form for the convenience. Coordinates z, y are divided by the half thickness y_1, velocity components u and v – by v_0, pressure – by the value of dynamic head $\rho_0 u_0^2$, temperature T – by θ_0, density, yield point, coefficients of thermal capacity, viscosity, thermal conductivity – by their values at the temperature θ_0. The equations in the dimensionless form include Reynolds number Re, Prandtl number Pr and Eckert number Ec.

The system of Eqs. $(2) - (13)$ is solved numerically at boundary conditions of Eqs. (14)-(18) [7,9]. The considered zone is broken down into elementary cells with sides $\Delta z_i, \Delta y_j$. Difference analogues of the motion equation (10) and energy equation (12) were obtained by the Crank-Nicolson method of the second order precision, and difference analogue of Eq. (11) – by two-layer scheme of the second order precision. Pressure gradient is defined by the splitting method [7,8] from the condition of flow rate conservation (Eq.(13)).

Discussion of the Calculated Data

Calculations were carried out for the slurry with account of rheological properties before and after ultrasonic exposure. In Fig.2. the distributions of the temperature and the longitudinal component of the velocity in three thermal contours of the flat bushing at the thickness of the cavity of $2y_1 = 0.0015\,m$ and molding velocity of $u_0 = 0.2\,m/min$ without and with ultrasonic exposure, are demonstrated. The longitudinal component of the velocity and the temperature of the slurry at the inlet, of the channel are constant along the cross-section, and are equal to $u = u_0, T = T_0$. The profile of the longitudinal component of the velocity attains the shape of shear flow of the fluid near the inlet section due to high viscosity of the thermoplastic slurry (Fig.2).

Sliding velocity at the wall is almost zero. Wall temperature in the first cooling contour is $\theta_1 =$ 73℃ and the temperature field is changed from 75℃ to 73 ℃ in this zone. Temperature isolines (isotherms) show the zones of the constant temperature and internal structure of the slurry being in liquid state.

Wall temperature is $\theta_1 = 59$℃ in the second cooling contour. Dynamic viscosity, $\mu(T)$, density, $\rho(T)$, and yield point, $\tau_0(T)$, increase with temperature decrease, and viscous-plastic property of the slurry begins to be evident. The slurry slides along the cavity wall, and sliding velocity increases along the length of the second contour during motion down. It resulted in that profile of the longitudinal component of the velocity down the flow will level with constant center in the near-axial zone (Fig.2).

A growth of heat extraction of wall in the second cooling contour leads to a reduction of the temperature field (Fig.2). There is a transition zone in the beginning of the second contour, where the temperature field is variable and expresses the transition of the slurry from the liquid state into the viscous-plastic state. The temperature of the slurry is changed from 73 ℃ to 59 ℃ and defines upper boundary of the zone with constant temperature 59 ℃. The slurry is in viscous-plastic state near the wall due to the heat extraction, while the slurry in the central part of the cavity is in a liquid state. The presence of different structural states along the cross-section results in the change of the rheological and thermo-physical properties of the slurry.

The wall temperature in the third cooling contours is equal to $\theta_3 = 45$℃, which leads to the further cooling of the slurry and reduces the temperature from 59 ℃ to 45 ℃ in the transition zone. According to the experimental data, change in aggregate state takes place at the temperature of $\theta_f = 55$℃. In Eq. (12) for energy, the heat release during the change of aggregate state occurs due to solidification of the viscous-plastic slurry. Solidification leads to a density change of the slurry.

There are density gradients $\frac{\partial \rho}{\partial z}, \frac{\partial \rho}{\partial y}$ in the transition zone, and the heat of change of the aggregate state influences on the distribution of the temperature field.

Further growth of sliding velocity is observed in the third contour. This results in leveling of the longitudinal component of the velocity u along the cross section of the cavity and there is almost piston-like distribution of u at the outlet of the bushing (Fig.2). The transition from viscous-plastic state (green zone in Fig.2) into solid-plastic state (blue zone in Fig.2) takes place in this zone, where rheological and thermo-physical properties of the slurry are homogeneous.

Comparing the temperature field of the slurry in the cavity without ultrasonic (Fig.2a) and with ultrasonic exposure (Fig.2b) one may notice the difference in isotherm distributions. Structural change of the slurry occupies more area in the case of ultrasonic exposure (Fig.2b), than without ultrasonic exposure. It is explained by the increase of the slurry fluidness during ultrasonic exposure due to the change of rheological properties.

Calculation data confirm the experimental fact that, ultrasonic exposure, raising the fluidness of the slurry, reduces the molding velocity during the formation process to get ceramic fabrications.

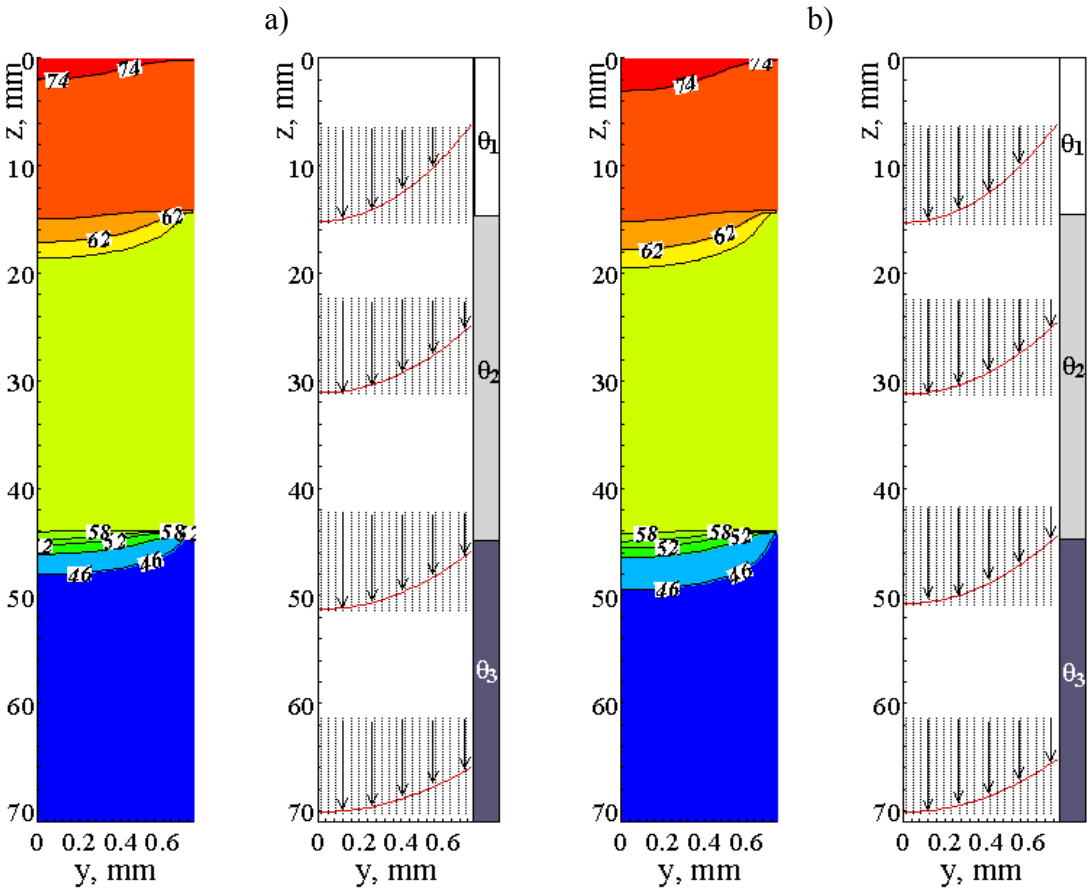

Fig. 2. Distribution of the temperature and longitudinal velocity in the cavity without (a) and with (b) ultrasonic exposure: $h = 0.00075\ m,\ u_0 = 0.2\ m/min$

Increase of molding velocity $u_0 = 0.4\ m/min$ by twice, while the other parameters stay the same, influences on the structural change of the slurry (Fig.3). Calculation data for without ultrasonic exposure (Fig.3a) and with ultrasonic exposure (Fig.3.b) here are also shown. In contrast to the previous regime of formation, the increase of molding velocity leads to the extension of the

transition zone of structural changes from one state into another. It is evident from the temperature distribution (Fig.3): the transition zone from liquid state (red) to viscous-plastic state (green) and the transition zone from viscous-plastic state (green) to solid-plastic state (blue).

Transition zones are expanded in the case with ultrasonic exposure and this is explained by a change in rheological properties of slurry and increase of slurry fluidity (Fig.3).

It can be seen from Figs.2 and 3 that transition zones have curvilinear convex surfaces with different areas. It can lead to uneven shrinkage of the slurry along the section of the form-building cavity.

The density of thermal flow at the wall describes a heat exchange between the slurry and the wall of cavity and can be expressed as:

$$q_w = -\lambda \left(\frac{\partial T}{\partial y}\right)_w$$

Variation of the density of thermal flow by the length of the cavity of flat bushing is shown in Fig.4. The wall temperature in the first cooling contour is $\theta_1 = 73$℃, a small change of thermal flow density q_w at wall is observed and this is due to minor difference between the initial temperature of the hot slurry θ_0 and the wall temperature θ_1. The reduction of wall temperature till $\theta_2 = 59$ ℃ in the second cooling contour leads to a sharp increase of thermal flow density q_w in the narrow area of transition zone due to uneven reduction of the wall temperature from $\theta_1 = 73$ ℃ to $\theta_2 = 59$ ℃. Downwards by the direction of the motion, thermal flow density, q_w, steadily approaches zero due to leveling of the slurry temperature field.

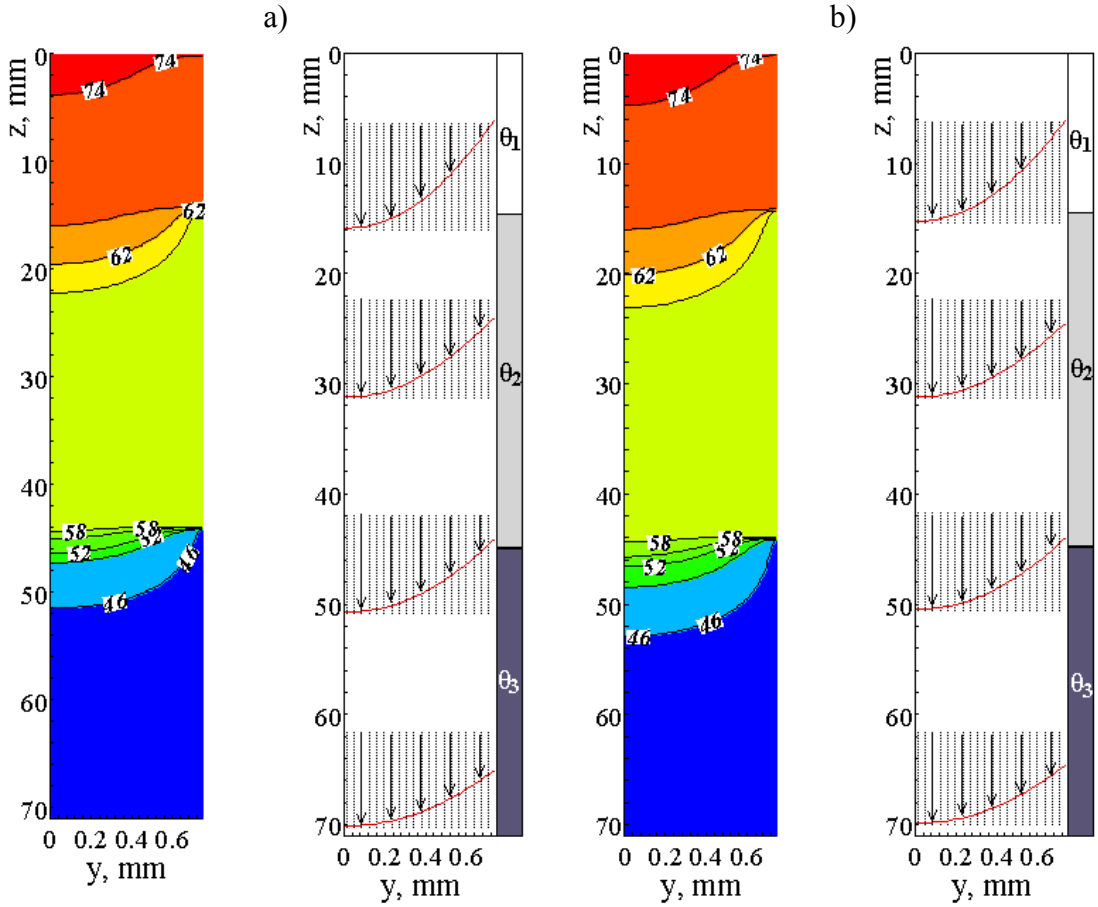

Fig. 3. Distribution of the temperature and longitudinal velocity in the cavity without (a) and with (b) ultrasonic exposure: $h = 0.00075\ m,\ u_0 = 0.4\ m/min$

Thermal flow density, q_w, in the third cooling contour changes similarly due to abrupt reduction of the wall temperature from $\theta_2 = 59$ ℃ to $\theta_3 = 45$ ℃ with a monotonic decrease by leveling of temperature field.

Process of transition of the slurry from one structural state into another in the cavity can be also analyzed through the change of the density. Change of the slurry density along the length of the axial plane of the cavity is demonstrated in the Fig.5.

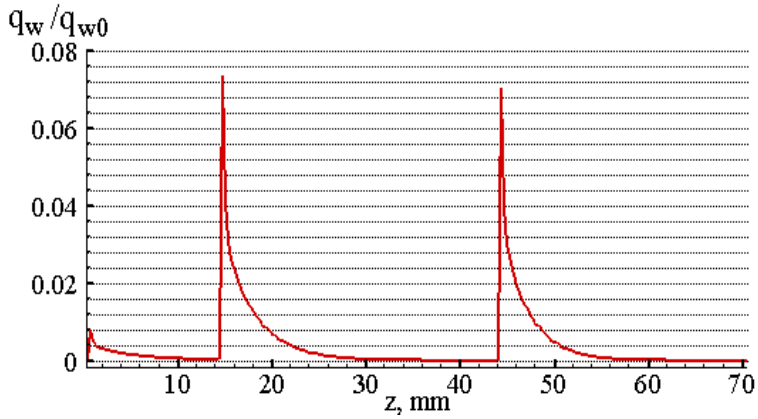

Fig. 4. Change of the thermal flow density at the wall along the length of the cavity: $h = 0.00075\ m,\ u_0 = 0.2\ m/min$

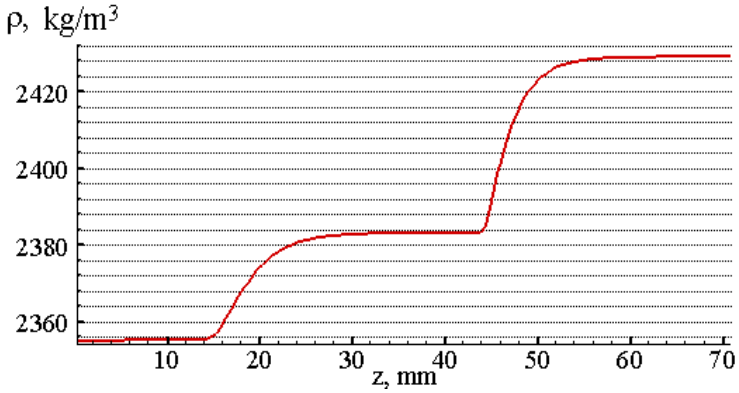

Fig. 5. Change of the density of the slurry along the length of the cavity: $h = 0.00075\ m,\ u_0 = 0.2\ m/min$

A change of density along the first cooling contour is small, i.e. the slurry maintains the initial liquid state. In the second contour, density of the slurry increases from 2355 to 2383 and is stable all the way of this part, i.e. a transition of the slurry from liquid state into viscous-plastic state is taken place. Density of the slurry increases from 2383 to 2429 in the third contour, the slurry is hardened and turns from viscous-plastic state into solid plastic state [5].

Conclusion

Investigation results show that the mathematical model describes all the stages of the ceramic molding including the changes of aggregate state. Ultrasonic exposure enhances the rheological properties and increases the fluidity of the thermoplastic slurry in the form-building cavity. All the stages of the hot molding method of the thermoplastic slurry (liquid state, viscous-plastic state, solid-plastic state) can be presented by the changes of the longitudinal velocity and temperature along the length of the cavity. Density of heat flow at the wall of the form-building cavity is changed in accordance with the boundary conditions and expresses heat extraction at the wall. The slurry density increases during the transition from the liquid state into viscous plastic and solid-plastic states. Such a density distribution expresses balancing mechanism of volumetric changes of the slurry and is in a satisfactory compliance with the experiment [2,6].

Optimum conditions of the ceramic molding process by the hot molding method can be found with calculations, which will allow obtain the hardened fabrication with homogeneous structure of beryllia at the outlet.

Keywords: $Cu(In,Ga)Se_2$; Thin-Film Solar Cells; Sputtering; Selenization

Abstract: $Cu(In,Ga)Se_2$ (CIGSe) thin films were prepared by sputtering with single CIGSe or Cu-Ga-In_2Se_3 target and subsequent selenization at 550-700°C. The one- and two-step selenization procedures and the ceramic and cermet targets were used for process comparisons. Microstructure, film growth and film composition were used to evaluate the growth performance. CIGSe films sputtered from the CIGSe target had a low Cu content. CIGSe films prepared with single Cu-Ga-In_2Se_3 target had shown different performance after the one- and two-step selenization procedures. The two-step process did not grow the dense films due to the vaporization of Se-containing species from the incomplete reaction. The high-temperature requirement is the major disadvantage for the post-selenization approach.

Introduction

$Cu(In_{1-x}Ga_x)Se_2$ solar cell devices with efficiencies above 20% have become a leading material for thin film solar cell applications [1,2]. These quaternary compounds semiconductors have a direct band gap, high efficiency, high absorption coefficient, and long term stability [3]. The most efficient solar cells are obtained from absorber layers with a Cu/(In+Ga) ratio of 0.8-0.92 [1,4].

CIGSe films have been successful made by vacuum-type co-evaporation and non-vacuum-type hydrazine methods below 600°C. Their advantage is the incorporation of Se together during film formation. Post-annealing instead of post-selenization is needed. If the CIGSe films are made by stacking the metallic or alloy layers, these films need a post-selenization procedure to form compounds [5,6]. For the quaternary compound, the multiple precursor sources or targets have been used for the composition control. Single $Cu(In,Ga)Se_2$ target [7] and single cermet target containing metallic Cu and Ga and ceramic In_2Se_3 are less been adapted for CIGSe thin films.

Here, CIGSe films are prepared by sputtering with single CIGSe or Cu-Ga-In_2Se_3 target followed by post-annealing at 550-700°C. Film growth, microstructure and film composition are investigated.

Experimental Procedure

$Cu(In,Ga)Se_2$ (CIGSe) thin films grown on Mo-coated soda-lime glass plates were prepared by the post-selenization of the precursor films deposited by dc-magnetron sputtering with a CIGSe or Cu-Ga-In_2Se_3 target. The CIGSe target was formed at 800°C for 1 h by hot pressing the powder mixture of Cu_2Se, In_2Se_3 and Ga_2Se_3. The Cu-Ga-In_2Se_3 cermet target was hot pressed the powder mixture of Cu, Ga and In_2Se_3 at 550°C for 1 h. The target compositions were based upon the $Cu_{0.9}(In_{0.7}Ga_{0.3})Se_2$ formula. The substrate temperature and growth time were 400°C and 8 h for using the CIGSe target, but they were 150°C and 3 h for the cermet target. The sputtering power was 80 watt. Our post-selenization was executed with one-step and two-step heating procedures in a tube furnace. For the one-step method, the film was heated to 550-700°C with a holding time of 1 h. The two-step method was heated to 300°C with a holding time of 0.5 h and followed by heating to 550-700°C for 1 h. During selenization, the precursor films were loaded in a lid-covered ceramic crucible with a Se or ($SnSe_2$+Se) pellet together for atmospheric control.

Phase identification of CIGSe layer was analyzed by X-ray diffractometry (XRD, Rigaku D/Max-RC). A field-emission scanning electron microscope (SEM, JEOL JSM 6500F) equipped with energy dispersive spectroscopy (EDS) was used for composition analysis and microstructural characterization.

Results and Discussion

Fig. 1(a) shows the SEM image for the as-deposited CIGSe film from a CIGSe target. It had nanometer-sized grains. After selenization, grains were bigger but the surface was rough (Fig. 1(b)). The problems for this approach were a prolonged deposition time of 8 h, the small grain size and a severe deficiency of Cu in CIGSe with the Cu/(In+Ga) ratio of 0.6. The rough surface on the annealed sample is related to the condensation of Se vapor on CIGSe films, the dissolution of Se with CIGSe, and the vaporization of the Se-rich phase. To make a modification, the cermet Cu-Ga-In_2Se_3 target for CIGSe was used. To avoid the preferential formation of $CuInSe_2$ and phase separation, In_2Se_3 ceramic instead of metallic indium was used.

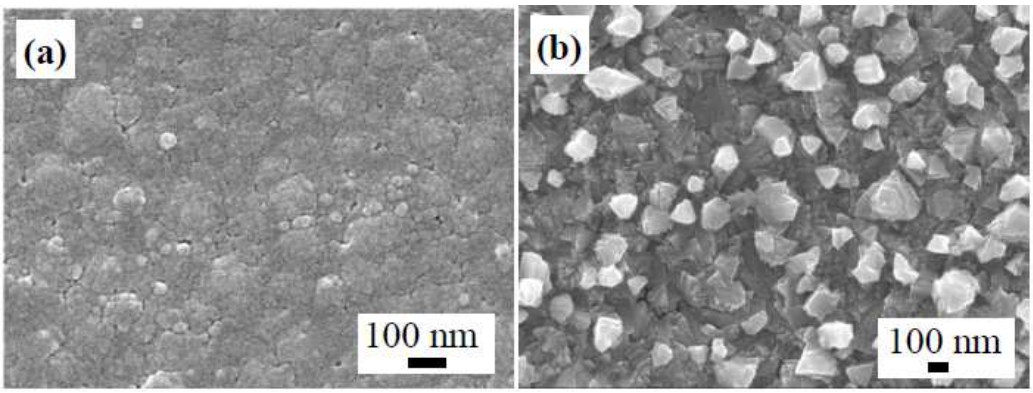

Fig. 1 Surface SEM images of CIGSe films (a) after deposition at 400°C with a CIGSe target followed by (b) selenization at 550°C with a one-step heating procedure.

Fig. 2 Surface SEM images of CIGSe films after deposition with a cermet target at 150°C followed by selenization at different temperatures with a one-step heating procedure. After selenization at 550°C, there were small and white particles on surface. These particles existed before and after selenization and were related to the formation of $CuInSe_2$ from the metallic Cu-In phase. With increasing the selenization temperatures to 600 and 650°C, the grain sizes remained smaller than 0.8 μm. The CIGSe film was difficult in grain growth. Until selenization at 700°C, the fast grain growth led to a non-uniform distribution in grain size ranging from 1 to 6 μm. The CIGSe films obviously need high thermal energy at 700°C to enhance grain growth. These films from the Cu-Ga-In_2Se_3 target basically had smooth and continuous surfaces.

Fig. 3 Surface SEM images of CIGSe films after deposition with a cermet target at 150°C followed by selenization at different temperatures with a two-step heating procedure. Except for 700°C-annealed CIGSe with large grains and a smooth surface, other films were covered with island-like particles and had a loose surface. The two-step selenization procedure obviously is not suitable for the CIGSe films deposited from a Cu-Ga-In_2Se_3 target. The selenization procedure becomes an important issue. The major difference in the one- and two-step procedures is the holding period at 300°C for half an hour. The holding is pretended to have Se vapor cover on as-deposited films for further reaction and selenization. If the reaction of forming CIGSe is not complete due to the insufficient thermal energy, the partially reacted Se-rich compounds will escape from substrate. The escape of partially reacted compounds leaves the voids and gaps on CIGSe films.

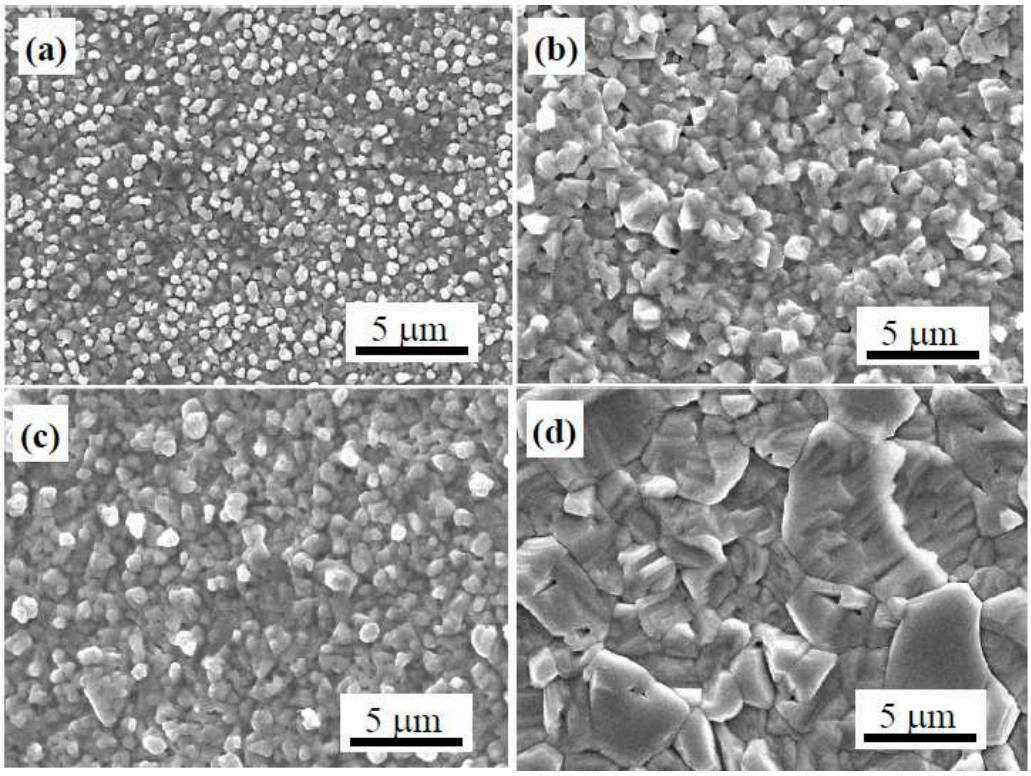

Fig. 2 Surface SEM images of CIGSe films after deposition at 150oC followed by selenization at (a) 550ºC, (b) 600ºC, (c) 650ºC and (d) 700ºC with a one-step heating procedure.

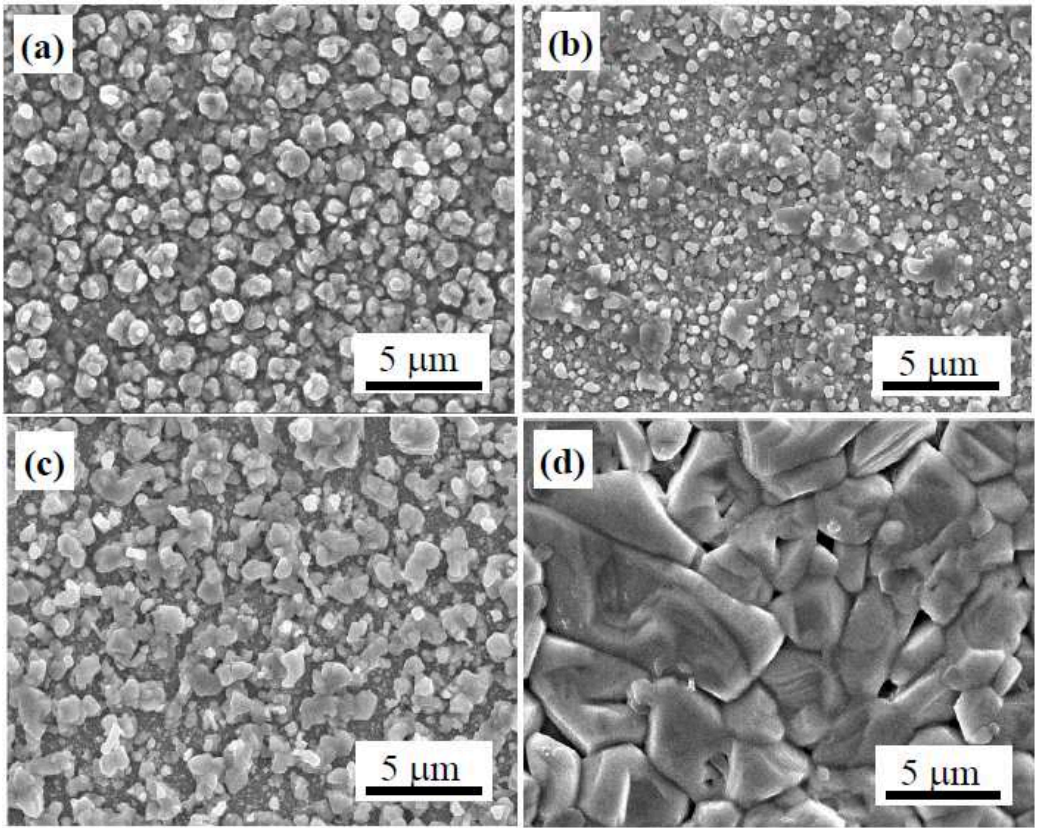

Fig. 3 Surface SEM images of CIGSe films after deposition at 150ºC followed by selenization at (a) 550ºC, (b) 600ºC, (c) 650ºC and (d) 700ºC with a two-step heating procedure.

Fig. 4 shows XRD analyses of CIGSe films obtained by sputtering and post-selenization at 550-700ºC with the (a) one-step and (b) two-step selenization procedures. The three main diffraction peaks from the (112), (220)/(204), and (312)/(116) planes were observed at 2θ angles of ~27º, 44.7º, and 53º, respectively. The Mo bottom electrode was observed for each condition. No

observable second phases were detected. The major difference for the one- and two-step processes is the peak intensity of Mo, from which we can identify that the CIGSe films after the two-step selenization procedure become much thinner. This evidence also supports the loose microstructure with voids due to the composition vaporization.

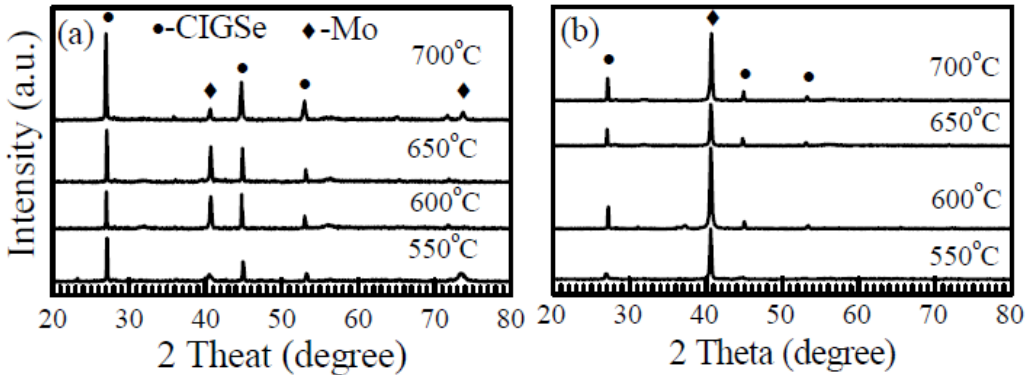

Fig. 4 XRD analyses of CIGSe films after selenization at different temperatures with the (a) one-step and (b) two-step selenization procedures.

Fig. 5 shows XRD analyses of CIGSe films obtained by sputtering and post-selenization at 550-700ºC with the (a) one-step and (b) two-step selenization procedures. For the one-step method, CIGSe films were Se excessive at low selenization temperature but became Se deficient at high temperature. The Cu ratio, on the opposite way, increased with selenization temperature. The Ga/(In+Ga) ratio was close to 0.3. For the two-step method, CIGSe films had the same Se content at ~0.5 for different conditions. The Cu ratio, relating to the Se ratio, was unchanged. The point to note is the Ga ratio decreased with the increase in selenization temperature, which made the Ga/(In+Ga) ration much lower than 0.3. From the composition analyses, the CIGSe films from the two-step procedure look the favorite. However, it has a serious problem in the film microstructure. Its loose microstructure with stable composition indicates the composition vaporization, which has caused the voids, does not have affected its crystallization, phase formation, and composition uniformity.

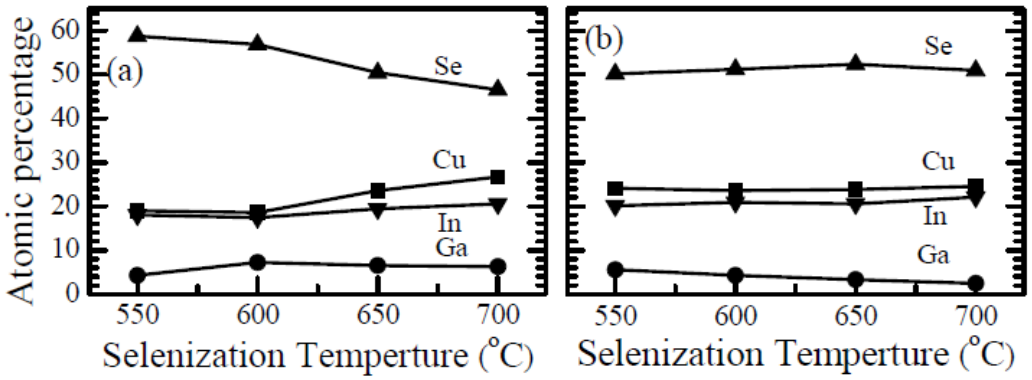

Fig. 5 Compositional analyses of CIGSe films after selenization at different temperatures with the (a) one-step and (b) two-step selenization procedures.

The mechanism of forming the loose and void microstructure needs to be classified in order to know the compositional and microstructural controls. The two-step selenization procedure with a holding at 300ºC before reaching the reaction temperature actually provides a sufficient Se vapor to condense on the as-deposited films. The Se liquid dissolutes the constituents of the as-deposited film with the formations of the selenide compounds and the Se-rich liquid solution. The major selenide is $Cu(In,Ga)Se_2$ and the Se-rich liquid solution can be easily vaporized to form the voids. Therefore, CIGSe films remains to show the CIGSe diffraction peaks and the voids after post-selenization. Because the CIGSe phase is the only phase to stay, the composition from the EDS

analyses does not have an apparent difference. On the other hand, the one-step procedure does not have the sufficient time for the Se vapor to build the over-pressure over the as-deposited films, no excessive Se species cover on the films for reactions. The Se content on the as-deposited films is not a lot to form the Se-rich liquid phase. The limited Se content on substrate reacts to form the CIGSe phase. Because there were no Se-rich species, no composition vaporization occurs and the film remains smooth. The small grain size for CIGSe films after selenization by the one-step method is attributed to the need of higher thermal energy for grain growth of ceramic-containing films deposited from the Cu-Ga-In_2Se_3 target.

Summary

Cu(In,Ga)Se_2 films were deposited by sputtering with single Cu(In,Ga)Se_2 and Cu-Ga-In_2Se_3 targets followed with a one- or two-step selenization procedure. CIGSe films from the sputtering of a CIGSe target had a severe Cu-deficient problem, but it did not occur for sputtering with a cermet target. The performance of CIGSe films from a cermet target was strongly related to the selenization procedure. The two-step procedure is to provide more Se amounts for reactions. If the reaction temperature is not high enough, the reactions are not complete and the generated Se-rich compounds will vaporize to leave a porous CIGSe film. There are no Se-rich compounds generated for the one-step procedure. The control of the Se dissolution reactions is important for the densification, grain growth and composition, which are all related to the temperature-dependent reactivity of reactants to form the CIGSe films.

Keywords: silicon thin film, microstructure, hydrogen dilution ratio, substrate roughness

Abstract. Intrinsic microcrystalline silicon (μc-Si:H) thin films were deposited on four kinds of substrates (polished quartz glass: PG, Rough quartz glass: RG, Textured SnO_2:F coated glass: TG, Textured ZnO:Al coated glass: ZG) by 13.56 MHz plasma enhanced chemical vapor deposition (PECVD) with different hydrogen dilution ratio (R_H=H_2/SiH_4) under the pressure of 2 Torr. The film thickness, crystalline volume fraction (X_C) and substrate surface roughness (R_a) were measured by surface profilometer, Raman spectra and atom force microscopy (AFM), respectively. The results revealed that with the increase of R_H, the deposition rate decreased and X_C increased monotonously for the films deposited on the same substrate, but the substrate R_a had an obvious impact on the film microstructure. A physical model was proposed to illustrate the growth of the μc-Si:H thin films deposited on substrates with different R_a.

Introduction

The μc-Si:H thin films were introduced by Veprek and Marecek in 1968 [1]. Since then, a lot of works have been devoted to investigate the μc-Si:H materials and solar cells [2,3]. Hydrogen dilution ratio (R_H=H_2/SiH_4) is one of the most important parameters in depositing the μc-Si:H materials. The materials with high crystalline volume fraction (X_C) can be obtained at high R_H, but with low growth rate. Then high pressure high power method is proposed to diminish the high energy ion bombardments and improve the deposition rate of the μc-Si:H thin films [4]. Although there are three interrelated models to explain the μc-Si:H growth: the surface diffusion model by Matsuda in 1983 [5,9], the chemical annealing model by Nakamura et al in 1995 [6] and the selective etching model by Tsai et al. in 1989 [7], the growth mechanism of μc-Si:H and the effect of substrate surface roughness (R_a) are not yet clear.

In this paper, the influence of RH and Ra on the microstructure of μc-Si:H thin films deposited at plasma excitation frequency 13.56 MHz by plasma enhanced chemical vapor deposition (PECVD) were investigated in detail.

Experiment

The μc-Si:H thin films were deposited in a capacitive coupled radio frequency glow discharge reactor with RH ranging from 1.1 to 25. The deposition power, the substrate temperature, the electrode gap and the deposition pressure were 200 W, 220 °C, 12 mm, and 2 Torr, respectively. The film thickness was measured by thickness profiler (Dektak 150). The crystalline volume fraction (XC) characterized by Raman scattering was determined as (Ic+Ii)/(Ia+Ic+Ii), where Ia, Ii and Ic represented the integrated intensity of amorphous, intermediate and crystalline phase peaks, respectively. The surface morphology and Ra of substrates were observed by atom force microscopy (Bruker, Model Icon).

Results and Discussion

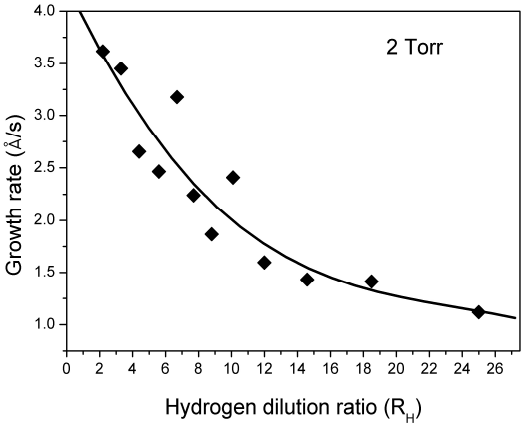

Fig. 1 Growth Rate of Thin Films Deposited on PG Substrate as a Function of R_H at 2 Torr. The Solid Line is Guide to the Eye

As seen in Fig. 1, when the RH increases from 2.2 to 25, the growth rate of thin film deposited on polished quartz glass (PG) substrate decreases slowly from 3.6 to 1.1 Å/s at 2 Torr. It is well known that there are three ways to increase the deposition rate: the first is to increase the flux of active radicals, the second is to create more sites for growth, and the third is to increase the probability for the active radical to occupy a growth site [8]. Here, we attribute the increase of the deposition rate at low RH to the increased flux of active radicals (SiH, SiH2 and SiH3) to the growth surface. And according to the 'etching model', the deposited silicon atom is easily etched and bombarded by hydrogen atom at high RH, which also results in the low deposition rate at high RH.

The crystallinity of μc-Si:H thin films is investigated by the Raman spectroscopy. The Raman spectra of the deposited thin films on four kinds of substrates (TG, ZG, PG, RG) with different RH at the deposition pressure of 2 Torr are shown in Fig. 2. The three peaks at 480 cm-1, 510 cm-1 and 520 cm-1 are attributed to amorphous phase, intermediate phase and crystalline phase, respectively. It is obviously that the Raman spectra of thin films deposited on the four kinds of substrates are different while RH is the same. The crystalline volume fraction XC was calculated by Gaussian fitting [10,11], and listed in Fig. 3. One can see from Fig. 3 that when the deposition pressure is 2 Torr, the XC increases with the RH increase on the same substrate. And when RH is the same, the film deposited on PG has the highest XC and the film on RG has the lowest XC. The deposition conditions are the same except for the type of substrates. Thus, the different kinds of substrates influence the microstructure of the μc-Si:H thin films.

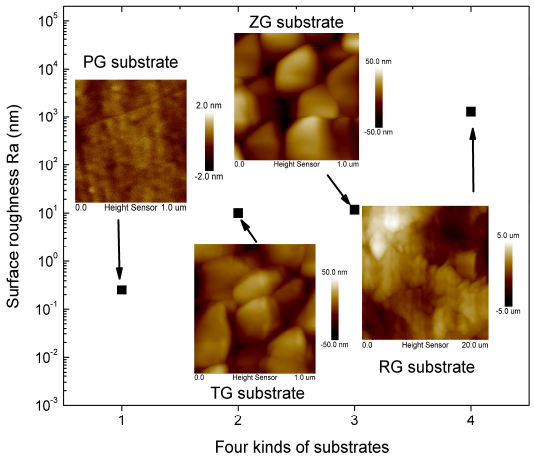

Fig. 4 Surface Roughness R_a and AFM Images of the Four Kinds of Substrate Surface

Fig. 4 shows that the surface roughness Ra of the four kinds of substrates (PG, TG, ZG and RG) is 0.255 nm, 9.94 nm, 11.17 nm and 1278 nm, respectively. However, the varied Ra of the different kinds of substrates affects the microstructure of the deposited thin films. A physical model drawn from our experimental results is proposed as the following.

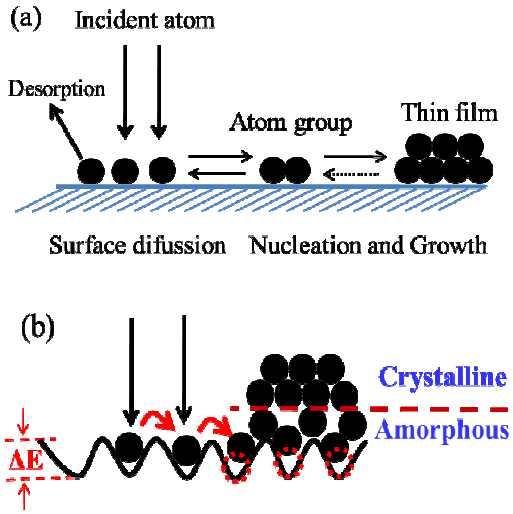

Fig. 5 A Physical Model for the Deposited Atoms with Relatively High Energy Achieving the Flat (a) and the Rough (a) Substrate Surface

The growth of silicon thin films deposited by PECVD usually goes through several processes: precursors (SiHx) in the plasma are adsorbed on the substrate surface, the absorbed precursors start to migrate on the substrate surface and make chemical bonds at the lowest energy sites, forming an amorphous or microcrystalline silicon network structure, while others are desorbed, depending on their sticking coefficients at the surface [12]. The sticking coefficients of precursors are mainly influenced by the substrate temperature [13]. In our experiment, the deposition temperature is the same for all the samples. The deposited atoms with relatively high energy achieve the substrate surface and some adatoms can cross the surface barrier (ΔE), reach the lowest energy position, and form condensation and nucleation in the growing thin films surface, shown in Fig. 5a. The rougher the substrate surface is, the greater the surface barrier ΔE will be. Then adatoms can not all find the lowest energy position (Red dotted line circle in Fig. 5b) at substrates with high Ra, and the initial stage of the film growth forms amorphous structure shown in Fig 5b, namely incubation layer [14,15]. The thickness of incubation layer is proportional to the Ra, and the low crystallization of prepared thin films forms with high Ra. Therefore, the XC of the grown films is inversely proportional to the surface Ra.

The surface coverage of the hydrogen atom is crucial in depositing high quality microcrystalline materials [16]. Then, in order to increase the atomic hydrogen flux density on the growing surface, high hydrogen dilution RH is necessary for μc-Si:H thin film growth. The high RH increases H atoms on substrate surface so as to benefit the film precursor migration on substrate surface, and influences the initial condensation and nucleation of thin films to make them crystallize easily.

Summary

The μc-Si:H thin films were deposited on four kinds of substrates (PG, RG, TG and ZG) with different Ra via PECVD method at various RH under the pressure of 2 Torr. The results revealed that with the increase of RH the deposition rate decreased and XC increased monotonously for the films deposited on the same substrate. The XC of the grown films is inversely proportional to the surface Ra. The effects of the four kinds of substrates on the microstructure and growth behavior of μc-Si:H thin films were attributed to their different surface structures.

Keywords: Silicon rich oxide; Luminescence; Eu; Yb; Rare earth compounds; Energy transfer

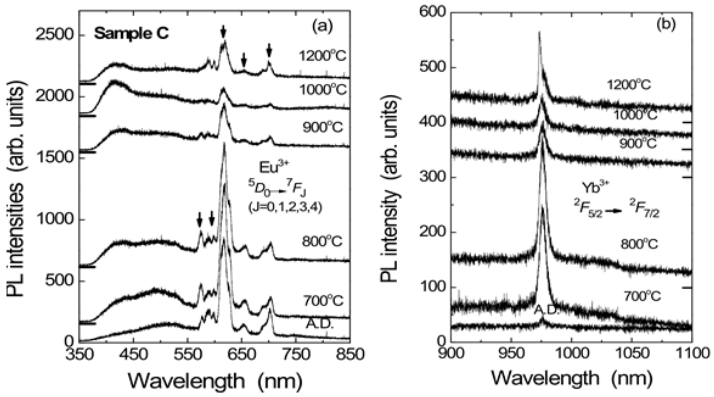
Abstract. We report on photoluminescence (PL) properties of europium (Eu) and ytterbium (Yb) co-doped silicon oxide films with different Si excess**.** After annealing the films in N_2, strong PL were observed from Eu and Yb^{3+} ions and their intensities are correlated. The PL intensity of Eu is mainly from 3+ for no and relatively low temperature anneals (<900 °C) while the Eu^{2+} emission is dominating for annealing at 1000 °C or above in the co-doped Si-rich oxide films. Transmission electron microscopy shows amorphous (Eu, Yb, Si, O)-containing precipitates in the Si-rich oxide during 1000-1200 °C annealing and these precipitates are considered to be responsible for the Eu^{2+}-related luminescence.

Introduction

Recently, spectral conversion in solar cells by the use of rare earth doped films has emerged as a potential application [1]. In particular, down conversion schemes using co-doping by Eu and Yb have attracted interest [2-6]. The down conversion scheme is possible by the energy of the $4f^6 5d \rightarrow 4f^7$ transition of Eu^{2+} being approximately twice that of the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition in Yb^{3+} ions. The Yb^{3+} ions will emit photons around 980 nm, which matches the largest spectral response of crystalline Si solar cells. Eu can be found in the 3+ or the 2+ state in different host materials under different conditions and one of the challenges of the scheme has been to find a suitable host matrix for Eu and Yb that will promote the 2+ for Eu [4-7]. Si-rich silicon oxides (SRSO, composition SiO_x, $x<2$) is here chosen as host here as it's optical absorption appears suitable, partly caused by Si nanostructures. The wide band gap of Si nanostructures can also reduce energy loss in thermalization of photo exited carriers [8], and are widely studied for Si-based solar cells [9-11]. In this work, we deposited (Eu, Yb) co-doped SRSO films, and studied the effects of the SRSO matrix and the anneal temperature on the photoluminescence (PL). The emphasis is on identifying the PL contributions and the processes responsible by correlating with micro-structural characterization after annealing of samples of different composition.

Experimental Details

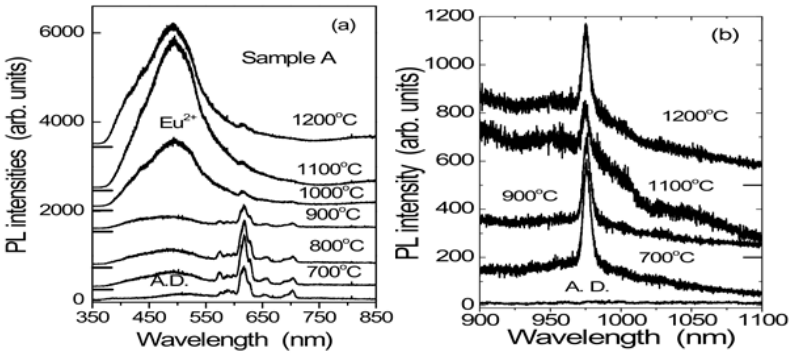
The (Eu, Yb) co-doped SRSO films were deposited on single crystal Si substrates by sputtering from a $Si+SiO_2+EuYbO$ composite target in a pure Ar plasma under a working gas pressure of 0.8 Pa. The EuYbO target was made by hot-pressing a mixture of high purity Eu_2O_3 (99.99%) and Yb_2O_3 (99.99%) powders. Quartz plates were attached on the surface of the EuYbO target to control the doping concentrations of Eu (Yb), and small pieces of Si plates were put on the surface of quartz plates to adjust the Si excess in the final films. We will report on samples from two different SRSO sputter runs with different Si excess, here called sample A and sample B, where B has nominally the largest Si excess. As reference we use a sputtering with no Si excess, called sample C. The



composition of the films was measured by Rutherford Backscattering Spectrometry and listed in Table I.

TABLE I. THE FILM COMPOSITIONS OF SAMPLES A, B AND C.

Sample	Si [at.%]	O [at.%]	Eu [at.%]	Yb [at.%]	Thickness [Å]
A	30.6	65.7	2.3	1.4	3900
B	33.1	63.5	1.8	1.6	3100
C	30.8	66.3	1.5	1.4	4100

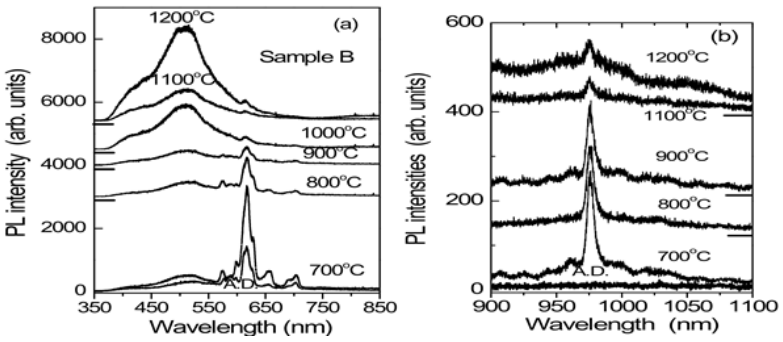


The samples were cleaved into small pieces and annealed in flowing N_2 for 30 minutes at temperatures in the range of 700-1200 °C. The structure of the films was studied by transmission electron microscopy (TEM) equipped with energy dispersive X-ray spectroscopy (EDS). The PL was excited using the 325 nm line of a He-Cd laser and was detected in the range of 350-1100 nm by a spectrometer employing a charge-coupled device (CCD) array. Time-resolved emission spectrum was recorded by using an FLS920 fluorescence spectrophotometer. All the PL measurements were performed at room temperature.

Results and Discussion

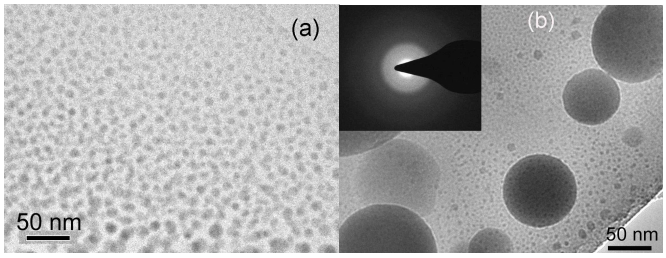
Figs. 1 The Pl Spectra of Sample c, a.d. or Annealed in N_2 for 30 Minutes at the Temperatures as Indicated.

Figure 1(a) Shows the PL spectra of sample C as-deposited (A.D.) or annealed in N_2 at the temperatures as is indicated. The spectra are recorded in the range of 350-850 nm indicative of emissions from Eu ions and the host matrix. The spectrum of the A.D. sample has a weak broad band (450-560 nm) and several sharp peaks at 579, 598, 617, 655, and 704 nm, respectively. The peaks are corresponding to the $^5D_0 \rightarrow {}^7F_J$ (J= 0, 1, 2, 3, 4) transitions of Eu^{3+} ions. Among them, the 617 nm peak is the dominant emission. After 700 °C annealing, the intensity from the Eu^{3+} 617 nm peak reaches the maximum value, the broad band is enhanced with peak position at 500 nm, and a ~ 430 nm shoulder appears on the spectrum. Increasing the anneal temperature further to 1000 °C, results in a large decrease of the Eu^{3+} emissions and the broad bands decrease in intensity leaving the 430 nm band the dominant component. However, after 1200 °C annealing, the 430 nm band intensity decreases while the Eu^{3+} peak become dominant again. Figure 1(b) shows Yb^{3+} PL spectra of the reference sample C after the above anneal temperatures. The Yb^{3+} PL from the A.D. sample is very weak which is consistent with that the excitation of Yb^{3+} ions is non-resonant to the 325 nm laser line. After 700 °C annealing, the Yb^{3+} PL increases drastically and the PL intensity reaches a maximum value for the 800 °C anneal. Then the intensity decreases gradually with increasing the anneal temperature up to 1000 °C, and the peak intensity is only 36% of the maximum value after the 1000 °C annealing. The intensity of Yb^{3+} PL increases again after the 1200 °C annealing, indicating that after annealing the variation of Yb PL is correlated to that of Eu PL. Since neither Yb^{2+} nor Yb^{3+} ions have emissions in the 450-560 nm region under UV excitation [12], it is then reasonable the broad band comprises contributions from silicon oxide matrix and Eu. Note that the intensity of the broad band decreases with increasing anneal temperature. Defects in the oxide matrix are generally believed to have such an annealing characteristic and could be the source for the band here for this sample.



Figs. 2 The PL Spectra of Sample A, A.D. or Annealed in N_2 for 30 Minutes at the Temperatures as Indicated

Figure 2(a) shows the PL spectra of sample A as a function of the anneal temperature. It can be seen that the A.D. sample has similar spectrum to that of sample C: the Eu^{3+} 617 nm emission is the dominant peak while the 450-560 nm broad band has a peak position at around 515 nm. Also the Eu^{3+} PL intensity reaches the maximum intensity at a 700 °C anneal, the 450-560 nm broad band is enhanced but its peak position blue-shifts to ~ 490 nm. The Eu^{3+} PL intensity then decreases gradually with increasing the temperature further to 900 °C, and the PL peak intensity is 46% of the maximum value after 900 °C anneal. Interestingly, upon 1000 °C anneal the 450-560 nm broad band is enhanced significantly and becomes the dominant emission in the spectrum, while the Eu^{3+} emission peaks are much weaker, together indicating that luminescent centers have formed in the oxide upon 1000 °C anneal. After that, the spectrum intensity from the 490 nm band doubles after 1100 °C anneal, the long wavelength emissions (≥750 nm) are also enhanced implying that Si nanostructures have formed in the oxides. The PL intensity decreases at 1200 °C anneal, but the width of the 490 nm band varied little upon the 1000-1200 °C annealing indicating that the identity of the luminescence centers responsible for the strong band could be constant in this annealing range. The variation of Yb^{3+} PL from sample A with anneal temperatures is similar to that of C as is indicated in Fig. 2(b). Almost no Yb^{3+} PL were observed from the A.D. sample, and after 700 °C annealing the Yb^{3+} emission increases drastically and the PL peak intensity reaches a maximum value. Then the PL intensity decreases gradually with increasing the temperature up to 900 °C. The Yb^{3+} peak becomes stronger again upon the 1100 and 1200 °C annealing, and the peak position is superposed on the emissions possibly from the Si nanostructures, which are precipitated upon high temperature anneal.



The 490 nm broad bands could be attributed to defects in the oxide matrix or to the $4f^6 5d \rightarrow 4f^7(^8S_{7/2})$ transition in Eu^{2+} [2]. The concentration of oxide defects usually decreases with increasing anneal temperature, and the strong increase in this broad band intensity after annealing to 1000 °C and higher is thus not attributed to oxide defects, but is taken as an indication of the formation of luminescent Eu^{2+}-containing silicates. Time-resolved PL of the 490 nm band (not shown) indicates that the luminescence does not have a single exponential decay but can be characterized by a mean decay lifetime (τ_{ave}) given by $\tau_{ave} = \int_0^\infty t \times I(t)dt / \int_0^\infty I(t)dt$, where I(t) is the luminescence intensity as a function of time t [4]. The average lifetime is calculated to be about 20 ns. This value does not conflict with the many indications for the radiation being due to transitions in Eu^{2+}. Luminescent Eu^{2+}-containing silicates may thus have formed in sample A.

Figures 3(a) and 3(b) show the PL spectra of sample B after annealing in N_2 at the temperatures similar to those of A. The variation of the PL spectrum with increasing anneal temperature is similar to those of A, but the Yb PL intensities decrease much, more for the B sample than for the A sample, especially upon high temperatures (1100 and 1200 °C) annealing.

Figs. 3 The PL Spectra of Sample B, A.D. or Annealed in N_2 for 30 Minutes at the Temperatures as Indicated.

TEM study was performed to investigate the correlation between structural evolutions and the PL of the films. For film A, after 700 °C annealing an unevenly distribution of grey tones was observed; some degree of phase separation seems to have occurred and precipitates are interconnected to form a network (not shown). After 1000 °C anneal, Fig. 4(a) shows that many well-defined dark dots have formed in the film with sizes of tens of nanometers. The dots are (Eu, Yb, Si, O) mixtures from EDS analysis, while the Eu and Yb concentrations remaining in the SRSO matrix are very low from EDS line-scanning analysis around the dots (not shown). Figure 4(b) shows that after 1200 °C anneal, larger precipitates have aggregated with sizes ranging from tens to hundreds of nanometers. These precipitates have amorphous nature from their selected area diffraction patterns as shown in the inset of Fig. 4b. Recalling the PL results (Fig.2(a) and Fig. 3(a)), there is a transition when the Eu^{3+} PL decrease after 800-900 °C annealing followed by an increase of Eu^{2+} PL after 1000 °C and higher temperature anneal. The amorphous (Eu, Yb, Si, O) mixtures are then believed to the silicates we above expected to be responsible for the Eu^{2+} luminescence. High resolution TEM observation confirms that Si nanocrystals have also formed after the 1200 °C annealing. The nanocrystals have clear lattice fringes with an average size of ~ 5 nm (not shown). This fact infers that tiny Si clusters (or Si-rich clusters) may have formed in sample A upon the 1000 °C or even 700 °C annealing, but are not detected by standard imaging TEM. Similar phenomena were observed in the sample B after 1200 °C anneal, but no Si nanoclusters were observed in sample C.

Figs. 4 TEM Images of Film A after Annealing in N_2 at (a) 1000 °C and (b) 1200 °C.

The decrease of Eu^{3+} PL in the samples is interpreted as part of the Eu^{3+} ions being reduced to Eu^{2+} ions. The reason for no Eu^{2+} PL being observed in the annealed samples below 1000 °C annealing, could be attributed that the Eu^{2+} ions exist dispersively in the oxides and the excited electrons in the energy levels of the Eu^{2+} ions may non-radiatively relax into the ground state, since the high covalency of Eu-O bond could produce a large offset of the 5d configuration. Similar phenomena were reported by Liu et al [13].

If we compare the visible PL intensities of the above annealed samples, those PL intensity of sample B are stronger than those of A, while those of A and C have comparable PL strength for annealing temperatures below 900 °C. The differences of the PL strengths are likely due to the highest Si excess in sample B while only a small excess in sample A. Generally a suitable Si excess will promote formation of small Si nanostructures (~ 1-3 nm) upon annealing. The nanostructures (clusters, dots, frameworks) have wide "band gaps" and enhance the Eu^{3+} emission by absorbing the radiation and transferring the excitation energy to Eu ions [14]. And for the PL intensities of samples A and B are considerably stronger than those of C upon higher temperature (≥ 1000 °C) annealing. The

overall (course) picture is that in all these samples Eu^{2+}-containing silicates have formed yielding higher PL intensity. The Yb PL intensities of sample A are several times larger than those of C, those of B are also stronger than those of C but the increments are less. Note that the Yb^{3+} PL vary correlated with the Eu^{3+} (or Eu^{2+}) PL for all the samples. This kind of correlation can be observed if there is a transfer of excitation energy from Eu to Yb, or the Yb^{3+} PL and the Eu PL are excited through a common energy transfer process such as by the oxide defects and/or Si nanostructures. Detailed excitation mechanism of Eu and Yb^{3+} ions is being examined and will be reported elsewhere.

Summary

We have investigated the annealing behaviors of PL from (Eu, Yb) co-doped in SiO_2 or SRSO sputtered films. Compared to SiO_2 host, SRSO gives stronger emissions from the Re ions. Luminescent Eu^{2+}-related silicates have formed under high temperatures annealing and the silicates seen by TEM contain (Eu, Yb, Si, O) aggregates. These results could be of interest in Si based solar cells as well as for other applications like lightening, displays and optical storage.

This work was financially supported by grant from Specialized Research Fund for the Doctoral Program of Higher Education (SRFDP) (20111101120021).

Keywords: Polyvinylidene difluorid; Polyurethane; Composite tubular membrane; Compatibility; Water flux

Abstract： The compatibility of polyvinylidene difluorid (PVDF) and polyurethane (PU), the thermodynamics of the PVDF/PU/DMF (N-N-Dimethylformamide) membrane-forming systems were studied, and the composite tubular membranes of PVDF/PU-PET knitted fabric tube were prepared by the immersion precipitation phase inversion method. The results showed that the PVDF/PU system was partly compatible by the measurements of the solubility parameter theory, the mixing enthalpy, the viscosity. With PU content increasing, the gelation values increased and the instantaneous liquid-liquid phase separation was preferred to occur. The water flux of the composite tubular membranes were enhanced from 1264.81 to 2165.35 $L/m^2.h$ with PU content increasing from 10wt% to 40wt%, which resulted from the an increment of the membrane porosity and the improvement of the hydrophilicity.

Introduction

Membrane and membrane process have been applied extensively in many application fields. Asymmetric PVDF ultrafiltration and microfiltration membranes have some advantages with a high temperature resistance, difficulty to blocking and easy to cleaning. Nevertheless, there are still some troublesome problems for PVDF ultrafiltration and microfiltration membranes. The very low surface energy of PVDF results in the poor hydrophilicity of PVDF membrane, which not only decreases low pure water fluxes, but also causes the membranes to be easily contaminated by protein and other macromolecules[1]. To prepare hydrophilic PVDF membranes, hydrophilic polymer additives[2], such as polyethylene glycol (PEG), polyvinyl-pyrrolidone (PVP), perfluorosulfonic acid and poly(methylmethacrylate) (PMMA), amphiphilic copolymers like poly(methyl methacrylate polyoxy- ethylene methacrylate), poly(ethylene oxide-polypropylene oxide- polyethylene oxide) and many inorganic nanoparticles, such astitanium dioxide (TiO_2) and aluminum oxide (Al_2O_3), have been used. Polyurethane (PU) with excellent toughness and good hydrophilicity is a proper modified material for PVDF membrane because PU could compensate greatly the tenacity and hydrophilicity. Xi et al. prepared the asymmetric blend hollow fiber membranes made from a casting dope containing poly(vinylidenefluoride)/thermoplastic polyurethane/ polyvinyl-pyrrolidone/N, N- dimethylacetamide[3]. Hu et al. fabricated the PVDF/PU blend flat membranes through the method of immersion-precipitation process[4]. On the other hand, due to the poor intensity of PVDF homogeneous membrane, the composite PVDF membranes with a support layer also have been paid more and more attentions. For example, Bottino et al. prepared

PVDF membranes cast on the outer surface of a porous braid tubular support. The stretching action of the support on the forming membrane during water coagulation may be responsible for the formation of pore with sizes in the range of a few hundred of nanometers[5]. Tang et al. fabricated the PVDF-HFP composite polymer electrolyte membranes supported by non-woven fabrics which boast good mechanical strength and excellent electrochemical properties[6].

In this work, the PVDF/PU compatibility was discussed by the solubility parameter, mixing enthalpy, the viscosity of PVDF/PU casting solutions. The composite tubular membranes of PVDF/PU-PET knitted fabric tube with high intensity and good hydrophilicity were prepared by the immersion precipitation phase inversion of a binary PVDF/ PU-solvent solution cast on the outer surface of a polyester tubular knitted fabric and the effects of PVDF/PU ratios on the structure and properties of the composite membranes were investigated.

Experimental

Materials

PVDF (FR904, Mw = 2×10^6, Mn = 4.7×10^5) was supplied by Shanghai 3F Ltd. China. PU was supplied by Yantai Wanhua Co., Ltd, China. N-N-Dimethylformamide (DMF) was the reagent grade, and used as the solvent. Polyvinylpyrrolidone (K30) was used as additives in PVDF/DMF solution. Distilled and deionized water was used as coagulant.

Preparation of Blend Solutions And Determination Of The Gel Values

A certain percentage of PVDF, PU and DMF mixtures at 60 ^{0}C were heated and stirred to dissolve, until a homogeneous solution were obtained. The viscosities of PVDF/PU blend solutions with different components were measured by the rotating viscometer. The gel values of blend solutions were determined through the turbidity method [7]. Here the gel value referred to the amount of non-solvent water that made 15g blend solution gel.

Preparation Of Pvdf/Pu Composite Tubular Membranes

Set the woven PET tube on the glass rod, and immerse the glass rod into the casting solution for 10s. The casting solution was fully saturated with the woven PET tube, then the glass rod with the woven PET tube was lift from the casting solution and the excess solution flowed into the casting solution. The tube was dipped into in deionized water, and the casting solution quickly gel to obtain the tubular composite membrane.

The Performance Determination of Pvdf/Pu Composite Tubular Membrane

Membrane module was prepared firstly. 10 tubular membranes were placed in the glass tube with a length of 30 and the inner diameter of 5cm, and both ends were encapsulated by the epoxy. Water flux was test in view of the outside pressure and the cross-flow mode. The membrane module was pre-pressured at 0.1MPa for 20min, until the water flux was basically stable, and the data were recorded. After washing with the buffer solution with pH 7.4, the static contact angles were measured for10 times. The morphologies of the membrane surfaces were examined on a scanning electronic microscope (JSM-6510, JEOL, Japan) after coating with gold under vacuum.

Results and Discussion

Prediction of PVDF/PU Compatibility with Solubility Parameter Theory

Generally, if the absolute difference of solubility parameters of the two kinds of polymers was greater than 0.5 $(J/cm^3)^{1/2}$, two kinds of polymer are partly miscible; if the absolute difference was less than 0.5 $(J/cm^3)^{1/2}$, the blend system is homogeneous miscible. That is to say, the closer the solubility parameter of two kinds of polymers, and the better the miscibility[8]. The solubility

parameter of PVDF (δ_1) is 23.2 $(J/cm^3)^{1/2}$, the solubility parameter (δ_2) of polyurethane is 20.8 $(J/cm^3)^{1/2}$. A difference of 2.4 $(J/cm^3)^{1/2}$ of the solubility parameters is greater than 0.5 $(J/cm^3)^{1/2}$, then the blend of PVDF and PU is partially compatible.

Mixing Enthalpy Calculation of the Mixture and Prediction of Blend Compatibility

It can be seen by the thermodynamic theory that polymer blends can form a fully miscible system when the free energy of mixing is less than zero ($\Delta G = \Delta H - T\Delta S < 0$). Because the change of mixing Entropy (ΔS) is small for polymer blend, mixing enthalpy (ΔH) of the system can be used to determine the miscibility. Schneier raised the mixing enthalpy calculation of two polymer blend[9].

$$\Delta H = \left\{ x_1 M_1 \rho_1 (\delta_1 - \delta_2)^2 \left[\frac{x_2}{(1-x_2)M_2\rho_2 + (1-x_1)M_1\rho_1} \right]^2 \right\}^{1/2} \quad (1)$$

Where $x_{1,2}$, $\rho_{1,2}$, and $M_{1,2}$ a are the mole fraction of polymer, the polymer density, and molecular weight of monomer unit, $\delta_{1,2}$ is the polymer solubility parameter.

The critical value of mixing enthalpy for the thermodynamic miscible system is 41.868×10^{-3} J/mol (10×10^{-3} cal/mol). When the mixing enthalpy is below the critical value, the blend system is fully miscible, when the mixing enthalpy is above the critical value, the blend system is fully immiscible, while the blend was a part compatible system, as the mixing enthalpy intersects the critical value. The mixing enthalpy was calculated with varying the ratio of PVDF and PU. The curve of the mixing enthalpy with varying the ratio of PVDF and PU was shown in Fig. 1. Mixing enthalpy curves of the blends and the baseline 41.868×10^{-3} intersected each other, which suggested that PVDF and PU blend was a partly miscible system in view of the thermodynamics. When the mass ratio of PU was less than 30%, the mixing enthalpy was lower than 41.868×10^{-3}, which suggested that polymer blends were compatible and were proper to prepare the membranes.

Viscosity of PVDF/PU Blend Solution and Compatibility

The viscosity of polymer blend solution was used to describe the compatibility. The curves of viscosities of blend solution with varying the ratio of PVDF and PU were shown in Fig. 2. If the curves were linear, the polymer blend was miscible thermodynamically. If the curves were non-linear, the polymer blend was partly miscible thermodynamically. If the curve was S-like, the polymer blend was not fully miscible thermodynamically[10]. As seen from Fig. 2, the curve of viscosity and PU mass ratio took on a non-liner relation, therefore PVDF/PU blend system was partly compatible, which accorded with the prediction above.

Thermodynamic Properties of Casting Solutions with Different PVDF/PU Ratio

Coagulation value reflects the stability of the thermodynamic properties of polymer solution[11]. As shown in Fig. 3 for PVDF/PU/DMF blend solutions, the coagulation value gradually increases with PU content increasing, which reveals that the coagulation value of neat PVDF solution is smaller than that of the neat PU solution. The gel value implies the ability to resist the gel for the polymer solution. The higher the gel value, the stronger the resistance ability to gel， and vice versa. On the phase diagram of PVDF/PU/DMF system, the area of homogeneous phase increases with the coagulation value increasing, more non-solvent was needed to make the blend solution precipitate.

PVDF is a crystalline polymer, so the solid-liquid phase separation happens, which induces the gelation of the casting solution[12]. While the liquid-liquid phase separation mainly happens for PU of a non-crystalline polymer. The gelation and crystallization starts simultaneously for crystalline polymer. On the ternary phase diagram, the line of the solid-liquid phase separation lies in the homogeneous zone of the liquid-liquid phase separation. During the coagulation process of casting solution, the components of the blending system firstly go through the line of the liquid-solid phase separation, and then reach the liquid-liquid phase separation area. Therefore, the coagulation value

causing the liquid-solid phase separation is less than that of the liquid-liquid phase separation. For PVDF and PU, with PVDF content reduction and the increase of PU content, the coagulation value increased, which suggested that the phase separation was transformed from the solid-liquid demixing to the liquid-liquid deminxing for PVDF/PU blend casting solution. As a consequence, compared with the liquid-liquid deminxing, the solid-liquid demixing was the delayed phase separation behavior. The instantaneous phase separation leads to the formation of membranes with macrovids, while the delayed phase separation easily induces the formation of the cellular pores in the membrane cross-section.

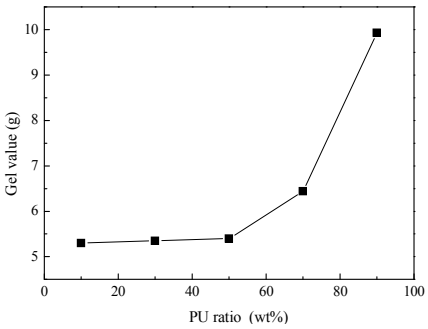

Fig. 3 The relation of gelation values of casting solution

Performance of Tubular Composite Membranes

The round tubular knitted fabric was woven on the 12-pin hand flat knitting machine weft through the way of the weft. The process parameters were as followed: 10-pin, yarn count of 32, the yarn root of 2. The parameters of woven tube are as follows, the inner diameter of 4.48mm, full coefficient of 11.28, the horizontal density of 44, the vertical density of 36, and total density of 1584. The ratio of PVDF to PU with 90/10, 80/20, 70/30, 60/40 was choose to prepare the tubular PVDF/PU-knitted fabric composite membranes. As seen from Tab. 1, the change of the tube diameters and membrane thicknesses were negligible with using different *w*(PVDF)/*w*(PU). Contact angles of several membranes changed little. But, with PU content increasing, water flux gradually increased. SEM surface photos of PVDF/PU tubular composite membranes were presented in Fig.5. With PU content increasing, surface morphologies of four types of tubular composite membranes were very distinct, and more PU was used, the membrane surface was more rough and porous, which resulted in water fluxes of composite membranes enhancing.

TAB.1 STRUCTURE AND PERFORMANCE OF FIVE TYPES OF PVDF/PU TUBULAR COMPOSITE MEMBRANES

Composite membranes	*w*(PVDF) /*w*(PU)	Outer diameter/mm	Membrane thickness/mm	Contact angle/ °	Water flux/L·(m^2·h)$^{-1}$
A	90:10	5.54	0.72	90.4	1264.81
B	80:20	5.24	0.70	86.8	1407.22
C	70:30	5.12	0.60	82.1	1521.37
D	60:40	5.44	0.60	78.2	2165.35

Note: the casting solution *w*(PVDF/PU)/*w*(PVP)/*w*(PgOH)/ *w*(H_2O)/*w*(DMF)=10:3:3:2:82.

Changes in the structure and properties of several tubular composite membranes were mainly due to the increase of PU content which decreased the viscosity of the casting solution, changed the thermodynamic properties of casting solutions and made the PVDF/PU compatibility be worse. On one hand, with PU content increasing, the decrease of the viscosity of the casting solution made the exchange speed of solvent and nonsolvent increase and speeded up the phase separation process, which was propitious to the generation of membranes with macroporous structure. On the other

hand, as described in Section 3.4, with PU content incresing, the phase separation of PVDF/PU/DMF/H_2O membrane-forming system was shift from a slow solid-liquid demixing to a rapid liquid-liquid phase separation, and then the membrane with a high porosity tended to be fabricated. As a result, the water flux was improved. In additional, the decline of PVDF/PU compatibility with PU content increasing led to the phase separation in the membrane and the formation of the interface pores, which could enhance the water flux[5]. But, as PU content increased to 30wt% and 40wt%, the size stability of the composite membrane decreased and membrane surface was coarse, therefore, PU content was controlled under 30wt%.

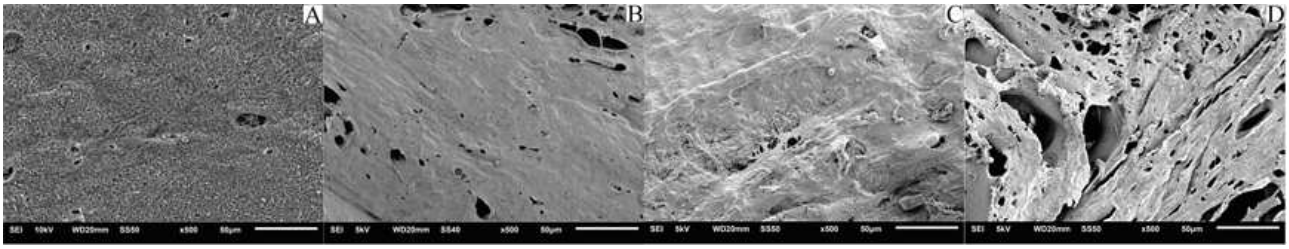

Fig 4. SEM surface photos of PVDF/PU tubular composite membranes
A: PVDF/PU=90/10 B: PVDF/PU=80/20 C: PVDF/PU=70/30 D: PVDF/PU=60/40

Conclusions

PVDF/PU blend was a partially compatible system through the measurements of solubility parameters, the theoretical calculation of the mixing enthalpy, the viscosity of PVDF/PU casting solutions and the structure of PVDF/PU flat sheet membranes. Blends significantly changed the thermodynamic properties of the PVDF/PU/DMF casting solutions. The coagulation values increased with PU content increasing, i.e. the phase behavior of the membrane-forming system transformed from the solid-liquid demixing to the liquid-liquid demixing. With PU content increasing, water flux of the composite tubular membranes of PVDF/PU-PET tube gradually increased, which resulted from the enhancement of membrane porosity and membrane hydrophilicity.

Keywords: PVDF, two-dimensional braid, hollow fiber membrane, heterogeneous-reinforced

Abstract: The two-dimensional braid heterogeneous-reinforced (BHR) polyvinylidene fluoride (PVDF) hollow fiber membranes which include PVDF polymer solutions (coating layer) and the two-dimensional braid as a reinforcement were prepared through the dry-wet spinning process. The influence of PVDF concentration in polymer solutions on performance of BHR hollow fiber membranes were investigated by terms of pure water flux, protein rejection, a mechanical strength test, and morphology observations by a scanning electron microscope (SEM). The results of this study indicated that the tensile strength of the BHR PVDF hollow fiber membranes was nearly 75 MPa and the hollow fiber membranes were endowed with better flexibility performance. The BHR PVDF hollow fiber membranes had a favorable interfacial bonding between the coating layer and the two-dimensional braid. The pure water flux decreased, while the rejection ratio increased with the increase of polymer concentration.

Introduction

Nowadays, the applications of membrane technologies have been extensively used in separation facilities to separate mixtures because of their flexibility and capacity to remove contaminants from wastewater to low levels [1].The hollow fiber membranes are mechanically self-supporting and easy to assemble in modules which are attractive for industrial use. And such membranes have been widely applied in Membrane Bioreactor (MBR) systems [2]. The MBR has emerged as an attractive technology for advanced municipal and industrial wastewater treatment, and offers many advantages over conventional wastewater treatment processes, including low sludge production, very good quality effluent and reduced footprint [3]. But in the MBR filtration process, hollow fiber membranes are liable to be damaged and broken by the high-pressure water cleaning process or disturbance of the aerated airflow. In the use of such water treatment, the filtration membrane is required, not only for its being superior in separation performance and permeation performance, but also for its high mechanical property [4].

Currently, the most popularly used Ultrafiltration (UF) and Microfiltration (MF) hollow fiber membranes which composed of skin layer and support layer, are prepared through the immersion-precipitation method. Normally, these hollow fiber membranes have high permeability but low mechanical endurance [5]. As a semi-crystalline polymer, PVDF has widespread applications because of its excellent properties, such as good mechanical strength, stability against vigorous chemicals, and good thermal stability [6, 7]. In the past, PVDF membranes prepared by wet or dry–wet spinning method were known as filtration membranes. Further, since these

membranes were produced by being separated in microphase, an adequate molecular orientation is not obtained, and the tensile strength of the filtration membranes is as little as about 3 MPa [8, 9].

In this study, according to the theory of thermodynamic compatibility and the principle of skin/core composite spinning of chemical fiber, hollow fiber membranes that included PVDF casting solution as the coating layer and the two-dimensional braid which has an excellent mechanical strength as the support for the separation membrane were prepared through the dry-wet spinning process. The process was called the two-dimensional braid heterogeneous-reinforced (BHR) method. The mechanical properties of the BHR hollow fiber membranes and the effects of the PVDF concentration in the polymer solutions on the membrane structure and membrane filtration properties were studied.

Experimental

Materials

PVDF (W no. 1300 powders, Tm = 170 °C) was purchased from Kureha Chemical Industrial Co., Ltd. (Tokyo, Japan). PAN filaments were supplied by Xiangying Special Fiber Co., Ltd (Changshu, China). N,N-dimethylacetimide (DMAc, > 99%) and Polyvinylpyrrolidone (PVP,K30, Mw = 30,000) were obtained from Tiantai Fine Chemical Co., Ltd. (Tianjin, China). Tween 80 (Tw-80) was purchased from Tianjin Fengchuan Chemical Reagent Science and Technology Co., Ltd. (Tianjin, China).

Preparation of Two-Dimensional Braid Heterogeneous-Reinforced PVDF Hollow Fiber Membranes

The PAN filaments were braided into a two-dimensional hollow tubular braid as the reinforced matrix via two-dimensional braid technology. The two-dimensional braid were cleaned with a neutral liquid detergent for removing the oil which coating the PAN filaments surface during spinning process, dried at 25°C，and winded for next process. Fig.1 showed the surface SEM morphology of the two-dimensional braid which showed a rhombus structure.

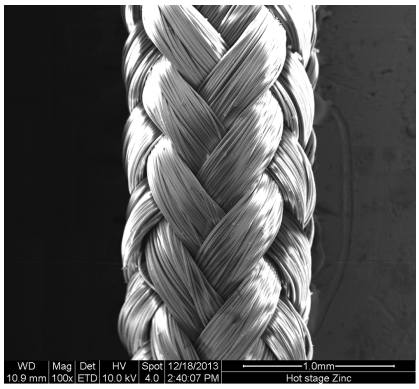

Fig.1. The two-dimensional braid structure

The BHR hollow fiber membranes were prepared using the dry–wet spinning method. Fig. 2 showed the spinning apparatus. According to the method described, the PAN two-dimensional braid were coated with the polymer solutions and guided through a precipitation bath, where the polymer solutions were converted into a microporous layer. The polymer solutions were prepared by the blending of different compositions consisting of PVDF, PVP K30, Tw-80 and DMAc (Table 1), under constant mechanical stirring in a three-necked round-bottom flask for 6 h at 70°C. All the membranes were prepared under an environmental temperature of 25°C and at an environmental

humidity of 60%. The BHR hollow fiber membranes with the different PVDF concentrations, i.e., 8, 10, 12, 14 and 16 weight (wt.%) were labeled F8, F10, F12, F14 and F16, respectively. Before the scanning electron microscope (SEM) tests, we put the resulting membranes in glycerol water solutions (three parts glycerol to two parts water) and then dried them in air, so as to retain the porous structure.

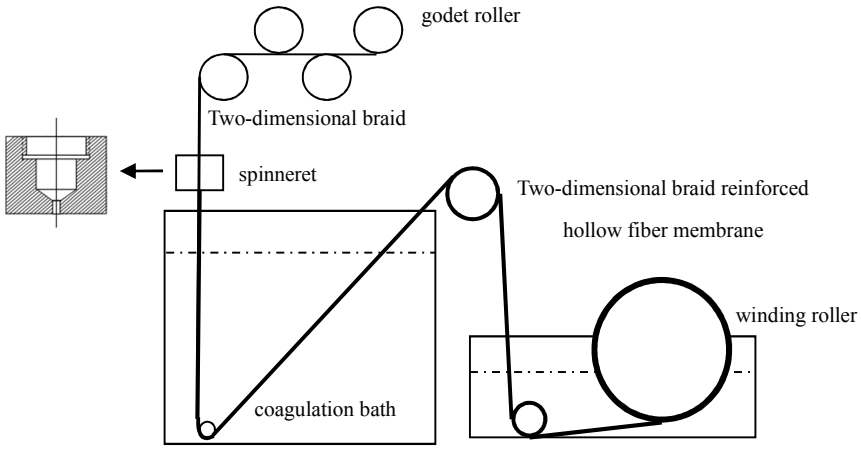

Fig.2. Schematic diagram describing the BHR PVDF hollow fiber membrane induced by the dry–wet spinning process

TABLE 1 SPINNING PARAMETERS OF BHR PVDF HOLLOW FIBER MEMBRANES WITH DIFFERENT DOPE COMPOSITION

Prepared membrane	Dope composition			
	PVDF [wt.%]	PVP [wt.%]	Tw-80 [wt.%]	DMAc [wt.%]
F8	8	8	2	82
F10	10	8	2	80
F12	12	8	2	78
F14	14	8	2	76
F16	16	8	2	74
Dope solution temperature		70 [°C]		
Extra coagulation Water		25 [°C]		
Air gap		15 [cm]		
Take up speed		15 [cm·min^{-1}]		

Membrane Characterizations

Tensile Break Strength Measurements

The tensile strength and elongation at break of the hollow fiber membranes were determined at room temperature by using a CMT4204 electronic universal testing machine (Shenzhen, China). The tensile rate was 10 mm·min^{-1}, and the clamping length was 100 mm.

Morphology Examination

The morphology of the membranes was observed using SEM (Quanta200, FEI, Czech). The samples were frozen in liquid N_2, followed by fracturing to expose their cross-sectional areas. Thereafter, they were sputtered with gold and recorded through SEM.

Membrane Permeability

The pure water flux (PWF) of the membranes was determined using Eq. (1). The pressure difference across the membrane was 1 bar under the condition of outside feeding. The membrane module contained three hollow fiber membranes with an effective length of 18–20 cm.

$$J = \frac{V}{S \times t \times P} \quad (1)$$

Where J is the PWF ($L \cdot m^{-2} \cdot h^{-1} \cdot bar^{-1}$), V is the quantity of the permeate (L), S is the membrane area (m^2), t is the testing time (h), P is the pressure (bar).

The filtration experiments were carried out using the protein solution. The rejection of the membranes was measured with 1 $g \cdot L^{-1}$ bovine serum albumin (BSA) solution and calculated using Eq. (2).

$$R\ (\%) = \left(1 - \frac{C_p}{C_f}\right) \times 100\% \quad (2)$$

Where C_p and C_f are the concentration at permeate and feed, respectively.

Each membrane was initially pressurized for 20 min at 1.5 bar. The pressure was then reduced to the operating pressure of 1 bar, and the PWF was measured. Before the protein filtration, the membranes were compacted at 1 bar for 60 min, then, the rejection was measured at 1 bar.

Porosity Determination

The membrane porosity (ε) was defined as the pores' volume divided by the total volume of the porous membrane. It can be determined by Eq. (3):

$$\varepsilon = \frac{(w_1 - w_2)/\rho_1}{(w_1 - w_2)/\rho_1 + (w_2 - w_3)/\rho_2 + w_3/\rho_3} \times 100\%, \quad (3)$$

where W_1 and W_2 are the weights of the wet and the dry membranes, respectively, W_3 is the weight of the two-dimensional braid, ρ_1 is the water density, ρ_2 is the polymer density (1.78 $g \cdot cm^{-3}$), ρ_3 is the two-dimensional braid density (1.15 $g \cdot cm^{-3}$).

Maximum Pore Size of the Membrane

The maximum pore size of the membranes was obtained using the bubble point method with alcohol as wetting liquid and calculated using Eq. (4)

$$r_p = \frac{2\gamma}{P} \quad (4)$$

Where r_p is the maximum pore size of the membrane (μm), γ is the surface tension at the alcohol/air interface ($N \cdot m^{-1}$), and P is the pressure. At room temperature (20 °C), γ is equal to 22.32 $\times 10^{-3}$ $N \cdot m^{-1}$.

Results and Discussions

Mechanical Properties of the BHR PVDF Membrane

Fig. 3 showed the tensile strength of the PAN two-dimensional braid and its heterogeneous-reinforced PVDF hollow fiber membrane. The traction of the winding device made the fibers braided into a tubular fabric such as a hollow fiber, during the two-dimensional braiding process. The different systems fibers were braided each other, and produced a lot of space between the fibers. Therefore, some of the casting solutions could infiltrate into the space in the spinning process, which could improve the interface between the two-dimensional braid and the surface separation layer after being immersed into coagulation bath [9]. When the two-dimensional braid was stretched, there was only a small tension could produce a great tensile deformation which displayed a little stress and a large tensile region before point A from Fig. 3 (a). From point A to B, with the tension increasing, the braiding angle decreased due to the deformation of the rhombus

braiding structure. At this time, if removed the tension, the deformation could be restored. But the deformation was irreversible after point B.

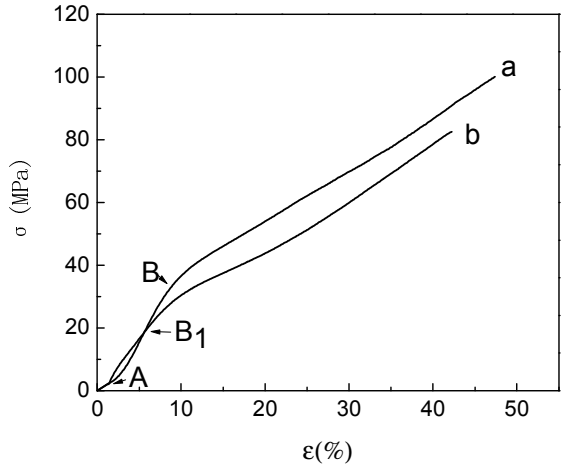

Fig.3. The mechanical properties of PAN two-dimensional braid reinforced hollow fiber membranes (a) Two-dimensional braid; (b) BHR PVDF hollow fiber membrane

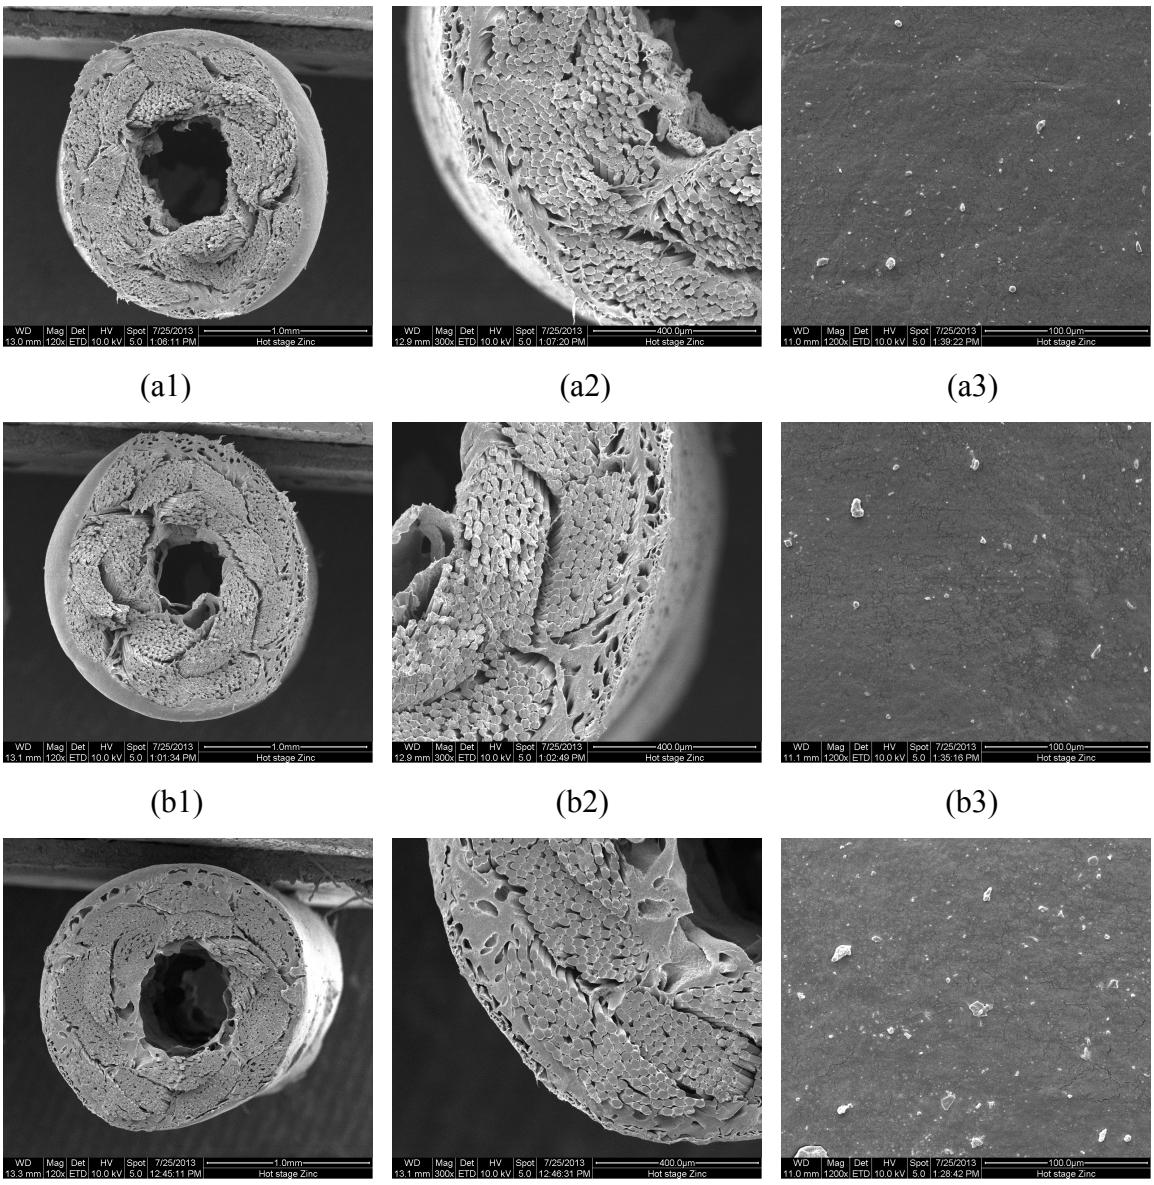

Fig. 3 showed that both of the breaking strength and breaking elongation of the BHR hollow fiber membrane were lower than that of the two-dimensional braid. But curve (b) and (a) were overlap before point A, then curve (b) was higher than curve (a) between point A and B1, and last curve (b) was lower than curve (a) after the point B1. This phenomenon occurred because the polymer solution were not only coated on the surface uniformly, but also permeated into the space of the two-dimensional braid. After immersed into coagulation bath to forming the surface separation layer which increasing the friction between the fibers and the part embedded within space which hindered the rhombus braid structure and pores deformation, thus the breaking strength and elongation of the BHR hollow fiber membrane were smaller than the two-dimensional braid. In the initial stage, before point A the polymer solution infiltrated into the partial space, but not completely filled all the interspaces, when subjected to axial tension the structure of the parts where polymer solution were not infiltrated were deformation which showed a little stress and a large tensile region. From point A to B1, with the stretch continuing the polymer that embedded in the space hindered the deformation of the braid structure. After point B1, the surface separation layer increased the friction between the fibers which made the breaking strength and breaking elongation of the BHR PVDF hollow fiber membrane lower than that of the two-dimensional braid.

We know that the tensile strength of PVDF membranes prepared by the wet spinning method was nearly to 1-3 MPa [10, 11]. A low tensile strength of PVDF membrane may easily cause fiber breakage in the state of serviceability. The BHR PVDF hollow fiber membranes prepared by the BHR method had higher mechanical properties. The tensile strength of the BHR PVDF hollow fiber membranes was nearly 75 MPa, which was adequate for MBR applications.

Morphologies of BHR PVDF Hollow Fiber Membranes

Fig. 4 showed the structure of the hollow fiber membranes prepared in different PVDF concentrations (8, 12 and 16 wt.%) in the polymer solutions by the BHR method. Fig. 4 (a1, b1, c1), (a2, b2, c2) and (a3, b3, c3) showed the whole cross-sectional structure of the membrane, the enlarged structure and outer surface, respectively. Fig. 4 (a2, b2, c2) showed three parts near the outer surface of the HR membranes. The outermost layer was the PVDF coating layer, and the

innermost layer was the two-dimensional braid. The middle layer, between the PVDF coating layer and the two-dimensional braid, was the interface layer. In the BHR process, some of the polymer solutions infiltrated into the space of the two-dimensional braid and formed the interface which endowed the BHR hollow fiber membranes with high interfacial bonding. Fig. 4 (a3, b3, c3) showed the SEM results of the outer surfaces of the hollow fiber membranes. The outer surface of the BHR PVDF hollow fiber membrane appeared a dense layer.

(a1) (a2) (a3)

(b1) (b2) (b3)

(c1) (c2) (c3)

Fig.4. Cross-sectional and outer surfaces SEM morphology of BHR PVDF hollow fiber membranes: (a) F8, (b) F12, (c) F16

Permeation Properties of the BHR PVDF Hollow Fiber Membranes

Fig. 5 showed the porosity and maximum pore size of the BHR PVDF hollow fiber membranes. The porosity and maximum pore size had the same decreasing tendency as the PVDF concentration increase in the polymer solutions. The BHR PVDF hollow fiber membranes had a denser outer surface, as shown in Fig. 4. This meant that the BHR PVDF hollow fiber membranes possessed a smaller maximum pore size which could improve the rejection of the membrane.

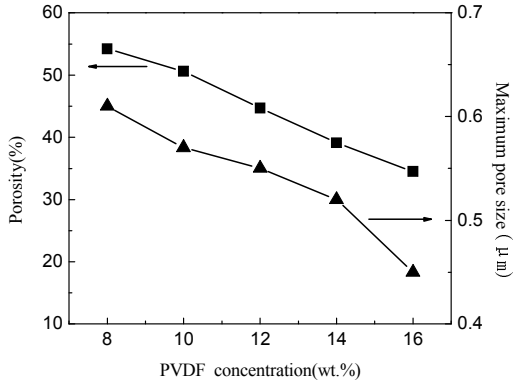

Fig.5. Effects of PVDF concentration on the porosity and maximum pore size

Fig. 6 showed the PWF and protein rejection of the prepared BHR PVDF hollow fiber membranes. According to Fig. 6, PWF of the BHR PVDF hollow fiber membranes decreased slightly from 551.8 (L·m-2·h-1·bar-1) for the F8 to 310.4 (L·m-2·h-1·bar-1) for the F16 membrane with the increase of PVDF concentration from 8 to 16 wt.%. But the rejection ratio increased with the increase of PVDF concentration. The BHR PVDF hollow fiber membranes had a thick wall, which extended the membrane filtration path and increased the intrinsic resistance of the membrane. Therefore, with the increase of PVDF concentration in the polymer solutions, the wall thickness became thicker and the PWF of the BHR PVDF hollow fiber membranes became lower. As the same time, the maximum pore size decreased with the increase of PVDF concentration in polymer solution from Fig. 5 and the pore size was a key factor impacting the membrane permeability. The rejection depended more on the denseness of the skin layer than on the structure of the cross-section [12]. The skin layers of the BHR PVDF hollow fiber membrane were dense and the maximum pore size of the BHR PVDF hollow fiber membranes were small. Thus, with the application of the BHR method, the increasing rate of the protein separation was significant for some special water treatment.

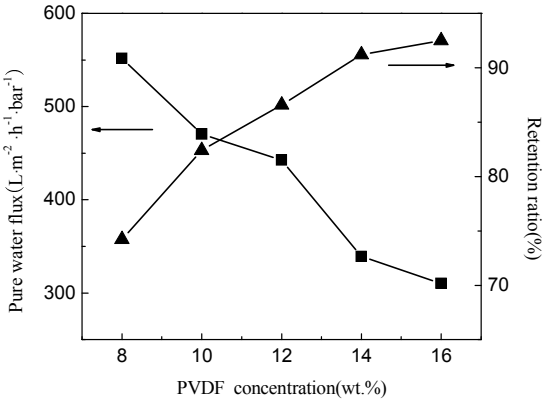

Fig.6.Effect of the PVDF concentration on pure water flux and protein rejection of the membranes

Conclusion

The BHR PVDF hollow fiber membranes were prepared through the dry–wet spinning method which coated PVDF polymer solutions on the two-dimensional braid surface. The BHR PVDF hollow fiber membranes prepared by the BHR method had excellent mechanical properties and its

tensile strength was nearly 75 MPa, which was adequate for MBR applications. The BHR PVDF hollow fiber membranes had a favorable interfacial bonding between the coating layer and two-dimensional braid due to the existence of the interface layer. The outer surface of the BHR PVDF hollow fiber membrane was a dense layer as the separating functional layer. The maximum pore size of the BHR PVDF hollow fiber membranes decreased with the increase of PVDF concentration, which could result in lower PWF and higher rejection of protein.

Ketwords: polyvinyl chloride; homogeneous-reinforced; hollow fiber membrane; coagulation bath

Abstract: Homogeneous-reinforced (HR) polyvinyl chloride (PVC) hollow fiber membranes consisting of coating layer and matrix layer were fabricated via coating process. The mixtures of polymer solutions were uniformly coated on the homogeneous PVC matrix membrane which was prepared by melt-spinning method. The influences of ethanol composition in water coagulation bath on structure and performance of HR membranes were investigated. The results showed that the pure water flux of the HR PVC hollow fiber membranes increased with the increase of ethanol weight fraction in coagulation bath, while the porosity changed slightly. The increase of ethanol weight fraction in coagulation bath brought about the decrease of the protein permeation flux and rejection rate. The tensile strength of HR PVC hollow fiber membranes was about 9.5 MPa, while the elongation at break was higher than 97 %.

Introduction

Dual-layer homogeneous-reinforced (HR) hollow fiber membranes were consisted of a functional outer layer and a porous matrix layer in which used the same polymer as the selective layer and the supporting layer. The HR hollow fiber membrane was prepared by HR process, which the matrix membrane was fabricated by the melt-spinning cold-stretching (MSCS) or thermally induced phase separation (TIPS) methods and the functional outer layer was fabricated by the nonsolvent induced phase separation (NIPS) method. The structure of the membrane prepared by MSCS and TIPS methods was more compact than NIPS method which gave the HR membrane the excellent mechanical property [1,2]. The membrane prepared by NIPS method usually had a dense skin layer which gave the HR membrane superior separation performance. Owing to the same polymer in the two layers of HR membrane, the adhesion of the functional outer layer to the matrix layer was better than that of the different polymers. Zhang et al. [3] prepared HR polyvinylidene fluoride (PVDF) hollow fiber membrane by HR method. They found that the HR PVDF hollow fiber membrane had a favorable interfacial bonding between the surface coating layer and the matrix membrane. Compared with the conventional polymeric membrane prepared by one single method, the HR membrane had a higher tensile strength than the membrane prepared via NIPS method, a better anti-fouling property than the membrane prepared via MSCS or TIPS method in the organic filtration.

Polyvinyl chloride (PVC) as a conventional and widely applied polymer, possessed superior performance, such as low cost, excellent physical, chemical (e.g. acids, alkalis and solvent resistance) and mechanical properties [4,5]. Thus, PVC had been widely used to prepare membranes [4-10]. In the previous studies, most of PVC hollow fiber membranes were prepared by NIPS method. These PVC hollow fiber membranes exhibited excellent water permeability, while the mechanical property of the membrane was poor [6]. Owing to the successful preparation of PVC hollow fiber membranes via MSCS method in our previous study [11]. The HR method was used to solve these problems[12] and the studies of ethanol composition in water coagulation bath effect on HR PVC hollow fiber membranes had not been found in open literature.

In this study, the HR PVC hollow fiber membranes were fabricated via coating process. During the spinning process, the mixtures of polymer solutions were coated on the homogeneous PVC hollow fiber matrix membrane uniformly. The influences of ethanol composition in water coagulation bath on structure and performance of HR membranes were investigated by morphology, pure water flux, protein permeation flux, rejection rate and mechanical property measurement.

Experimental

Materials

Polyvinyl chloride (PVC, fiber grade, DG-1000k, the average degree of polymerization is 1030±50) resin was purchased from Tianjin Dagu Chemical Plant (Tianjin, China). PVC hollow fiber matrix membrane was provided by State Key Laboratory of Hollow Fiber Membrane Materials and Processes in Tianjin Polytechnic University (Tianjin, China). N,N-dimethylacetamide (DMAc, Analytical Reagent), Ethanol (EtOH, Analytical Reagent) and Polyvinylpyrrolidone (PVP, Analytical Reagent, K30, Mw=10000) were bought from Tianjin Guangfu Fine Chemical Research Institute. Bovine serum albumin (BSA, Analytical Reagent, Mw=68000) was supplied from Beijing Aoboxing Universeen Bio-tech Co., Ltd.

Fabrication of HR PVC Hollow Fiber Membranes

The HR PVC hollow fiber membranes were fabricated via coating process[12]. The preparation process of HR PVC hollow fiber membranes were consisted of 3 steps. Firstly, the PVC hollow fiber matrix membrane went through the pre-wet solution which contained 60 wt% ethanol solutions. Secondly, the pre-wet PVC matrix membrane went through the coating device. In this process, the polymer solutions consisted of PVC, PVP and DMAc that were blended under constant mechanical stirring in a three-necked round-bottom flask for 4 h at 70 ℃ were coated on the PVC matrix membrane outer surface. Thirdly, the PVC matrix membrane coated with polymer solutions came into different ethanol fraction coagulation bath. After these 3 steps, the HR PVC hollow fiber membranes were prepared subsequently. The spinning parameters of HR PVC hollow fiber membranes were shown in Table 1.

TABLE 1 SPINNING PARAMETERS OF HR PVC HOLLOW FIBER MEMBRANES

Spinning conditions	Value
Dope composition (PVC/PVP/DMAc)/wt%	80/10/10
Matrix membrane	PVC hollow fiber membrane
Mixing temperature/℃	70.0
Spinning temperature/℃	20.0

Pre-wet solution	60wt% ethanol solution			
Pre-wet time/s	20.0			
External coagulation	Water	15wt% ethanol	30wt% ethanol	45wt% ethanol
External coagulation T/℃	20.0			
Air gap/cm	8.0			
Take up speed/m·min^{-1}	2.2			

Membrane Characterizations

Morphology Observation

Scanning electron microscope (SEM, Quanta 200, Netherlands FEI) was used to investigate the morphology of surface and cross-section of matrix and HR hollow fiber membranes. The membranes were immersed in liquid nitrogen for 10~15s and were frozen. Then the frozen membranes were broken for cross-section observation. Samples were all gold sputtered before testing.

Permeation Performance Experiments

The pure water flux (PWF) was measured with hollow fiber membranes at 0.1 MPa pressure under the condition of outside pressure and was calculated by Eq. (1):

$$J = \frac{V}{At} \tag{1}$$

Where J is the permeate flux of membrane (L·m^{-2}·h^{-1}), V is the quantity of permeation (L), A is the effective area of membrane (m^2), and t is the testing time (h).

The filtration experiments were then carried out by 1 g/L BSA solution. Before the filtration experiments, the deionized water was used to feed in the filtration experimental setup for 40 min to stabilize the permeation performance of HR PVC hollow fiber membrane at operating pressure of 0.1 MPa and temperature of 20 ^{o}C. Then the BSA solution was fed into the cross-flow membrane container. After 20 min, the protein permeation flux (PPF) was measured for 20 min and was calculated by Eq. (1). The concentration of feed solution and permeate solution were determined by UV spectroscopy at wavelength of 280 nm, using a PERSEE TU-1901 spectrophotometer (Beijing Purkinje General Instrument Co.,Ltd.). The separation efficiency of the membrane was defined by Eq. (2):

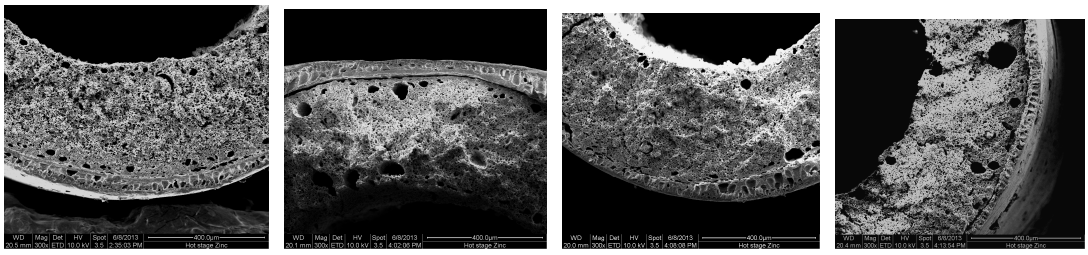
$$R = (1 - \frac{C_p}{C_f}) \times 100\% \tag{2}$$

Where C_f and C_p are the concentration of protein in the feed and the permeate solution, respectively. Porosity determination

The membrane porosity was defined as the pores volume divided by the total volume of the porous membrane. It can be determined by gravimetric method which calculated according to Eq. (3):

$$\varepsilon(\%) = \frac{W_1 - W_2}{(\pi/4)(D^2 - d^2)l\rho} \times 100\% \tag{3}$$

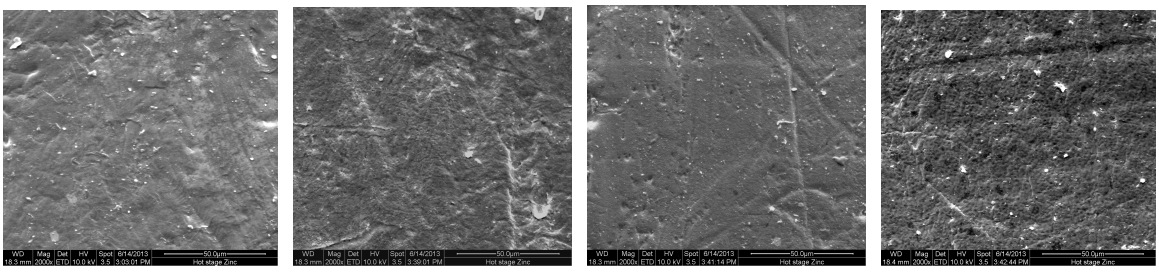
Where W_1 is the weight of wet membrane (g), W_2 is the weight of dry membrane (g), ρ is the water density (ρ=1.0 g·cm^{-3}), D is the outer diameter (cm), d is the inner diameter (cm) and l is the length of sample membrane (cm).



Measurement of Mechanical Property

At room temperature, mechanical properties of HR PVC hollow fiber membranes were measured by a universal mechanical testing machine (Instron3369, USA). The gripping range and the tensile rate were 50 mm and 100 mm·min^{-2}, respectively. Each sample was tested five times to evaluate the average value.

Results and Discussion



Morphologies

The PVC casting solution with 10 wt% concentration in polymer solutions were coated on the PVC hollow fiber matrix membrane to prepare the HR PVC hollow fiber membrane. The different weight fraction (0, 15, 30 and 45 wt%) of ethanol aqueous solutions as the coagulation bath were used to prepare HR PVC hollow fiber membrane. These cross sectional morphologies of prepared HR PVC hollow fiber membrane were shown in Fig. 1. It can be seen that the HR PVC hollow fiber membranes were consisted of the coating layer consisting of finger-like structure and the matrix layer consisting of sponge-like structure from Fig. 1. With the increase of ethanol weight fraction in coagulation bath from 0 to 45 wt%, the change of coating layer structure was not obvious. The outer surface morphologies of prepared HR PVC hollow fiber membrane were shown in Fig. 2. The prepared HR PVC hollow fiber membrane possessed a dense outer surface within no obvious big pores. It was obviously found that the outer surface became rough with the increase of ethanol weight fraction in coagulation bath from Fig. 2 (a), (b), (c) and (d). When the ethanol weight fraction was 45 wt%, some small pores appeared on the outer surface from Fig. 2 (d). This must be due to the delay phase separation which induced by the high ethanol weight fraction in the coagulation bath.

(a) (b) (c) (d)

Fig. 1. Cross Sectional Morphologies of HR PVC Hollow Fiber Membranes. (Ethanol Weight Fraction in Coagulation bath:a-0, b-15 wt%, c-30 wt%, d-45 wt%).

(a) (b) (c) (d)

Fig. 2. Outer Surface Morphologies of HR PVC Hollow Fiber Membranes. (Ethanol Weight Fraction in Coagulation bath:a-0, b-15 wt%, c-30 wt%, d-45 wt%).

Permeation Properties

The PWF and porosity of HR PVC hollow fiber membranes that prepared under different ethanol weight fraction in coagulation bath were shown in Fig. 3. It can be seen that the PWF first increased slowly when the ethanol weight fraction was lower than 30 wt% and then increased rapidly when the ethanol weight fraction increased from 30 to 45 wt%. But the porosity of the HR membrane was slightly changed with the change of coagulation bath. These results could be explained by the fact that the increase of the ethanol weight fraction increased the outer surface roughness from Fig. 2 and some small pores appeared on the outer surface when the ethanol weight fraction was 45 wt% (Fig. 2(d)) which decreased the filtration resistance, while the cross section morphologies of these HR PVC hollow fiber membranes almost unchanged from Fig 1.

Fig. 4 showed the PPF and rejection of HR PVC hollow fiber membranes that prepared under different ethanol weight fraction in coagulation bath. It can be seen that both of the PPF and rejection of HR PVC hollow fiber membranes decreased with the increase of ethanol weight fraction in coagulation bath. The rejection depended more on the denseness of the skin layer than on the structure of the cross section [13]. The outer surface of HR PVC hollow fiber membranes became rough and some small pores appeared on the outer surface with the increase of the ethanol weight fraction in coagulation bath from Fig. 2. Thus, the protein rejection rate decreased with the increase of the ethanol weight fraction in coagulation bath. Due to the existence of the small pores on the outer surface, the pollution of membrane inner pores became worse which decreased the membrane pores connectivity in the filtration process and increased the filtration resistance. These resulted in the decrease of the membrane PPF.

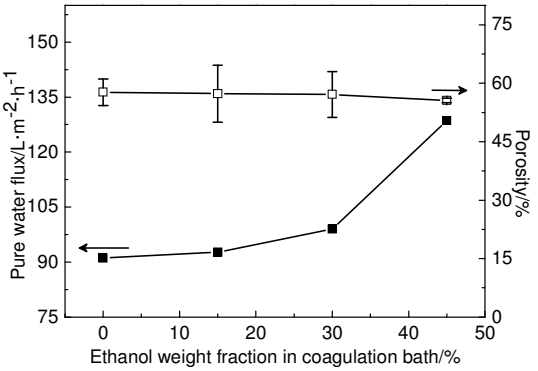


Fig. 3. Effects of Ethanol Weight Fraction in Coagulation Bath on PWF and Porosity of HR PVC Hollow Fiber membranes.

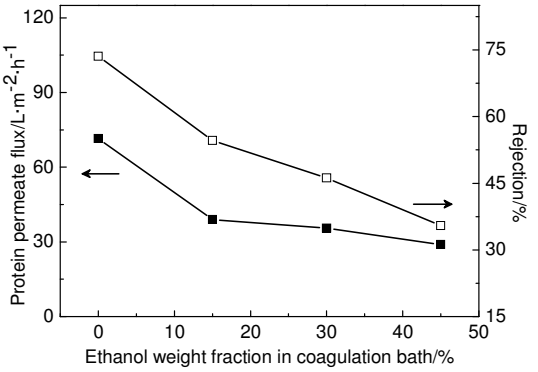

Fig. 4. Effects of Ethanol Weight Fraction in Coagulation Bath on PPF and Rejection of HR PVC Hollow Fiber Membranes.

Mechanical Properties

Fig. 5 showed the effects of ethanol weight fraction in coagulation bath on the tensile strength and elongation at break of HR PVC hollow fiber membranes. It can be seen that the tensile strength of the HR PVC hollow fiber membranes were lower than that of the matrix membrane. But the tensile strength of the HR PVC hollow fiber membranes were almost unchanged with the increase of the ethanol weight fraction in coagulation bath. The elongation at break of the HR PVC hollow fiber membranes were close to or higher than the matrix membrane. The tensile strength of HR PVC hollow fiber membranes mainly depended on the matrix membrane. In the preparation process, the dissolution of the matrix membrane in the polymer solution which contained high concentration solvent DMAc (80 wt%) might cause some unfavorable influence on the tensile strength of HR PVC hollow fiber membranes [12]. In this study, the tensile strength of HR PVC hollow fiber membranes was nearly 9.5 MPa which was higher than 1-5 MPa of membrane prepared by the wet spinning method [6]. The elongation at break of HR PVC hollow fiber membranes was higher than 97 %.

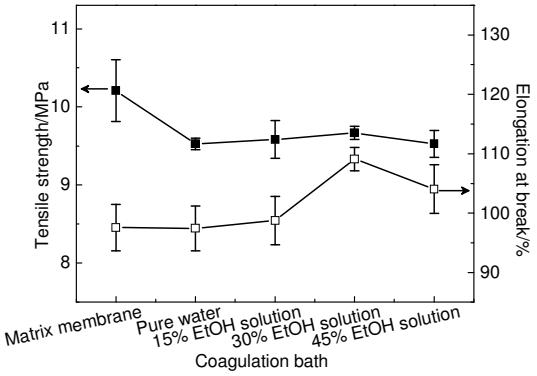

Fig. 5. Effects of Ethanol Weight Fraction in Coagulation bath on Mechanical Properties of HR PVC Hollow Fiber Membranes.

Conclusions

The HR PVC hollow fiber membranes including coating layer and matrix membrane were fabricated via coating process. The outer surface of the HR PVC hollow fiber membranes became rough with the increase of ethanol weight fraction from 0 to 45 wt% in coagulation bath. The PWF of the HR PVC hollow fiber membranes increased, while the porosity changed slightly with the increase of ethanol weight fraction in coagulation bath. The increase of ethanol weight fraction in coagulation bath also brought about the decrease of the PPF and protein rejection rate. The tensile strength of HR PVC hollow fiber membranes were lower than that of the matrix membrane and were about 9.5 MPa, while the elongation at break was higher than 97 %.

Keywords: Superhydrophobic surface; copper oxygen; contact angle; stearic acid

Abstract: A superhydrophobic copper oxygen (CuO) surface with hierarchical micro- and nanostructure was obtained by hydrothermally synthesized. The CuO surface was endowed with superhydrophobic property by modifying with stearic acid, which was referred to the STA-modified CuO film. The surface morphological study showed that different structures, such as petal-shaped, bulk-shaped, carambola-shaped CuO and cauliflower-shaped particles distributed on the copper substrate under the different synthesis conditions. The water contact angle and sliding angle of the as-prepared CuO surface were 157 ± 2.3º and 3º, respectively.

Introduction

Superhydrophobic surfaces with water contact angles large than 150 have recently attracted extensive attention due to their outstanding properties of self cleaning, low flow resistance, anti-sticking and anticorrosion [1,2]. It is well-known that the wettability of a solid surface is governed by both the surface chemical composition and geometrical microstructure [3]. Therefore, superhydrophobicity of a surface can thus be achieved by enhancing the surface roughness and lowering the surface energy.

Similar to many functional semiconductors, copper oxide as a kind of functional material has attracted extensive interests owing to its photoconductive and photochemical properties, which has been widely used as catalyst, gas sensors, semiconductor and solar cells[4]. Many novel CuO micro/nanostructures such as nanosheets, wheat grain-like and nanorods [5,6] structures have been fabricated by a range of techniques, including chemical vapour deposition, hydrothermal methods, and some solution processes. However, most of these reaction systems can only produce one or two morphologies. In particular, the obtained CuO nanostructures are mostly used to enhance the currently existing applications. Among these methods, the hexamethylenetetramine assisted solution method is relatively simple, inexpensive, and surfactant-free. Although this method has been used to fabricate flower-shaped or spindly-shaped CuO nanostructures, its ability to produce new structures at sufficiently large quantities for fabrication superhydrophobic CuO surface still needs to be demonstrated.

Herein, we describe a simpler one-step hydrothermal method to directly fabricate the uniform micro- and nanostructure hierarchical CuO surface on copper substrate. The so-called STA-modified CuO film, is modified with lower energy compound stearic acid at room temperature. The as-prepared CuO film exhibits good superhydrophobic property.

Experimental

Preparation of CuO Film

In a typical synthesis, the same volume ratio of the copper acetate solution and the HMTA solution with the concentration varied form 0.001 M to 0.075 M was transferred to a 100 mL Teflon-lined autoclave containing the cleaned copper substrate. The autoclave was then sealed and heated to 90 °C for 24 h. After the given reaction time, the autoclave was cooled downed to room temperature. The copper substrate was taken out from the solution. A black film was obtained (viewed through naked eye), which covered uniformly on the Cu substrate. The sample was rinsed with distilled water and dried at 60 °C for 6 h. It was then immersed in an ethanol solution (2.0 wt.%) of STA for 2 h at room temperature. The resulting film was rinsed with ethanol and then dried at 60 °C for 2 h, and then a porous superhydrophobic CuO surface with hierarchical micro- and nanostructures was obtained.

Characterization

The CuO powder was characterized by X-ray diffraction (XRD) (Rigaku D/max-2000PC) with copper target. The surface morphologies were examined by environmental scanning electron microscope (SEM) (FEI Quanta 200). The surface compositions of the samples were determined by X-ray photoelectron spectroscopy (XPS) (EscaLab 250Xi) with an Al Ka Xray source (15 kV, 10 mA) and an analytical chamber with a base pressure of 10^{-6} Pa. The sessile drop method was used for CA measurements using a Dataphysics OCA20 CA system at ambient temperature. The average CA value was obtained by measuring more than three different positions for the same sample.

Results and Discussion

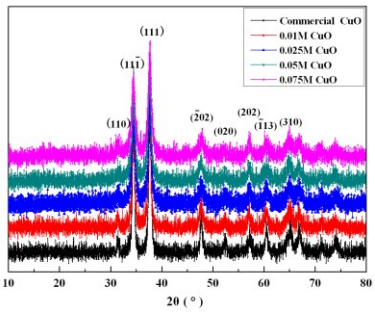

Fig. 1 XRD Patterns of the As-prepared CuO Powder

The crystalline structure of the as-prepared CuO surface was characterized using an X-ray diffraction as shown in Fig. 1. The diffraction peaks observed at 31.4, 34.5, 37.6, 47.8 and 52.5 in the XRD pattern were the typical character diffraction peaks of CuO which confirm that the formed material was copper oxygen. The main five diffraction peaks were identified to match up to the (110), ($1\,1\,\bar{1}$) and (111), ($\bar{2}02$) and (020) planes of the monoclinic CuO structure in sequence compared with the PDF card (JCPDS 45-0937). The XRD pattern showed that the samples were single-phase and no impurities were detected, indicating that the CuO powder was pure and well crystallined.

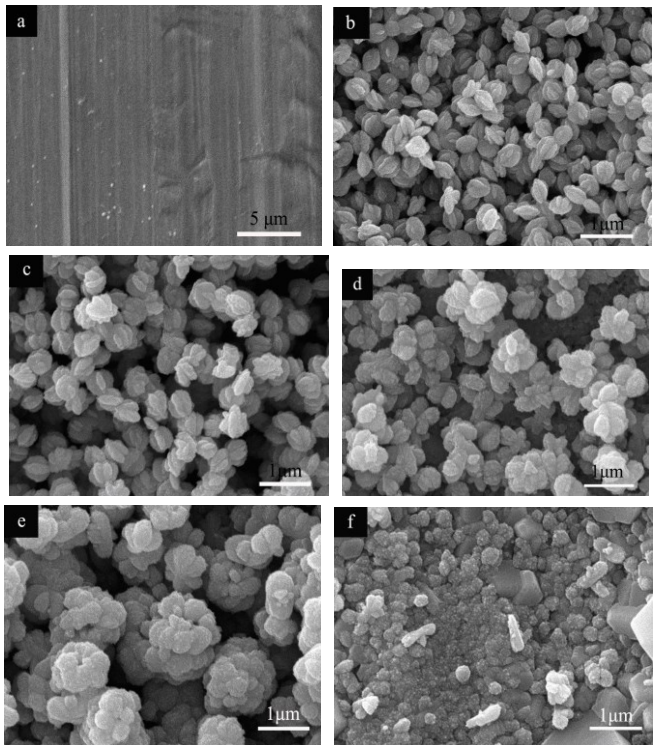

Fig. 2 SEM Images of the As-prepared CuO Surface at Different Initial Concentration (a) the Copper Substrate;

(b) 0.005 M; (c) 0.01 M; (d) 0.025 M; (e) 0.05 M; (f) 0.075 M

Fig. 2 showed the SEM images of the CuO nanostructure grown on the copper wafer substrates at different concentration. As could be seen from the top view, the different nanostructure covered the copper surface uniformly, which were different from the smooth copper substrate (Fig. 2a). When the initial concentration of the copper acetate solution and the HMTA solution increased from 0.01 M to 0.075 M, the surface morphologies of the CuO had also changed. It was clearly seen from Fig. 2b to d that the samples synthesized under the lower concentration of 0.05 M was of a carambola-shaped structure consisting of nanopetals with typical thickness of 80-120 nm. The size of a single carambola (Fig. 2c) was about 600 nm in width and 800 nm in lengths. While the initial concentration of reactants were 0.05 M, the nanopetals closely packed, gradually formed a cauliflower-shaped structure (Fig. 2e), and the size of the single cauliflower was about 1.0-1.2 μm. When the initial concentration was 0.075 M, in addition to generate a large number of carambola-shaped particle with the size of 200-300 nm, there also randomly appeared square shaped CuO particles on the copper wafer substrate. The size of the square shaped CuO particles were 1-8 μm (Fig. 2f). The above results showed that the size of the CuO increased with the increasing of the initial reactants concentration.

The CuO film was chemically modified with stearic acid, aiming at changing the surface wettability, since surface chemical composition had a remarkable effect on the hydrophobicity. Fig. 5a depicted the wide scan of the STA-modified CuO film. Fig. 5b showed the XPS spectra of the copper element obtained with copper substrate after hydrothermal synthesis. The peaks located at 932.26 eV (Cu 2p 3/2) and 952.11 eV (Cu 2p 1/2) were attributed to the Cu 2p region of metallic copper on the copper substrate. In addition to peaks at 932.26 eV (Cu 2p 3/2) and 952.11 eV (Cu 2p 1/2), there were two new peaks located at 943.61 eV (Cu 2p 3/2) and 962.31 eV (Cu 2p 1/2). It could be implied that the compound in the top surface mainly consisted of copper oxalate [7,8].

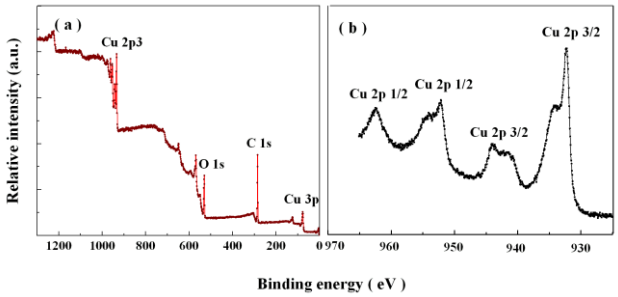

Fig. 5 (a) XPS Spectrum of the STA-modified CuO Film; (b) High Resolution Cu2p Core Level Spectrum

The nanoparticles and the particle clusters pack loosely, and a lot of pores could be observed. We tested the water contact angle of the as-prepared porous CuO surface, and the water contact angle was less than 5 ° [9], showing superhydrophilic property. In general, the wettability of a rough solid surface could be described by Wenzel [10] model shown in equation (1):

$$\cos \theta_r = r \cos \theta \quad (1)$$

Here, r was the roughness factor, and θ and θ_r were the equilibrium contact angle of a liquid on a smooth solid surface and a rough solid surface, respectively. According to the equation (1), if the roughness was increased, the contact angle of a hydrophilic solid surface would decrease. Note that CuO was an intrinsically hydrophilic material, rough surface should become more hydrophobic than those of smooth according to Wenzel model. Thus, the as-prepared CuO surface showed superhydrophilic property. However, the wettability dramatically changed after modification with stearic acid. Fig. 6a showed that the static contact angle was 157± 2.3º.on the as-prepared porous CuO surface synthesized under the conditions that the reaction time last 24 h under the initial concentration for 0.01 M at 90 ºC. Fig. 6b showed a digital photograph image of the shape of 10 µl

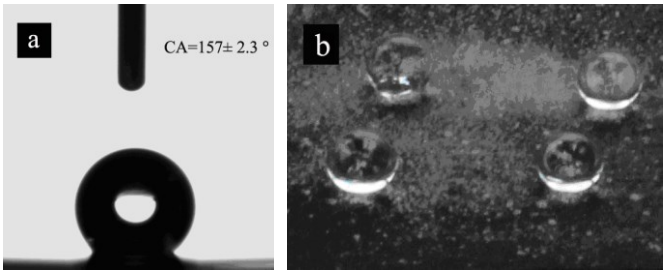

Fig. 6 (a) The Water Droplet on the As-prepared Superhydrophobic CuO Surface; (b) A photograph of Water Droplets on STA-modified CuO Film

water droplets on the superhydrophobic CuO surface. The digital photograph image of water droplets with uniform size on the surface showed a direct demonstration of the superhydrophobic property after the CuO film modified by stearic acid. A water droplet was hardly able to stick to the surface, which moved around rapidly when is was slightly disturbed, and dripped off the substrate rapidly when the substrate was tilted less than 3 º. The high water contact angle and low sliding angle indicated that the as-prepared CuO surface was a real superhydrophobic surface, which exhibited similar wettability with natural lotus leaf or rose petal. Most studies on natural and artificial superhydrophobic surfaces showed that the rough surface structure and low-surface-energy materials were crucial for a superhydrophobic surface [11,12]. Note that the water contact angle of the stearic acid surface coated on a smooth copper substrate was only 108° [9]. Therefore, it could come to the conclusion that the superhydrophobicity of the CuO surface resulted from the synergistic effect of their unique surface micro- and nanostructures and low energy compound.

Conclusions

A facile synthesis strategy for the direct construction of micro- and nanostructure CuO surface on copper substrate was investigated. The CuO surface was endowed with superhydrophobic property by modifying with stearic acid. The water contact angle and sliding angle of the as-prepared superhydrophobic CuO surface were 157 ± 2.3º and 3º, respectively. The presented method could be used to fabricate not only superhydrophobic but also superhydrophilic CuO surface. It could be easily scaled up to create large-area uniform superhydrophobic surface and could be applied in commercial manufacturing. It was believed that this method should be easily to other metals oxide, ceramics and alloys.

Keywords: aluminum titanate, film, sol-gel method, compound chelating agent

Abstract. Aluminum titanate(Al_2TiO_5) film was prepared via sol-gel method at low temperature, using ethyl acetoacetate and anhydrous citric acid as compound chelating agent, tetrabutyl titanate ($Ti(OC_4H_9)_4$) and aluminum chloride ($AlCl_3{\cdot}6H_2O$) as precursors, ethanol as solvent. The phase transformation of Al_2TiO_5 xerogel during heat treatment, the effect of different chelating agents on the synthesis of Al_2TiO_5, and the phase composition and morphology of film were investigated by means of differential thermal and thermo gravimetric analysis (DTA-TG), X-ray diffraction analysis (XRD), Fourier transform infrared spectroscopy (FTIR) and field-emission scanning electron microscopy (FE-SEM). The results demonstrate that Al_2TiO_5 can be synthesized at 750 ^oC by using compound chelating agent, rather than single chelating agent. Compound chelating agent contributes to the formation of Al-O-Ti heterogeneous bond, which is the key to preparing Al_2TiO_5 at low temperature. High quality Al_2TiO_5 film could be coated on the SiC substract at 750 ^oC.

Introduction

Aluminum titanate (Al_2TiO_5) is a ceramic material characterized by low thermal expansion, good thermal shock resistance, high melting point, low thermal conductivity and good corrosion resistance [1]. Al_2TiO_5 film can combine with SiC substrate firmly, which prevents the high temperature oxidation of SiC effectively, and enhances its corrosion resistance significantly [2]. In addition, Al_2TiO_5 film is a kind of ideal thermal barrier material. Therefore, Al_2TiO_5 film has appealing potential applications in the fields of aerospace, national defense and civilian industries, etc [3,4]. Various methods have been reported for the preparation of Al_2TiO_5 film, such as chemical vapor deposition method [5], radio-frequency magnetron sputtering method [6], and sol-gel method [2,4,7-9], etc.

Sol-gel method includes hydrolytic sol-gel method (HSG) and nonhydrolytic sol-gel method (NHSG). Usually, the synthesis temperature of Al_2TiO_5 film prepared by HSG method is above 1300 ^oC [2, 8]. Although Al_2TiO_5 film could be obtained via NHSG method at low temperature of 750 ^oC [9], the whole reaction process must be carried out in dry environment protected with inert gases, which is not beneficial to large scale production of Al_2TiO_5 film.

In this paper, Al_2TiO_5 film was prepared on silicon carbide (SiC) substrate at 750 ^oC in air atmosphere via sol-gel method, using ethyl acetoacetate and anhydrous citric acid as compound chelating agent, inorganic salt $AlCl_3{\cdot}6H_2O$ as aluminum source, and the crystallization water in $AlCl_3{\cdot}6H_2O$ as required water for sol-gel reaction. The reason for the low temperature synthesis of Al_2TiO_5 was investigated; meanwhile, the quality of film prepared was characterized.

Experimental

The molar ratio of aluminum chloride ($AlCl_3{\cdot}6H_2O$) to tetrabutyl titanate ($Ti(OBu)_4$) was calculated according to the chemical composition of Al_2TiO_5. A solution (S1) was prepared by dissolving $AlCl_3{\cdot}6H_2O$ (0.04 mol, 9.657 g) in ethanol (80.0 ml). Citric acid (0.02 mol, 3.842 g) dissolved in ethanol (20.0 ml), then mixed with $Ti(OBu)_4$ (0.02 mol, 6.8 ml) modified with ethyl

acetoacetate (0.04 mol, 5.1 ml) to form solution (S2). After that, solution S1 was dropwise added into solution S2. The resulting sol aged at room temperature for 48 h.

The xerogel film was prepared on clean SiC substrate by dip-coating, drying and low temperature heat treatment at 500 ^{o}C for three times. In order to obtain Al_2TiO_5 film, a high-temperature heat treatment at 750 ^{o}C was needed for the fourth coating. The heating rates of RT~500 ^{o}C and 500 ^{o}C ~750 ^{o}C were 1 ^{o}C /min and 2 ^{o}C /min, respectively.

Testing and Characterization

Differential thermal analysis (DTA) and thermo gravimetric analysis (TG) were achieved with NETZSCH STA 449C thermal analyzer. The phase compositions of samples were observed by Bruker D8 Advance X-ray diffraction (XRD) with Ni-filtered Cu Kα radiation in the 2θ angle range of 10–70°. Fourier transform infrared spectroscopy (FTIR) was carried out with Nicolet 5700 infrared spectrometer in the wavenumber range of 4000-400 cm^{-1}, and the morphology of samples was characterized by the JSM-6700F field-emission scanning electron microscopy (FE-SEM).

Results and Discussion

In order to study the phase transition of Al_2TiO_5 xerogel during the heat treatment, its DTA-TG test was carried out from room temperature to 1400 ^{o}C at the rate of 10 ^{o}C /min in argon atmosphere.

Fig. 1 shows that there is a broad endothermic peak at 217.8 ^{o}C, corresponding to 42.16% weight loss, which is due to the volatilization of organic compounds and decomposition of the residual alcohol oxygen groups from the gel [10]. The endothermic peak at 491.0 ^{o}C owes to the pyrolysis of citric acid [11]. An exothermic peak attributed to the crystallization of Al_2TiO_5 appears at 731.1 ^{o}C in the DTA curve, which can be deduced from the fact that the XRD pattern of the sample (Fig. 2) prepared at 750 ^{o}C has Al_2TiO_5 diffraction peaks while its counterpart at 700 ^{o}C has no Al_2TiO_5 diffraction peaks. Furthermore, there is an exothermic peak at 1126.8 ^{o}C and an endothermic peak at 1321.4 ^{o}C. Fig. 2 shows that there is no Al_2TiO_5 diffraction peak in the XRD pattern of the xerogel powder calcined at 1150 ^{o}C, which indicates: (1) Al_2TiO_5 formed at 750 ^{o}C decomposes into corundum and rutile, it is caused by its instability [12]; (2) the exothermic peak at 1126.8 ^{o}C can be assigned to the decomposition of Al_2TiO_5. Meanwhile, the endothermic peak at 1321.4 ^{o}C can be attributed to the synthesis of Al_2TiO_5 again, and it could be inferred from that there is Al_2TiO_5 crystal phase in the sample prepared at 1350 ^{o}C. It is noteworthy that due to the rapid weight loss before 500 ^{o}C, the heating rate should be slow in order to obtain high-quality Al_2TiO_5 film.

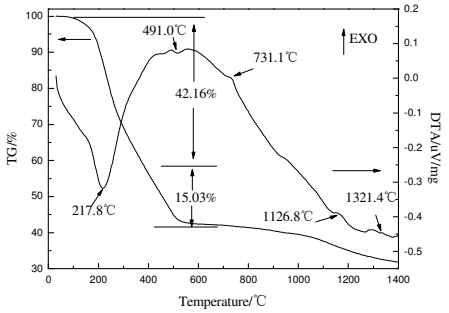

Fig. 1 DTA-TG Curves of the Xerogel

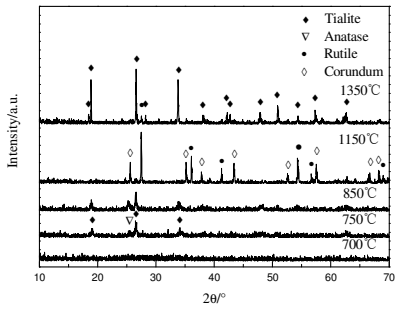

Fig. 2 XRD Patterns of the Samples Heated at Different Temperatures

Fig.3 shows the XRD patterns of samples prepared by selecting anhydrous citric acid and ethyl acetoacetate ($EC^{\#}$), ethyl acetoacetate ($E^{\#}$) and anhydrous citric acid ($C^{\#}$) as chelating agents respectively, and the calcinations temperature of samples was 850 ^{o}C. It can be seen from Fig.3 that the main crystalline phase of sample $C^{\#}$ and $E^{\#}$ is anatase. The sample $EC^{\#}$ has strong and sharp Al_2TiO_5 crystal diffraction peaks accompanied with a weak anatase crystal diffraction peak. It was apparent that Al_2TiO_5 can be prepared by using compound chelating agent, rather than the single one.

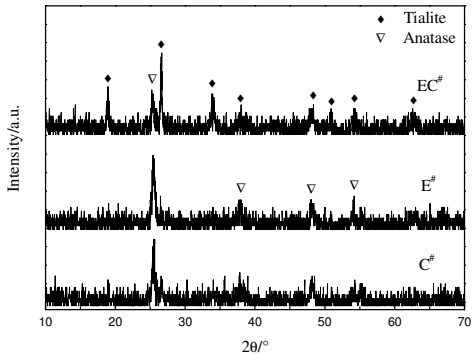

Fig. 3 XRD Patterns of Samples Prepared by Using Single and Compound Chelating Agents

In order to investigate the reason for low synthesis temperature of Al_2TiO_5, FT-IR test was performed to analyze the bonding of Al_2TiO_5 xerogel.

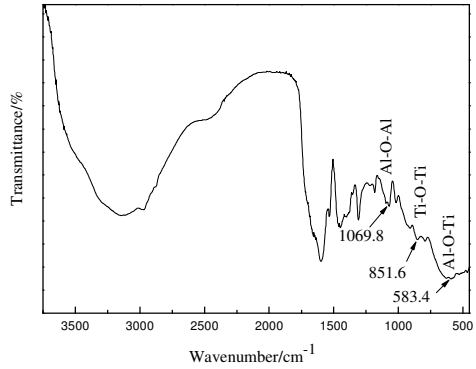

Fig. 4 FT-IR Spectrum of Aluminum Titanate Xerogel

The absorption bands at 1069 cm^{-1}, 851 cm^{-1} and 583 cm^{-1} in Fig. 4 are corresponding to the vibration of Al-O-Al, Ti-O-Ti [13] and Al-O-Ti bonds [14], respectively. The appearance of Al-O-Ti bond indicates that Al and Ti in gel have been mixed in atomic level, which is the key to synthesizing Al_2TiO_5 at 750 ^oC [14]. The reason for the formation of Al-O-Ti is as follows: the steric hindrance effect of the compound chelating agent reduces the activity of the tetrabutyl titanate, which changes the polarization of Ti-OBu in $Ti(OBu)_{4-x}(OH)_x$. This change leads to the fact that the polarization of OH in H_2O and Ti-OBu is insufficient to meet the requirement of further hydrolysis reaction [15]. Then Cl in Cl-Al= attacks on O-Bu bond in $Ti(OBu)_{4-x}(OH)_x$ to form Al-O-Ti bond. The process can be described as formula ((1)-(3)).

$$AlCl_3 \cdot 6H_2O + EtOH \longrightarrow AlCl_x(OH)_y(OEt)_z + HCl \quad (x+y+z=3) \tag{1}$$

$$Ti(OBu)_4 + xH_2O \longrightarrow Ti(OBu)_{4-x}(OH)_x + xBuOH \tag{2}$$

$$\equiv Ti-O-Bu+Cl-Al= \rightarrow =Al-O-Ti\equiv +BuCl\uparrow \tag{3}$$

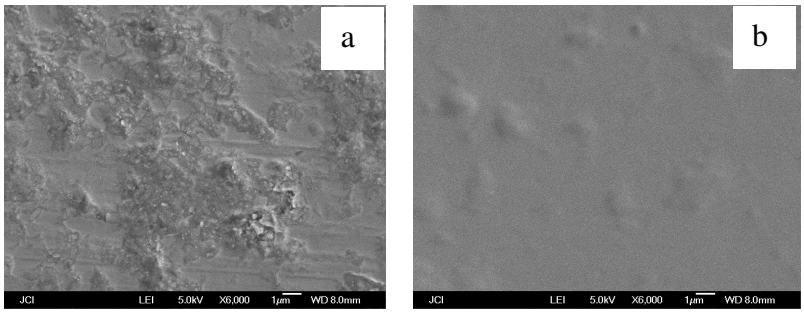

Fig.5 The Surface SEM Images of SiC(a) and Film Sample(b)

FE-SEM micrographs of the samples are shown in Fig.5. It can be seen from Fig.5 (a) that the surface of uncoated SiC substrate is rough and uneven. Comparatively, the aluminum titanate film on SiC substrate in Fig.5 (b) is smooth, homogeneous, compact and crack-free.

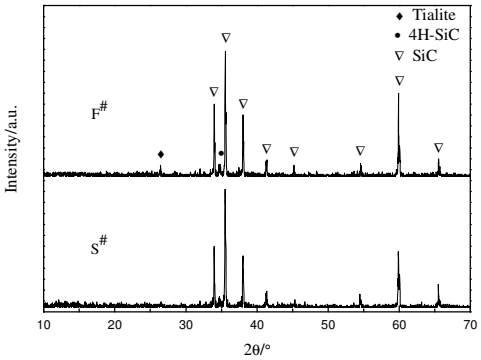

Fig.6 XRD Patterns of Silicon Carbide Substrate(S#) and Silicon Carbide Substrate Coated with Film(F#)

Fig. 6 shows the XRD of silicon carbide substrate and silicon carbide substrate coated with film. Both sample $S^{\#}$ and $F^{\#}$ contain strong diffraction peaks of SiC, however, $F^{\#}$ contains the first strong characteristic diffraction peaks of Al_2TiO_5, 2-theta angles of which is 26.62°, corresponding to (101) crystal plane of Al_2TiO_5.

Conclusions

In this paper, Al_2TiO_5 film was prepared via sol-gel method using ethyl acetoacetate and anhydrous citric acid as compound chelating agent, inorganic salt $AlCl_3{\cdot}6H_2O$ as aluminum source, and the crystallization water in $AlCl_3{\cdot}6H_2O$ as required water for sol-gel reaction. The result indicates that Al_2TiO_5 can be synthesized at low temperature by using compound chelating agent, rather than the single one. The formation of Al-O-Ti heterogeneous bond plays the key role in the low temperature synthesis of Al_2TiO_5. The Al_2TiO_5 film which is smooth, compact, homogeneous and crack-free could be coated on the SiC substract at 750 ^{o}C in air atmosphere.

Keywords: multilayer, inclusion chemistry, layer by layer

Abstract

In addition to traditional PEM and hydrogen-bonding methods, a polymer multilayer film could be formed via inclusion complexation,. We demonstrate this layer-by- layer method. Due to the steric hindrance of polymer segments, the thickness levels off and is generally much higher than those from PEM and hydrogen-bonding.

Introduction

Owing to its simplicity and potential applications, the layer-by-layer(LbL)[1-6] assembly, mainly relying on alternate deposition, has aroused intense interest. In addition, a wide variety of materials, including polymers, nanoparticles(NP's), functional molecules, and even living cells[7-8] can be applied via this alternate depositions technique to make multilayer films. Among all LbL techniques, assembly between oppositively charged species, polyelectrolyte multilayer(PEM), and assembly through hydrogen bonding[9-12] are the most popular LbL techniques. But under some circumstances, hydrogen bonding and ionizable monomeric units are not always available to form complexes, for example, when solution PH value is greater than a critical value, the hydrogen-bonded LbL multilayer film may disintegrate[13-15]. Consequently, some other methods are required, while very few researchers[16-18] address this problem.

With the inner hydrophobic and outer hydrophilic properties of their cavities, cyclodextrins(CD's)[19-23], the macrocyclic and water-soluble oligosaccharides, could form inclusion complexes with guest molecules selectively, and consequently, are widely used in many areas, particularly in drug research and biotechnologies. In this study, we demonstrate this unconventional method, LbL assembly through inclusion complex(IC), to form multilayer films and discuss its limitation.

To form the multilayer film, the host polymer and the guest polymer, poly(acrylic acid)(PAA) and poly(methacrylic acid)(PMA), were synthesized and labeled with ß –CD and adamantane group respectively. Then, a glass slide substrate with ß –CD labelled surface was immersed alternatively into the polymer solutions containing ß –CD and adamantane group respectively. After each immersion the substrate was rinsed thoroughly in pure water, to eliminate the excess of polymer in contact with the surface but only weakly bound to the film. The deposition cycle was repeated until the film thickness didn't increase anymore and thus, the thin multilayer film was obtained.

Furthermore, multilayer film could be formed on the interface between swelled host polymer surface and guest polymer/DMSO solution.

Experimental

Synthesis of Monomer Containing ß –CD

ß –CD was reacted with p-TsCl in dry pyridine overnight. The dry residue was dissolved in water and precipitated in acetone. The white crystal(ß–CD-6-O-TsCl) after twice recrystallization, was reacted with excess amount of ethylene diamine(EDA) for 4 hr at 60°C to obtain a white solid(EDA-6-ß–CD). Then, the ß–CD containing monomer was synthesized by reaction between EDA-6-ß–CD and glycidyl methacrylate with a small amount of 1, 4-dihydroxyl benzene as inhibitor in DMF for 8 hr. After reaction, the monomer((GMA-EDA-6-ß–CD) was obtained by precipitation the solution into acetone and vacuum drying.

Preparation of Host Polymers:

Free radical copolymerization of acrylic acid and GMA-EDA-6-ß–CD was performed to obtain PAA-based host polymer(PAA-co-GMA-EDA-EDA-6-ß-CD).

Preparation of Guest Polymers

PMA-based guest polymers(PMA-g-3AD) was prepared by labelling adamantane group onto the PMA chain. Then the guest polymer obtained was purified by reprecipitation and dialysis.

Surface Treatment of Glass Slide:

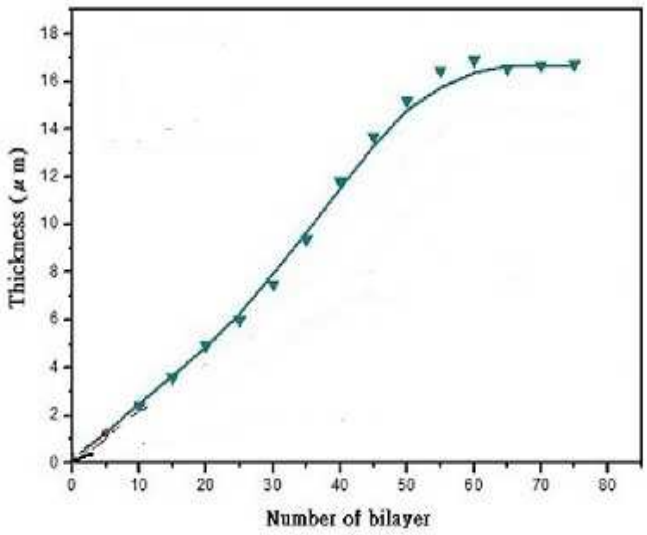
After washing, the quartz glass slides(2.5 cm x 2.5 cm x 0.1 cm) were treated with Piranha solution for 2 hr and subsequently reacted with 5% APTES/toluene solution for 12 hr. After washing with water, the slides were immersed in 5% aqueous solution of ß-CD-6-OTs for 24 hr. .

Multilayer Film Formation:

Two solutions were prepared by dissolving the PMA-based guest polymer(PMA-g-3AD) and the PAA-based host polymer (PAA-co-GMA-EDA-EDA-6-ß-CD) in water respectively, both containing 1.0 gram polymer in 100 ml water. The glass slide was immersed for 10 minutes into these two solutions alternately and after each immersion, the slide was rinsed in distilled water to remove the excess of polymer. The vacuum dried film thickness was measured by α-step and its weight was measured every five bilayers.

Results and Discusion

As shown in Table 1 was the characterization of polymers for multilayer film formation and both the contents of ß- CD and adamantane of polymers were determined by ^{1}H NMR.



It is clearly depicted in Fig. 1, that both the film thickness and the surface mass increase layer by layer as the alternate deposition proceeds. Also performed was the blank test(fig. 2) under the same procedures by using homopolymers, PAA and PMA, instead of the host and guest polymers. In sharp contrast, no polymer film could be formed on substrate. And this also assists to verify the same conclusion. In light of the fact that the polymer chain is not extended as polyelectrolyte and it has low contents of interacting groups, it is reasonable that the thickness per

bilayer, is much larger than those from PEM. As the alternate depotision proceedes, the thickness and the surface mass of polymer film increases until it reaches their final values. We can conclude that the multilayer film formation is limited. The reason is that, due to the steric hindrance of polymer segments, the number of inclusion complexation every layer is gradually decreasing and reaches a critical value and below which, the new layer is no more stable and would be easily eliminated by water rinsing. As a result, the film thickness levels off. Future study would focus on the critical number of inclusion complexation between adjacent layers.

Table 1. Characterization of host and guest polymers

Polymers	**M.W.** **(x10^5)**	**β-CD content** **(mole %)**	**adamantane content** **(mole %)**
PAA-co-GMA-EDA-6-β-CD	**3.2**	**8.1**	**0**

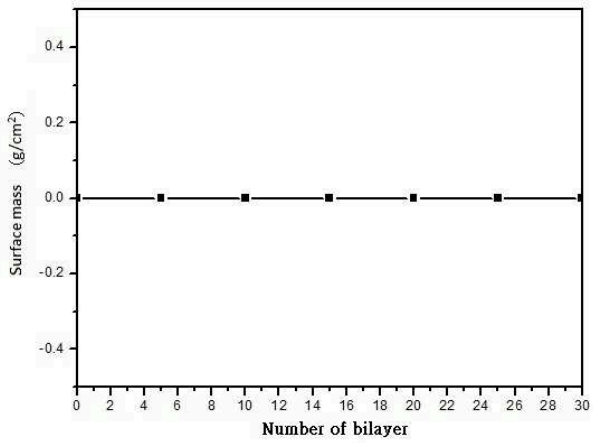

Fig. 2. Blank test with PMA and PAA, instead of host and guest polymers

Summary

Inclusion complexation could be employed to synthetic polymers to form multilayer films, in addition to traditional LbL methods. To form the multilayer film, two water-soluble polymers are synthesized and labeled with ß-CD and and adamantine group respectively. Despite its limitation to thickness, it offers a new alternative to fabricate synthetic multilayer films.

Keywords: bipolar membranes, multi-carboxylic metallophthalocyanine, modification

Abstract: The multi-carboxylic metallophthalocyanine derivatives were added into carboxymethyl cellulose cation layer to prepare the modified carboxymethyl cellulose/chitosan bipolar membranes (CMC/CS BPMs), which were characterized using electric universal testing machine, contact angle measurer and so on. The results showed that the mechanical properties were increased after modification. Moreover, the ion exchange capacity, and the hydrophilicity of the modified CMC membrane dramatically rose. As the catalytic centers, the metallophthalocyanine derivatives sped up water splitting, decreased the membrane impedance and cell voltage. In comparison with the BPMs modified by mononuclear metallophthalocyanine derivatives, the catalytic ability for water splitting of the binuclear metallophthalocyanine derivatives (especially with different central metal ions) was enhanced. At the current density of 60 $mA \cdot cm^{-2}$, the cell voltage of the BPM modified by $FeCoPc_2(COOH)_{12}$ was only 5.3V.

Introduction

At present, more and more attention has been paid to modification of cation layer or anion layer, and introduction of catalytic interlayer to promote water splitting [1]. Higher water splitting efficiency and lower membrane impedance are undoubtedly expected.

Phthalocyanine and its derivatives have aroused great interest as their distinctive structures and excellent properties such as good electrocatalytic characteristic，electrochemical behaviors [2] and high charge transfer efficiency[3,4]， which have been widely applied in the field of photoelectrochemistry [5], catalysis [6] and so on. The planar binuclear phthalocyanines have quite larger π electron conjugated system than mononuclear phthalocyanine, and exhibit high-electron storage and transfer abilities [7] .

In this paper, as a further research part of our previous study on SA/CS BPMs modified by CuTsPc and CuTAPc (here, SA: sodium alginate; CS: chitosan; CuTsPc: copper phthalocyanine tetrasulfonic acid; CuTAPc: copper tetraaminophthalocyanine)[8], the preparation and characterization of CMC/CS BPMs modified by mononuclear or planar binuclear metallophthalocyanine derivatives with carboxyl groups have been studied.

Experimental

Materials

Carboxymethyl cellulose, chitosan with an N-deacetylation degree of 90% and glutaraldehyde (25% by volume in water) were purchased from Guoyao Chemicals Co, Ltd. $FeCl_3$, $CoCl_2$ and other chemicals were analytical grade.

Preparation of BPMs

Preparation of multi-carboxylic metallophthalocyanine derivatives

The preparation method of iron(Ⅲ) octocarboxylphthalocyanine($FePc(COOH)_8$), planar binuclear iron(Ⅲ) phthalocyanine ($Fe_2Pc_2(COOH)_{12}$), planar binuclear cobalt(Ⅱ) phthalocyanine($Co_2Pc_2(COOH)_{12}$) and planar binuclear iron(Ⅲ)-cobalt(Ⅱ) phthalocyanine($FeCoPc_2(COOH)_{12}$) were detailedly described in the literature[9].

Preparation of the BPM modified by multi-carboxylic metallophthalocyanine derivatives

The multi-carboxylic metallophthalocyanine derivatives-THF solution was added into the CMC aqueous solution (3 wt.%), and then the modified CMC aqueous solution was poured onto a glass plate and dried at room temperature. The membrane was cross-linked with $CrCl_3$ solution (9 wt.%) for 30 min and dried to form the cation exchange layer (area 50 cm^2).

The CS solution was made by mixing 100 mL chitosan solution (3 wt.%) and 3 mL glutaraldehyde (0.25% by volume in water) and stirred for 30 min. The solution was poured over the prepared cation exchange layer and dried to form the modified BPM.

The $-COO^-$ groups of the multi-carboxylic metallophthalocyanine derivatives were combined with the $-COO^-$ groups of CMC by means of Cr^{3+} to form a metal chelate polymer with a net structure(*Figure 1*). At the same time, hydrogen bonds formed between the −OH groups of CMC and the $-COO^-$ groups of the multi-carboxylic metallophthalocyanine derivatives. Both of the above two factors helped to improve the dimensional stabilities of BPMs and structure stabilities of the interlayers.

Furthermore, in the CS anion membrane, the aldehyde groups of glutaraldehyde were combined with the $-NH_2$ groups of CS, which helped to form net structure in the membrane layer to improve the mechanical properties of the BPM. (*Figure 2*)

Preparation of Cr-CMC/CS BPM

In comparison with the previously prepared BPMs, the Cr-CMC/CS BPM was prepared. The preparation method was similar to the above method, except that multi-carboxylic metallophthalocyanine derivatives were not added into the CMC aqueous solution**.**

Characterization of BPMs

Determination of Hydrophilicity of Cation Exchange Membrane

The contact angles of the modified CMC membranes were determined using the contact angle measurer (SL 200B, S&L (Shanghai) Inc. in China).

Determination of Ion Exchange Capacity of Cation Exchange Membrane

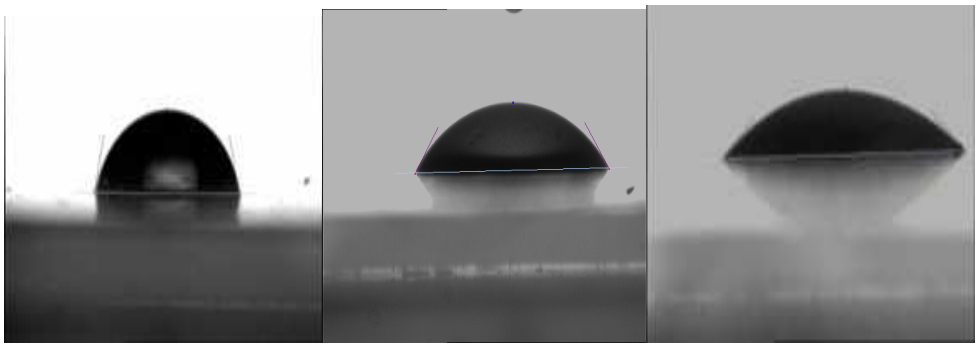
The determination method of the ion exchange capacity was clearly described in the literatures[10].

Determination of Mechanical Properties of BPM

The determination method of the mechanical properties was clearly described in the literatures[11].

Measurement of the Current-Voltage Curve (J-V curve) of BPM-equipped cell

The *J-V* curve of the BPM-equipped cell was measured using a direct current source (DF1720SB5A, Ningbo Zhongce Electronics Co., Ltd in China). The determination method of the current-voltage curve was clearly described in the literatures[12].



Measurement of the AC impedance spectroscopy of BPM

An electrochemical workstation (CHI660C, Shanghai Chenhua Instrument Company in China) was used to measure the AC impedance spectroscopies of the BPMs. The determination method of the AC impedance spectroscopy was clearly described in the literatures[13].

Results and discussion

The hydrophilicity of cation exchange membrane

After the modification by $FePc(COOH)_8$ and $FeCoPc_2(COOH)_{12}$, the contact angles of the CMC membrane decreased from 75.67° (*Figure 3-a*) to 54.54° (*Figure 3-b*) and 34.52° (*Figure 3-c*), respectively. Because the hydrogen bonds formed between water molecules and a large number of $–COO^-$ groups of the multi-carboxylic metallophthalocyanine derivatives, which led to the improvement in hydrophilicity of the modified CMC membrane. The good hydrophilicity could help the water in the interlayer to be supplied in time from outside of the BPM to avoid the formation of depletion layer[14].

(a) (b) (c)

Figure 3 The contact angles of the different cation exchange membranes

(c) $FeCoPc_2(COOH)_{12}$-CMC membrane

The Ion exchange capacities of cation exchange membranes

The ion exchange capacities for the different cation exchange membranes were showed in *Figure 4*. The ion exchange capacity for the unmodified Cr-CMC membrane was 14.63 $mmol \cdot g^{-1}$, and the ion exchange capacities of the modified CMC membranes dramatically rose due to a large number of $–COO^-$ groups in the multi-carboxylic metallophthalocyanine derivatives.

(c) $Fe_2Pc_2(COOH)_{12}$-CMC membrane (d) $FeCoPc_2(COOH)_{12}$-CMC membrane
(e) $Co_2Pc_2(COOH)_{12}$-CMC membrane

The Mechanical properties of BPMs

The mechanical properties of the different BPMs were listed in *Table 1*. Because the $-COO^-$ groups of the multi-carboxylic metallophthalocyanine derivatives were combined with the $-COO^-$ groups of CMC by means of Cr^{3+} to form a metal chelate polymer with a net structure and the metallophthalocyanine derivatives were rigid molecules, the tensile strength, maximum load and Young's modulus of the modified BPMs were evidently increased, and the mechanical properties were noticeably enhanced. On the other hand, with the improvement in the rigidity of the BPMs, the molecule chains were uneasy to be stretched, and the elongation at break was declined in a way.

Table 1 Mechanics capabilities of the different BPMs

BPM	Maximum load [N]	Tensile strength [MPa]	Elongation at break [%]	Young's modulus [MPa]
Cr-CMC/CS	23.67	10.33	40.33	200.87
$FePc(COOH)_4$-CMC/CS	29.81	23.29	27.11	214.64
$FePc(COOH)_8$-CMC/CS	50.78	32.55	25.68	248.63
$FeCoPc_2(COOH)_{12}$-CMC/CS	36.88	23.95	18.76	213.11
$Co_2Pc_2(COOH)_{12}$-CMC/CS	43.78	28.43	24.62	224.58
$Fe_2Pc_2(COOH)_{12}$-CMC/CS	44.07	30.61	23.08	243.85

J-V curves of BPM-equipped cells

The *J-V* curves of the BPM-equipped cells were shown in *Figure 5*. The cell voltages of the BPM-equipped cells got larger with the increase of the current density. After modification using multi-carboxylic metallo-phthalocyanine derivatives, the cell voltages and *IR* drops of BPMs reduced obviously. Moreover, the *IR* drops for the modified BPMs changed gently with the increase of current density, due to a high charge density area formed in the interlayer of a BPM after

modification, which sped up water splitting, promoted the efficiency of water splitting and lowered the membrane impedance.

At the same current density, the cell voltages of the BPMs modified with binuclear metallophthalocyanine derivatives (especially with different central metal ions) were lower than that modified with mononuclear metallophthalocyanine derivatives. It was because that the charge density of the former was more concentrated, and their catalytic ability for water splitting was stronger than that of the latter. At the current density of 60 $mA \cdot cm^{-2}$, the cell voltage of the BPM modified by $FeCoPc_2(COOH)_{12}$ was only 5.3 V.

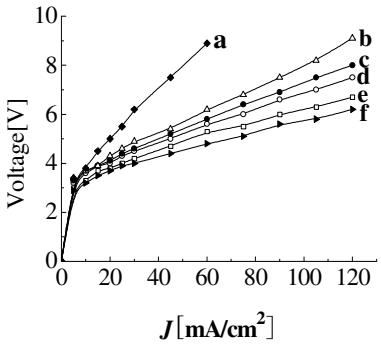

Figure 5 J-V curves of BPMs-equipped cells

(a) Cr-CMC/CS BPM (b) $FePc(COOH)_8$-CMC/CS BPM

(c) $Co_2Pc_2(COOH)_{12}$-CMC/CS BPM (d) $Fe_2Pc_2(COOH)_{12}$-CMC/CS BPM

(e) $FeCoPc_2(COOH)_{12}$-CMC/CS BPM (f) no membrane

AC impedances of BPMs

The *AC* impedance spectroscopies of the BPMs were shown in *Figure 6*. The illustration was the equivalent electrical circuit of AC impedances for the BPMs. C_d was the capacitance impedance of the interlayer, R_r was the impedance of membrane, R_l was the impedance of bulk solution. In *Figure 6*, the intersection point of the high-frequency semicircle and real aris indicated the impedance value of the membrane. The membrane impedances of the BPMs were as follows: Cr-CMC/CS BPM > $FePc(COOH)_8$-CMC/CS BPM > $Co_2Pc_2(COOH)_{12}$-CMC/CS BPM > $Fe_2Pc_2(COOH)_{12}$-CMC/CS BPM > $FeCoPc_2$- $(COOH)_{12}$-CMC/CS BPM, which corresponded to that of the cell voltages of the BPM-equipped cells at the same current density, shown in *Figure 6*.

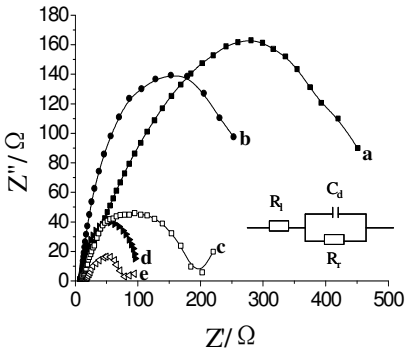

Figure 6 *AC* impedances of the different BPMs

(a)Cr-CMC/CS BPM (b)$FePc(COOH)_8$-CMC/CS BPM

(c)$Co_2Pc_2(COOH)_{12}$-CMC/CS BPM (d)$Fe_2Pc_2(COOH)_{12}$-CMC/CS BPM

(e) $FeCoPc_2(COOH)_{12}$-CMC/CS BPM

Conclusion

The multi-carboxylic metallophthalocyanine derivatives were added into CMC cation layer to prepare the modified CMC/CS BPMs, which were characterized using electric universal testing machine, contact angle measurer and so on.

The $-COO^-$groups of the multi-carboxylic metallophthalocyanine derivatives were combined with the $-COO^-$ groups of CMC by means of Cr^{3+} to form a net structure, which lowered the swelling degree of the BPMs, enhanced the dimensional stabilities, mechanical properties of the BPMs and the structure stabilities of the interlayer.

Moreover, the ion exchange capacities, and the hydrophilicity of the modified CMC membranes dramatically rose. After modification, high charge density area formed in the interlayer, which sped up water splitting, and decreased the membrane impedances and cell voltages. The charge density of the catalytic centers of the BPMs modified by binuclear metallophthalocyanine derivatives(especially with different central metal ions) was more concentrated than that modified by mononuclear metallophthalocyanine derivatives. Therefore, the catalytic ability for water splitting of the former was stronger than that of the latter. At the current density of 60 $mA \cdot cm^{-2}$, the cell voltage of the BPM modified by $FeCoPc_2(COOH)_{12}$ was only 5.3 V.

Keywords: silicon nitride, compressive stress, tensile stress, PECVD, strained Silicon

Abstract: The mechanism of high stress in silicon nitride thin film is studied systematically in this paper. The effects of the various process parameters on the stress in silicon nitride thin film deposited by PECVD are analyzed and discussed. The silicon nitride thin film with high compressive and tensile stress has been deposited on the optimized process parameters and the compressive and tensile stress are up to -1.38GPa and 866MPa, respectively. Finally, the method of further improving the stress in silicon nitride thin film is presented.

Introduction

Strained silicon technology is the new trend in the future silicon process, which can be used to enhance the hole and electron mobility in PMOS and NMOS, not only the performance of transistors is improved, but also a lot of challenge due to the decreasing device scale can be settled [1]-[4]. There are many ways to introduce the stress to silicon. With the development of this technology, using high stress silicon nitride thin film to realize stress introduction has been a main measure in advanced Si CMOS, considering some aspects, such as cost and performance, etc., which means silicon nitride thin film is not only used as passivation layer in traditional process but also used as stress material to provide local stress. There are great deals of good qualities in silicon nitride thin film, such as good physical and chemical properties, high dielectric constant, reliable thermal endurance performance, resist performance and excellent mechanical performance. The compressive stress and the tensile stress in silicon nitride thin film deposited in current silicon nitride thin film deposition methods, such as reactive sputtering and plasma enhanced CVD (PECVD). The formation of stress in silicon nitride thin film is due to transformation from atom planar grid structure to low-energy silicon-centered cubic structure, and the atomic numbers, the magnitude and the covalent bonds of silicon atom and nitrogen in silicon nitride thin film are different, which result in the stress in silicon nitride. Silicon nitride thin film will split when it is in extra tensile stress, but, drape and flake when it is in extra compressive stress [5-8]. The mechanism of the stress formation in silicon nitride is depicted in this paper, and on the basis of this mechanism, the high compressive and tensile stress silicon nitride thin film which can be used in strained silicon technology is fabricated.

Highly Strained Silicon Nitride Thin Film

The stress in silicon nitride thin film deposited by SiH_4, ammonia and nitrogen is intrinsic tensile, but the stress in silicon nitride thin film is compressive due to the high energy particle bombardment in the low frequency power source, when both high and low frequencies are all used simultaneously.

The distortion of thin film structure due to atoms or ions combination and renewed distribution because of high energy particle can result in the compressive stress in silicon nitride thin film. And the atoms or ions combination and renewed distribution will make the thin film compact. To obtain higher and available silicon nitride thin film for actual manufacture, the process parameters, including the low frequency and high frequency ratio (LF/HF ratio), the SiH_4 and ammonia ratio (SiH_4/NH_3), temperature and pressure, etc. have been optimized to improve the effect of particle bombardment. Fourier Transform Infrared Spectrometry (FTIR) shows that the higher the hydrogen concentration is, the bigger the compressive stress is. According to the current theory, hydrogen and subsequently renewed distribution lead to the compact thin film and the stress. On the other hand, the distribution of atoms is compact and the extrusion effect of atoms is increasing because of a great deal of hydrogen atom, which can also produce the further compressive stress in silicon nitride thin film [4]. Consequently, the mechanism of the formation of the compressive stress in silicon nitride thin film is that the energy transformation makes the atoms renewed distributed more compactly because of the high energy particle bombardment in low frequency power source in microcosmic structure in reaction course, which results in the higher atoms concentration and extrusion effect, and the eventually macroscopic compressive stress in silicon nitride thin film. Similarly, macroscopic tensile stress can be obtained in silicon nitride thin film in high frequency power source.

Experiments and Result Analysis

PECVD is the integrated technology which is combined with radio frequency glow discharge physical course and chemical reaction. High energy electron and active ion (Plasma) is inspired by high frequency electric field of radio frequency source in the vacuum chamber in which there are a certain concentration of SiH_4, ammonia and nitrogen at appropriate pressure. Because of the effective collision of high energy electrons, the relative linked bonds are split, and the atoms will be renewed combined and deposited on the substrate, by which the chemical reaction course takes place and at relatively low temperature and silicon nitride thin film is deposited. To obtain the high compressive stress silicon nitride thin film, 100K~300KHz low frequency power source is used in radio frequency power source, temperature is in 200~400℃, pressure is in 300~500mτ, the SiH_4/NH_3 ratio is in 2~4, and the deposition time is in 4~5 minutes. The compressively and tensely strained silicon nitride thin film has been deposited on 4 inch silicon wafer at different process parameters, such as temperature, pressure, frequency, SiH_4/NH_3 ratio and time, etc., by PECVD. The best compressive stress results are shown in Fig.1 and Fig.2, and the compressive stress is up to -1.38GPa. In addition, the experiments show that annealing in nitrogen is helpful to higher tensile stress in silicon nitride thin film, which is mainly due to the combination and release of hydrogen atom in silicon nitride formation. The best tensile stress results are shown in Fig.3 and Fig.4, and the tensile stress is up to 866MPa. The stress in silicon nitride thin film is determined by the process parameters from the experiment results. Although the original stress are different from each other because of the different initial conditions, the stress increment in subsequent course is determined by the process parameters, such as the SiH_4/NH_3 ratio, the power and frequency in power source, under the initial conditions. Consequently, the process parameters will play a decisive role in the stress magnitude.

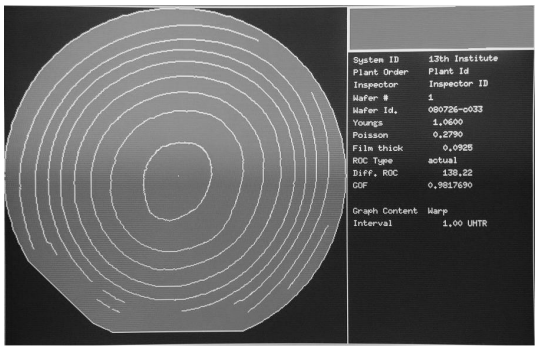

Fig.3. Tensile stress (platform)

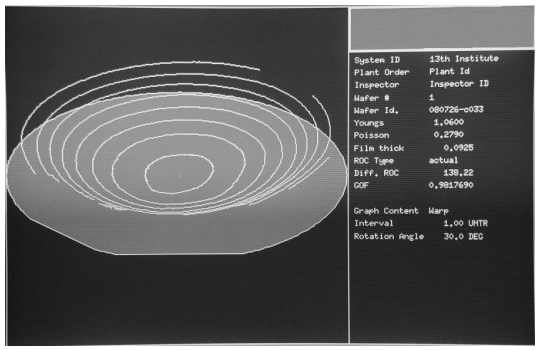

Fig.4. Tensile stress (30°rotation angle)

On the basis of the analysis to the effects of process parameters on stress in silicon nitride, we can draw the conclusion that the primary stable Si-N bond length can change in the diversified bond split and renewed combination under the certain conditions, which results in Si-N bond in excited state in the chain structure is much weaker than that in the circle structure. That is to say, under the same condition, the Si-N bond in the chain structure is easier to split than in circle structure, which means the Si-N bond in the circle structure is more stable. It is obvious that the atoms are compact, the bonds are not easy to split, and the physical and chemical properties are more stable in the circle structure, comparing these two structures. So we can infer that the chemical properties are stable, the stress is high, and the Si-N bond is not easy to split in the compact thin film. In general, the Si-N bond energy has great effect on the stress in the silicon nitride thin film, and the lower the bond energy is, the lower the stress is.

On the other hand, there are great effects of impurity on the stress in silicon nitride thin film deposited by PECVD, according to the other relative references and recent works. In the mean time, the bond length can affect the stress in silicon nitride thin film. So we can foresee that the integral stress will increase, if the ingredients are adjusted in the fabrication of silicon nitride thin film. For example, SiH_4 is replaced by SiH_3-CH_3, which adds the C-N bond in the reaction course, and the length of C-N bond is longer than that of Si-N bond, which can result in the compact atom arrangement. We obtained several sets of reasonable and optimized data from the analysis to the relative theory and the experiment results. We can obtain the higher stress thin film by not only the optimized process parameter but also the subsequent process, such as annealing, ultraviolet assisted thermal processing, etc., to improve the performance of Si CMOS devices and circuits.

Summary

The mechanism of the high stress in silicon nitride thin film is studied in this paper. The effects of the various process parameters on the stress in silicon nitride thin film by PECVD are analyzed

and discussed. The highly compressive and tensile stress in silicon nitride thin film has been obtained on the optimized process parameters, and the compressive and tensile stress are up to -1.38GPa and 866MPa, respectively. Finally, the method of further improving the stress in silicon nitride thin film is presented. The highly strained silicon nitride thin film deposited by PECVD in this paper may be used in the local strained silicon technology to improve the performance of Si CMOS devices and circuits.

Keywords: SAPO-34 Zeotype, Electrophoretic Deposition, Fine Layer Formation, Hydrothermal Crystallization

Abstract: Fine layer growth of SAPO-34 crystals on the steel and α-alumina substrates has been investigated by electrophoretic deposition (EPD) followed by secondary growth. At first step, two sizes of SAPO-34 seeds with different composition of precursor solution were synthesized. Thereafter the best quality of the seeds in term of crystal size was selected for seeding operation. All seeded samples were prepared by electrophoretic deposition (EPD) with 0.4 wt% powder in solution, voltage of 4.5 V and deposition time of 90 min, followed by the secondary growth in a Teflon lined autoclave for crystallization at 473K for 24 hr.

The prepared fine seeds characterized by XRD and SEM analysis. Also the substrates were broken and characterized by SEM methods in terms of surface coverage and mean size of the particles. The results revealed a better quality of the coated film on the surface of steel rather than α-alumina on the base of homogeneity and crystal size.

Introduction

Within the two previous decades, application of zeolite membranes for separation purposes has been widely developed. The significant mechanical resistance and suitable performance in different and even difficult conditions for temperature and pressure, is the most important specifications of these membranes [1]. Up until now, various types of zeolites with different pore size such as MFI, DDR, FAU have been used for the membrane production on different types of substrates [2]. Among various kinds of zeolites, the zeolite-like SAPO-34 having chabazite type framework with pore size of 0.038 nm, would be suitable for separating mixtures of light gases [3].

The in situ hydrothermal synthesis is the most frequently used approach for fabrication of zeolite membrane, in which the substrate is immersed into the precursor solution, and then the membrane is formed by direct crystallization [4]. However, it is difficult to fabricate high quality and defect free zeolite membrane by this method. Coating the zeolite seed on the support surface before hydrothermal synthesis has recently been developed for the preparation of zeolite membranes. This method is called secondary growth, which it's key benefit is greater control over the nucleation step and the zeolitic layer thickness by separating the crystal nucleation and growth with a shortened crystallization time [1,5].

The quality of the final membrane layer, depends entirely on the quality of the zeolite seeds [5]. Reduction in zeolite crystal size, is an important issue in recent years because the properties of the materials are greatly influenced by the change in zeolite crystal dimensions [6].

Different methods have been proposed for ceramic's seeding. Jabbari et al [7] investigated three different seeding methods including rubbing, dip-coating and EPD performed on tubular α-alumina

supports followed by one time hydrothermal crystallization, and concluded that suitable layer of SAPO-34 was formed by rubbing or EPD method of seeding.

Electrophoretic deposition (EPD) is one of the colloidal processes in ceramic production and has advantages of the short time formation, requires simple apparatus and it is less restricted by the shape of substrate [8].

In the current contribution, the comparative study between two kinds of substrates for seeding by fine SAPO-34 seeds via EPD method in constant voltage and seed concentration in aqueous solution has performed. The size of the seeds are the most influential parameter in layer formation during secondary growth and in this work two different sizes of seeds are investigated.

Experimental

Two kinds of SAPO-34 powders with stoicheometric formula of 1Al2O3:0.5SiO2:1P2O5:100H2O:mTEAOH:n Morpholin in reaction mixture were prepared for seeding operation. Aluminum isopropoxide (white powder, 98 wt%, MERK) and phosphoric acid (85 wt%, MERK) have been used as alumina and phosphorus source, respectively. The synthesis condition of making precursor solutions are shown in Table 1, for two different sizes. Aluminum isopropoxide was added to solution of H3PO4 and water to form a cream-like homogenous gel. Then, templates and silica source was added to this solution. The prepared synthesis gels were poured in Teflon lined steel autoclave and the crystallization step was performed at 473 K for 24 hr. After hydrothermal crystallization the content was washed with distilled water, centrifuged and dried at 373 K for 3 hr.

The mean particle size of each sample are calculated from SEM images from Fig. 1 and they are shown in Table 1. The results shows that using TEOS as silica source makes formation small particles even if we use a lower concentration of TEAOH.

TABLE 1: SPECIFICATION OF TWO KINDS OF SAPO-34

Sample no.	Silica source	Template	m,n	mean particle size (μm)
P1	TEOS(98% MERK)	TEAOH,(20 wt%, MERK), Morpholine	1.2,0.4	0.4
P2	Colloidal silica in water (40 wt%, MERK)	(TEAOH, 35 wt%, Aldrich)	2.2,0	1

Stainless steel tube of inner diameter 9 mm, thickness 1 mm and 10 mm length and α-alumina of inner diameter 7 mm, thickness 3 mm and 10 mm length were used as the support for synthesis of SAPO-34 membrane. Before seeding, the substrates were cleaned with deionized water in ultrasonic cleaner for 15 min.

0.4 wt % SAPO-34 seeds were dispersed in deionized water under ultrasonication for 30 min. Then the EPD operation performed with 4.5 volts and deposition time of 90 min. Thereafter, the seeded substrates were placed vertically in an autoclave. The autoclave was filled with reaction mixture having the same composition of the P1 seeds and the procedure was the same as seed synthesis. After secondary growth, the coated membrane was washed thoroughly with deionized water to approach neutral solution.

The XRD patterns of the SAPO-34 powders was obtained using high resolution X-ray diffraction, XRD, (INEL EQuinox 3000) diffractometer with the source of Cu Ka (k = 1.541874 ˚A). SAPO-34 powders and the formed membranes were analyzed by FESEM (Hitachi s-4160, at 20 keV).

Results and Discussion

The XRD pattern of Samples are shown in Fig. 1. The observed pattern confirms SAPO-34 formation by comparison with the [3,5].

Fig. 2 shows SEM image of two kinds of SAPO-34 seeds. These images clearly show that the particles P1 are smaller than the particles P2, therefore P1 was selected for seeding operation.

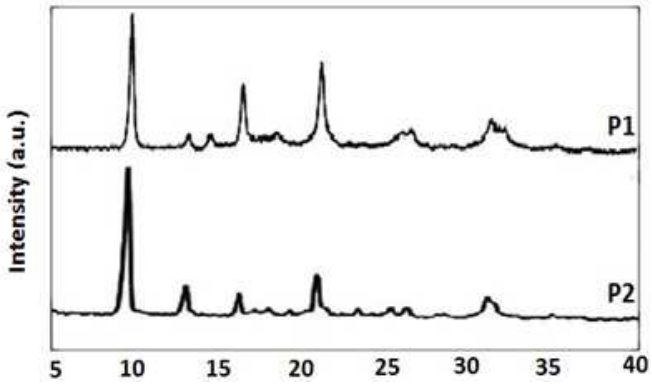

Fig. 1: XRD pattern of the as-synthesized SAPO-34 powder

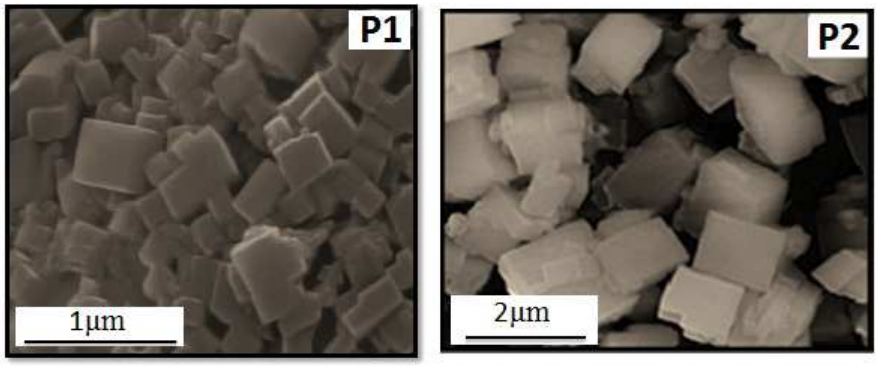

Fig. 2: SEM images of two kinds of SAPO-34 according to table 1.

Fig. 3 shows the SEM images of the top section and cross sections of the fine layers formed on each substartes. According to the SEM images, appropriate coverage has been achieved by samples using steel as the substrate rather than alumina.

Fig. 4 shows the particle size distribution of the coated particles that is measured from the top section figure. Particle size distribution of two samples are approximately the same and the mean size of the SAPO-34 particles is calculated about 0.3 μm.

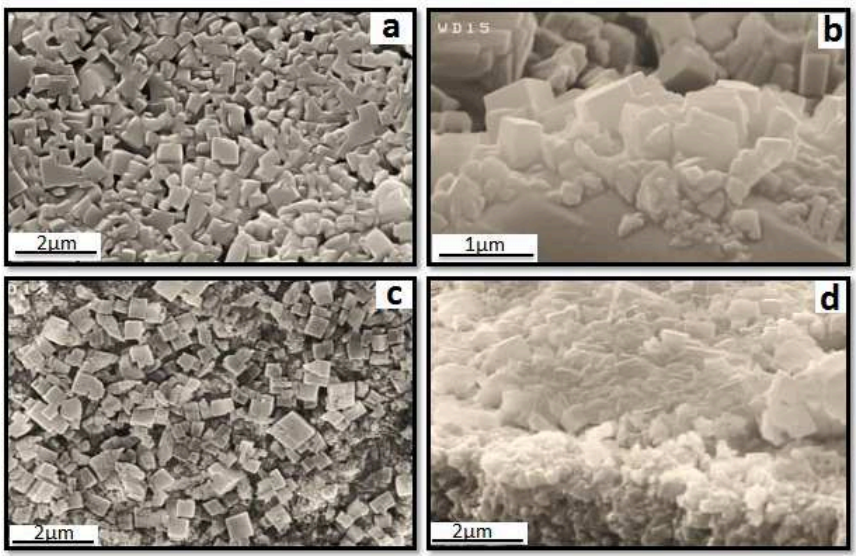

Fig. 3: SEM image of Samples, a) steel substarte top section. b) steel substarte cross section. c) α-alumina substarte top section. d) α-alumina substrate cross section

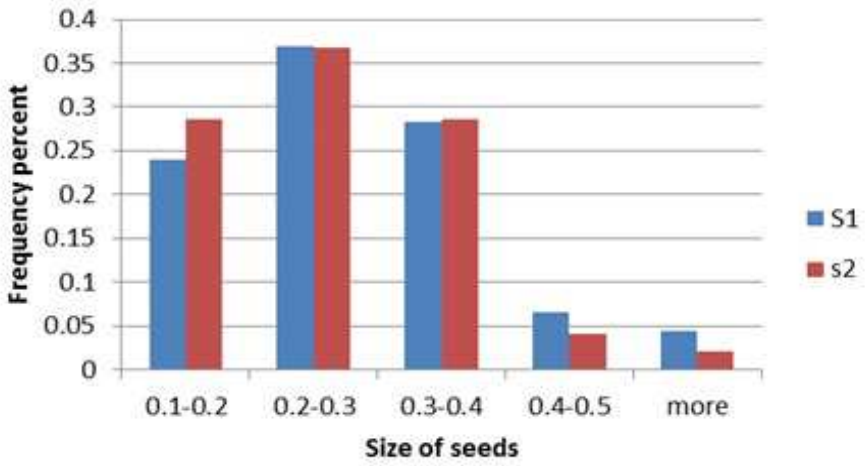

Fig. 4: Particle size distribution of samples

Conclusions

Membrane fabrication by hydrothermal method requires appropriate seeding methods for secondary growth crystallization to achieve uniform, fine and defect free membranes. EPD method would be a suitable approach to achieve this goal. Quality of the seeds prepared for EPD method and the type of substrate have shown significant role to achieve proper and uniform layer. It is concluded that the formed layer by EPD method with the uniform and less size of the particles on the surface of porous steel support is capable for qualified membrane fabrication.

Keywords: Microcrystalline silicon film. ECR-PECVD. Substrate effect. Ar-dilution.

Abstract: Microcrystalline Si films were deposited by electron cyclotron resonance plasma-enhanced chemical vapor deposition (ECR-PECVD) using Ar diluted SiH_4 gaseous mixture. The effects of the substrate on deposition rate, preferred orientation and roughness of the films were investigated. The results show that, the influence of the substrate surface chemical nature on the deposition rate is significant in the initial stage of the growth. And considering the crystallinity and roughness of the films, the substrate is favored in its preferred orientation with a rougher surface. Based on these results, it is confirmed that the combination of diffusion and etching is indispensable to describe the deposition of μc-Si with SiH_4 diluted by Ar, and the mechanism of μc-Si growth could be controlled by diffusion of Si and etching of the Ar^+ on the film surface.

Introduction

With the developments of the solar cells industry, microcrystalline silicon films have attracted considerable attention for its high-efficiency and stability. It is attractive and desirable that direct deposition of microcrystalline silicon films at low temperature with high deposition rate by plasma enhanced chemical vapor deposition (PECVD) [1]. Microcrystalline silicon films are widely produced using SiH_4+ H_2 gaseous system because it is believed that atomic hydrogen can balance the dangling-bonding defect and hydrogen ions can etch the weak Si-Si bonds, so as to promote stability and crystallinity of the films [2]. However, H_2 dilution would limit the deposition rate seriously and great amount of H existing in the film would draw back the photoelectric efficiency of micro-Si film due to acceptor-like defect formation and light-induced defect creation [3,4].

In our previous researches, Ar was used instead of H_2, and the results demonstrated that the deposition rate was 1.5-2 times higher than using H_2 [5]. At the same time, the concentration of hydrogen in the films decreased dramatically, which would limit the creation of the light-induced defect in microcrystalline silicon [3] and enhance the photoelectric efficiency of the films. In present work, the effects of the substrate on the deposition rate, the preferred orientations, and surface image as well as roughness of the films were investigated, along with the growth mechanisms of microcrystalline silicon film with Ar dilution of SiH_4.

Experiment

The μc-Si films were deposited on general optical glass and (111) Si substrates with SiH_4/Ar by ECR-PECVD. Pre-vacuum of the reaction chamber was 6×10^{-3} Pa. The substrates were ultrasonically cleaned in alcohol and acetone solutions individually for 10min, and then cleaned in Ar^+ plasma for 10min. The substrate temperature was 300℃. The microwave power was 600W. The flow rate of SiH_4 was fixed at 10sccm，and a sequence of Ar flow rate was chosen: 20sccm, 30sccm, 40sccm, 55sccm, 70sccm, 85sccm, and 100sccm.

The preferred orientations of as-deposited films were identified by X-ray diffraction (XRD). Atom force microscopy (AFM) was utilized to characterize the topography and surface roughness of the films.

Results and Discussion

Effects of Substrate on Deposition Rate

Fig. 1 shows the deposition rate as a function of argon flow rate on different substrates. As shown in Fig. 1, the variation trends of the deposition rate with the increase of Ar flow rate on two substrates exhibit uniform. And the deposition rate on Si wafer is faster than that on general optical glass in the beginning, but the gap decreases gradually. Namely, the influence of the substrate on the deposition rate becomes minor when the technological parameter increased.

It is because that substrate contributes significantly to the film initial nucleation rate which would be determined by the critical nucleation free energy ΔG^* given by

$$\Delta G^* = \frac{16\pi\gamma_{vf}^3}{3\Delta G_V^2}\frac{(2-3\cos\theta-\cos^3\theta)}{4} \quad . \tag{1}$$

Where θ is wetting angle, G_v is unit volume free energy, γ_{vf} is boundary energy between gas and film. As shown in equation (1), ΔG^* would decrease with the decrease of θ [6] . When μc-Si film was deposited on Si substrate, θ would be smaller, so that ΔG^* would be minor than that of the film deposited on glass substrate. Consequently, Si substrate would be favored for higher film initial nucleation rate which would increase with the decrease of ΔG^*.

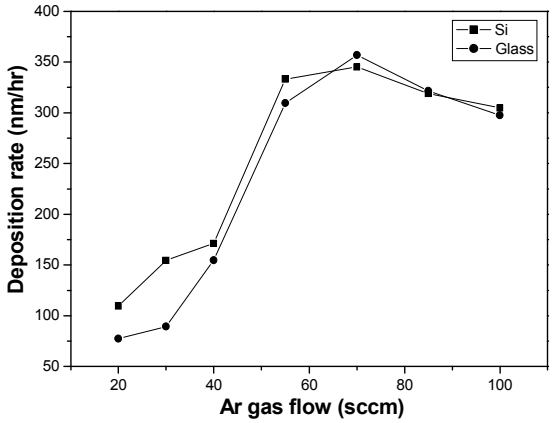

Fig. 1 Deposition rate of μ-Si films deposited on different substrates

When Ar flow rate is minor, the ionization rate of gas and the aggregation rate of atoms are lower, so that diffusion capability of active radicals are smaller and the mean staying time of sticking atoms on the film-growing surface would be shorter. The film growth depends mostly on the thermal fluctuation atoms absorbed on the surface, and nucleation would be initiated after the combination and merging of these atoms. That is to say, in this case, the contribution of initial nucleation rate to the film deposition rate would be quite major. In contrast to that the influence of initial nucleation rate on the deposition rate becomes less obvious for the improved gas ionization rate and the diffusion capability of active radicals when Ar flow rate increased. It is indicated that the substrate influence on the deposition rate would become less obvious with the increases of Ar flow rate.

Effects of Substrate on Film Preferred Orientation

The preferred orientations of the films fabricated on different substrates with different argon flow rate were characterized by XRD. As shown in Fig.2, with the increase of Ar flow rate, the dominant crystal textures of the films deposited on Si substrates are always <111> orientation, but the films deposited on glass substrate exhibit from amorphous (with Ar flow rate 20sccm, 30sccm, 40sccm, and 55sccm) to crystalline silicon whose dominant crystal textures are (111) and (220). It is suggested that the substrate would affect remarkably on the film quality, which could be explained with the surface chemisorption theory.

Many researchers have proved that, surface chemisorption would adhere to the rules of monolayer adsorption of Langmuir [7]. It is illustrated that ordering of the adsorption molecules is essential to the ordering of the film-growth. There exist great amount of dangling-bonds in the surface of (111) Si substrate, and these dangling-bonds would make the adsorption radicals resident on deposition surface for longer time, which would be favorable for crystallization. However, the radicals would be short lived on glass substrate. Some of them would depart from deposition surface, and the remains would aggregate with each other before finding proper position preparing for crystallization. So it would be easier to obtain the crystalline silicon film on (111) Si substrate than on glass substrate.

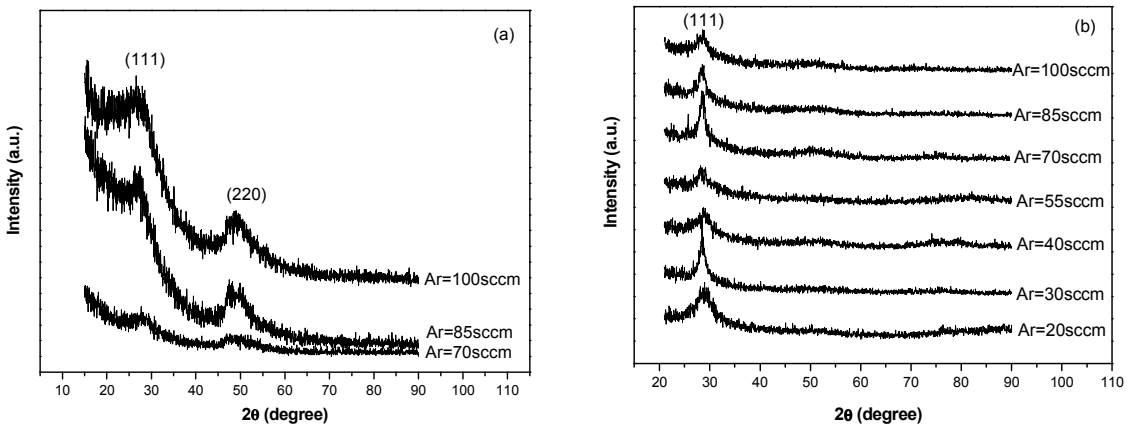

Fig. 2 XRD spectra of the films deposited with different Ar flow rate:
(a) on glass substrate, (b) on silicon substrate

On the other hand, the dominant crystal texture of the films deposited on silicon substrate is (111), which is mainly influenced by the substrate's orientation, in contrast to (111) and (220) on glass substrate. It could be explained by growth dynamics [8]. Atoms are known to be more easily absorbed on close-packed surface with higher surface energy than non close packed structure. So that the vertical growth of the non close packed plane is more rapid, and these planes would vanish gradually with the film growth. However, transversal growth of close-packed plane is quicker, resulting in that the orientations of these planes would become the film's preferred orientations, such as (111) and (220).

Effects of Substrate on Film's Surface Image and Roughness

The surface morphology of the films is a significant factor for device performance. Indeed, a rougher film allows for an increased light trapping in the acting *i*-layer of the cell, thereby to an increased short circuit current [9]. The representative surface morphologies of the films deposited on Si and glass substrates with different argon flow rate, respectively, are shown in Fig. 3.

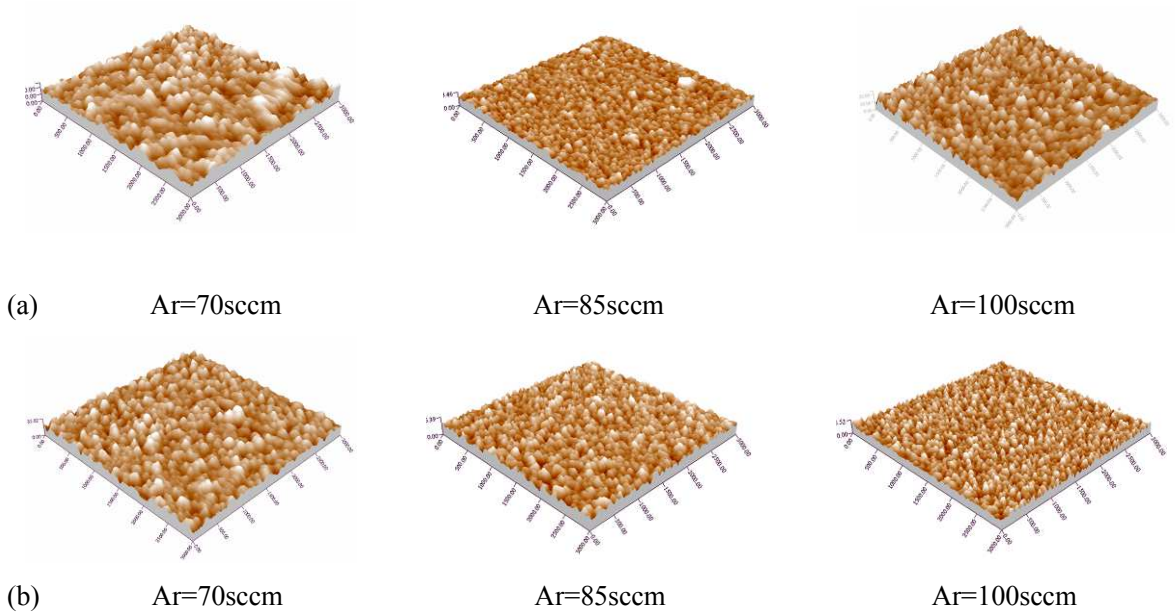

Fig. 3 AFM images of μ-Si deposited on different substrate: (a) glass, (b) Si

From Fig. 3, the distinguishing islands with a lager diameter were observed on glass, but its island density is smaller than that of on Si. It is attributed to the minor energy barrier of the film nucleation and higher nucleation rate on Si substrate than on glass. Table 1 lists surface roughness of the films shown in Fig. 3, and it is clear that the film deposited on Si is rougher. It is well known that the growth of the μc-Si film commences with the nucleation of 'islands' of the deposited material followed by columnar growth and coalescence, which makes the film more compact and continuous [10]. So a rougher film on Si substrate can be interpreted as: the vertical growth of the film is more rapid when the substrate is in its preferred orientation with a rougher surface, in contrast to a quicker transversal growth for the amorphous substrate.

TABLE 1 SURFACE ROUGHNESS OF FILMS DEPOSITED ON DIFFERENT SUBSTRATES WITH DIFFERENT ARGON FLOW RATE

Ar flow rate[sccm]	**roughness [nm]**	
	Glass substrate	**Si substrate**
70	2.95	3.27
85	3.08	4.27
100	3.7	4.38

As discussed above, substrate has a strong influence on the deposition rate and structure properties of the μc-Si film. Hence, it is necessary to analyze the growth mechanisms of microcrystalline silicon film with Ar dilution of SiH_4. Up to now details have been under discussion for μc-Si, but three models were favored: etching model, diffusion model, and chemical annealing [11].

According to our experiment results, the film crystallinity deposited on two substrates would increase with the increase of Ar flow rate, which agree with etching model. In addition, the experiment results also indicate that more exacting terms would be needed for obtaining crystalline silicon film deposited on glass substrate, which agree well with diffusion model. Above all, it is confirmed that the combination of diffusion and etching is indispensable to describe the deposition

of μc-Si with SiH_4 diluted by Ar. The growth model was considered as follows: Thermal fluctuation atoms absorbed on the growth surface plays an important role in the beginning of the film growth. Nucleation would be initiated after the combination and merging of these atoms. The dangling bond could be saturated by hydrogen atoms existing in the plasmas. Then mobility and diffusion of the SiH_x-radical on the surface of the films would remove these H atoms and produce the Si-Si bond. It is suggested that Ar^+ etching on the film surface would participate in the growth process which would remove the weak Si-Si bond and the crystalline silicon film would be formed.

Conclusions

The effects of the substrate on microcrystalline Si films deposited by ECR-PECVD using SiH_4+Ar were studied. The results indicate that the chemical nature of the substrate surface significantly influences the initial stage of the growth. Furthermore, the preferred orientation and roughness of the films would be affected remarkably by the substrate features. On the basis of the experiment results, the mechanism of μc-Si growth with SiH_4 diluted by Ar could be controlled by diffusion of Si and etching of the Ar^+ on the film surface.

Keywords: Ferroelectric thin film; Polarization reversal; Surface transition layer

Abstract. Utilizing the Landau-Khalatnikov equation of motion, the polarization reversal characteristics of a ferroelectric thin film with surface transition layers have been first investigated. We have discussed the effects of the thickness, the surface transition layer parameters and the temperature on the switching properties of a ferroelectric thin film. The results show that the stronger the surface transition layer effects are, the smaller the coercive field and switching time are.

Introduction

One of the increasingly hot topics is the polarization reversal in a ferroelectric thin film, which can provide a promising avenue for the future of nanoelectronic memories and logic devices [1-3]. To meet the need of the miniaturization of ferroelectric materials particularly in microelectronic devices, the understanding of the size and surface effects on the polarization reversal in a ferroelectric thin film is greatly urgent [4]. Therefore, the investigation for the effects of surface and film thickness on the polarization reversal properties of ferroelectric thin films has been an active research area from both a fundamental research and technological point of view [5].

Experimentally, Mitoseriu et al. [6] studied the polarization reversal properties of BaTiO3 ferroelectric ceramics at room temperature with two different grain sizes. The results showed that the switching time decreases with decreasing sizes. The thickness effects on the heteroepitaxial BaTiO3 films prepared on SrRuO3/SrTiO3 substrates by ratio-frequency magnetron sputtering employing a two-step deposition technique have been researched by Yanase et al [7]. A ferroelectric hysteresis loop was clearly observed in the heteroepitaxial BaTiO3 films even when the thickness was reduced to 12 nm, probably due to improved crystallinity at the interface between the ferroelectric film and the electrodes through optimization of the preparation technique. In theory, some models have been established to deal with the switching properties of ferroelectric thin films, such as Avrami theory [8], Kolmogorov- Avrami –Ishibashi (KAI) theory [9], non-KAI model [10], and discrete model based on the Landau-type-free energy [11, 12].

In the above theories, the surface effects on the polarization reversal in a ferroelectric thin film are not discussed. In recent years, Tilley-Zeks model of Landau Devonshire free energy expression by adding a Landau-Khalatnikov equation of motion is commonly used to study the phenomena of polarization reversal in ferroelectric thin films [13, 14]. The surface effect is considered in virtue of the extrapolation length. In this model, however, a sudden structure transition from surface to the interior for each constituent film is assumed, which is not realistic because the transition of structure

should be gradual. To avoid the insufficiencies brought by extrapolation length, the surface transition layer, representing the gradual transition of structure, was first introduced in a ferroelectric thin film by Lü and Cao [15]. They have studied the static properties (polarization distribution, phase transition temperature and dielectric susceptibility, etc.) of a ferroelectric thin film with surface transition layers [16-19]. As far as we know, the switching properties of a ferroelectric thin film by taking into account the surface transition layer have not been reported.

In this paper, we study the influences of the film thickness and temperature on the polarization switching characteristics of a ferroelectric thin film with the surface transition layers under the action of a step field, by means of the Landau- Khalatnikov equation of motion.

The model and theory

A ferroelectric thin film with surface transition layer located between two metallic electrodes is considered as the stacking of thin layers, as shown in Fig. 1. The properties of every layer with finite thickness Δz are homogeneous in planes parallel to the surface and the variation is only along the z direction. The number of the layer stack is N. Thus, the whole thickness of the ferroelectric thin film is $L = N\Delta z$. If the origin is located at the left surface, we set $z = 0$ then an arbitrary layer located at a position z can be recognized by the index i, i.e. $z = i\Delta z\ (1 \le i \le N)$.

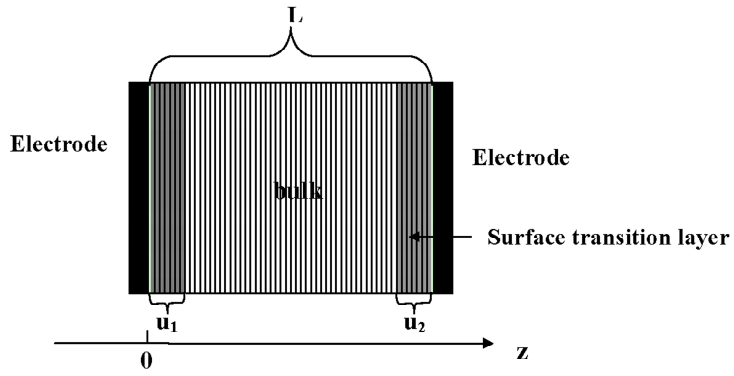

Fig. 1 Geometric structure of a ferroelectric thin film under study

To study this system, a modified Landau-type free energy for the system needs to be established. According to Ref. [16], we introduce a second power of polarization for each layer in the Landau-type free energy and assume its coefficient to be function of position in order to reflect the contribution of surface transition layers. So the free energy of the film can be expressed by Landau-type free energy expression [16, 20, 21]

$$G = \sum_{i=1}^{N}\left[\frac{1}{2}A\left(T - T_c\right)P_i^2 + \frac{1}{2}B\psi\left(z\right)P_i^2 + \frac{1}{4}CP_i^4 + K\left(P_i - P_{i-1}\right)^2 - EP_i\right], \tag{1}$$

with the boundary condition [15]

$$\left(\frac{\mathrm{d}P}{\mathrm{d}z}\right) = 0 \qquad \text{when} \quad z = 0 \text{ and } z = L, \tag{2}$$

where P_i is the polarization of the $n-$th layer; the coefficients A, B, C, and K are independent of temperature T and position z; T_c is the transition temperature of the bulk ferroelectric; E is the applied field. A new term (the second term) is added in Eq. (1) in order to reflect the contribution of the surface transition layer. Thereinto, $B>0$ denotes a decrease in the local polarization at surfaces, and $B<0$ expresses an increase in the local polarization at surfaces. In this paper, we only consider the case of $B>0$. The distribution function $\psi(z)$ reflects the surface effect. The $K\left(P_i-P_{i-1}\right)^2$ term in Eq. (1) represents the coupling effect between neighboring layers. The polarization gradient $\left(\mathrm{d}P/\mathrm{d}z\right)^2$ can be included in the finite difference expansion of the $K\left(P_i-P_{i-1}\right)^2$ term [20]. The time variation of the polarization during switching can be described by the Landau-Khalatnikov equation as follows:

$$\gamma\frac{\partial P_i}{\partial t}=-\frac{\partial G}{\partial P_i}=-A\left(T-T_c\right)P_i-B\psi\left(z\right)P_i-CP_i^3+K\left(P_{i+1}+P_{i-1}-2P_i\right)+E \tag{3}$$

where γ is the coefficient of viscosity, which causes a delay in domain motion.

It is convenient to rescale the variables into dimensionless forms. We set $f_i=P_i/P_0$ with $P_0=\sqrt{AT_c/C}$, $t_T=T/T_c$, $\delta=B/B_0$ with $B_0=AT_c$, $\zeta=z/\xi_0$ with $\xi_0=\sqrt{K/AT_c}$, $l=L/\xi_0$, $\eta=tAT_c/\gamma$, $k=K/AT_c$, $\sigma=(\varepsilon_0 AT_c)^{-1}$, $e=E/E_0$ with $E_0=P_0/\varepsilon_0$, where ε_0 is the dielectric constant of vacuum. Finally, we can obtain the normalized equation below:

$$\frac{\partial f_i}{\partial\eta}=\left(1-t_T\right)f_i-\delta\psi\left(\zeta\right)f_i-f_i^3+k\left(f_{i+1}+f_{i-1}-2f_i\right)+\sigma e \tag{4}$$

The corresponding rescaling boundary condition is

$$\left(\frac{\mathrm{d}f}{\mathrm{d}\zeta}\right)=0 \quad \text{when } \zeta=0 \text{ and } \zeta=l. \tag{5}$$

Another index j is introduced to represent the discretized time $\eta=j\Delta\eta$. The time dependent polarization at each layer is denoted as $f_{i,j}$. Through the forward difference in time for the left-hand side of Eq. (4), the difference equation for $f_{i,j}$ can be written as:

$$f_{i,j+1}=f_{i,j}+\Delta\eta\left[\left(1-t_T\right)f_{i,j}-\delta\psi\left(\zeta\right)f_{i,j}-{f_{i,j}}^3+k\left(f_{i+1,j}+f_{i-1,j}-2f_{i,j}\right)+\sigma e\right] \tag{6}$$

According to the finite difference for the derivative $\left(\mathrm{d}f/\mathrm{d}\zeta\right)$ in the second-order smallness, Eq. (5) becomes

$$\begin{cases} f_{0,1} = f_{1,j} = f_{2,j} & \zeta = 0 \\ f_{N,j} = f_{N-1,j} = f_{N-2,j} & \zeta = l \end{cases} \tag{7a, b}$$

The overall polarization of the whole film is defined as

$$\overline{f_j} = \frac{1}{N}\sum_{i=1}^{N} f_{i,j} \tag{8}$$

and the switching current is determined by

$$I_j = \frac{\mathrm{d}\overline{f_j}}{\mathrm{d}\eta} \tag{9}$$

Since there is no experimental data available on the effects of the surface transition layer, a simple form is chosen for the distribution function $\psi_i(\zeta)$. The peculiar choice of $\psi_i(\zeta)$ does not affect the generality of the results and conclusions [16]:

$$\psi_i(\zeta) = \begin{cases} \left(\dfrac{i\Delta\zeta - u_1}{\lambda_1}\right)^2 & 0 \le i < \dfrac{u_1}{\Delta\zeta} \\ 0 & \dfrac{u_1}{\Delta\zeta} \le i \le N - \dfrac{u_2}{\Delta\zeta} \\ \left(\dfrac{i\Delta\zeta - \left(N\Delta\zeta - u_2\right)}{\lambda_2}\right)^2 & N - \dfrac{u_2}{\Delta\zeta} < i \le N \end{cases} \tag{10}$$

where u_1 and u_2 are the thickness of the left and right surface transition layer, respectively. Parameter λ_1 (λ_2) reflects the variation intensity of the free energy density of each layer near the left (right) surface. For simplicity, the two surface transition layers are assumed symmetric, namely, $u = u_1 = u_2$, $\lambda = \lambda_1 = \lambda_2$.

It is useful to mention the bulk coercive field and derive from the equilibrium state as

$$e_{c0} = \pm\frac{2}{3\sqrt{3}}\left(1 - t_T\right)^{3/2} \tag{11}$$

Due to the polarization reversal often studied experimentally by a step electric field, we now show some results for switching in a step field. As stated, the polarization in the initial state is the negative remnant polarization, that is to say, the initial polarization is at zero field; then at the time $\eta = 0$ the field is switched to a positive value. The switching time is a key quantity, which is defined in several ways in the literatures. Here, we will use a definition of switching time as t_0, which is the time at which the polarization reaches zero [22].

Numerical results and discussions

The polarization profiles of the film during the switching process are shown in Fig. 2 which are calculated at selected times under different surface transition layer thickness and λ. The polarization of the film switches from the initial negative state to positive state by the applied field. From Fig. 2 (a), we can see that at the time $\eta = 0.4$, the polarization near the surfaces just starts to reverse, then gets to the interior and at the time $\eta = 0.6$ the polarization of the film has been completely switched. It is ascribed to the polarization of the surface transition layers smaller than that of the interior. The result is consistent with that obtained by Chew et al [23]. When the thickness of surface transition layer u increases (see Fig. 2(b)), the polarization near the surfaces takes a shorter time ($\eta = 0.2$) to reverse than that in Fig. 2(a). And it takes a shorter time ($\eta = 0.4$) to complete the switching process, compared with Fig. 2(a). When we decrease the value of λ, see Fig. 2(c), also a shorter time is required for reversing the polarization near the surfaces according to Fig. 2(a), but it takes a longer time to complete the switching process relative to Fig. 2(b). So the influence of the thickness of surface transition layer on the polarization distribution is more obvious than that of λ. Furthermore, with increasing the time, the polarization of the film reduces before the completion of the switching process, whereafter, the polarization of the film augments with increasing the time. Hence, it will take a shorter time to achieve the polarization reversal of the film if we increase the thickness of the surface transition layer or reduce λ.

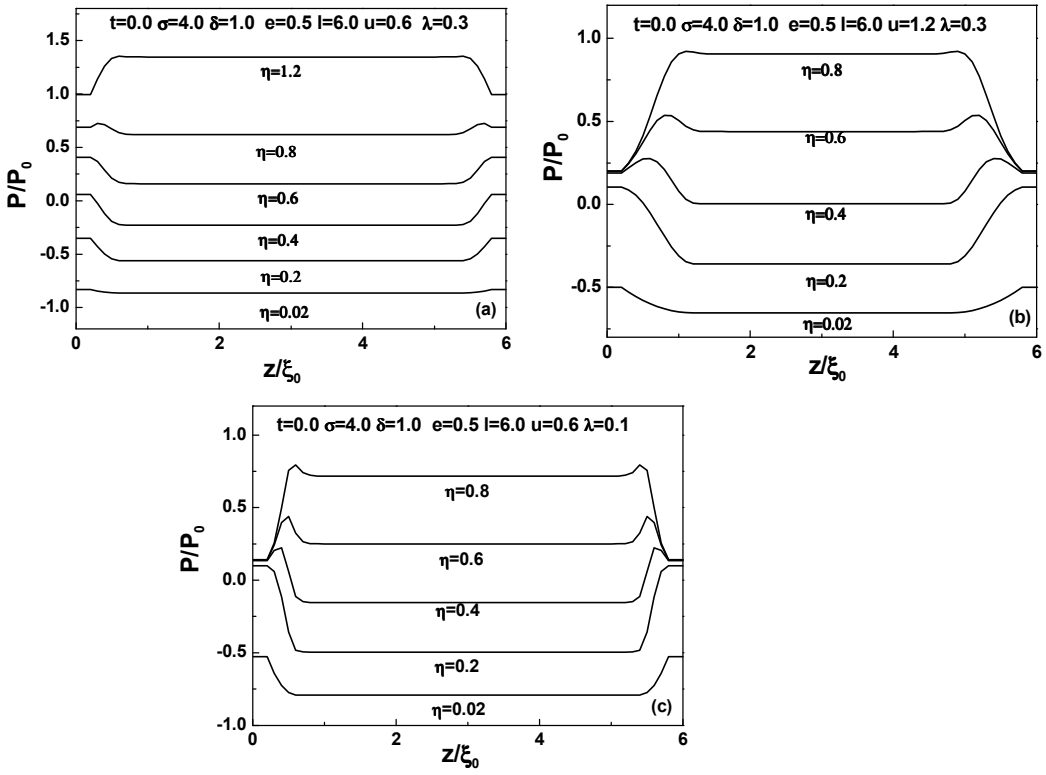

Fig. 2 Polarization distributions at selected times under different surface transition layer thickness and λ

The coercive field versus the thickness of the film for various surface transition layer thickness and λ is elucidated in Fig. 3. One can clearly see that when the surface transition layer thickness and λ are fixed, the coercive field decreases as the thickness of the film reduces. The trend is attributed to the increase of the ratio of surface transition layer to the whole film. According to Fig. 2, the stronger surface effects will make the polarization reversal of the film easier. For a given thickness of the film, the coercive field decreases with increasing the thickness of surface transition layer or reducing λ. It is worth emphasizing that the coercive field has a finite size behavior, where a phase transition from ferroelectric phase to paraelectric phase occurs at a certain critical thickness. And the critical thickness augments with increasing the thickness of surface transition layer or reducing λ. The above phenomena well coincides with those of Ref. [14]. Moreover, in accordance with Eq. (11), we gain the bulk coercive field is 0.097, which is larger than the coercive field of the film, as shown in Fig.3. That is to say, the polarization can be reversed by an electric field weaker than the bulk coercive field.

Figure 4 illustrates the switching time as a function of the thickness of the ferroelectric thin film. For a given applied field, the switching time is shorter for a thinner film, which is consistent with the experimental result of Ref. [24], and also accords with the theoretical result calculated by Wang et al. [25]. The physical reason is that as the thickness of the film reduces, the proportion of surface transition layer to the film augments. According to Fig. 2, it will take a shorter time to complete the polarization switching process with larger thickness of surface transition layer or smaller λ.

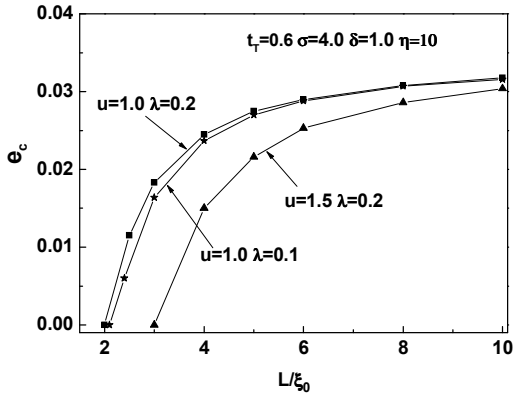

Fig. 3 Coercive field versus the thickness of the ferroelectric thin film for different surface transition layer thickness and λ

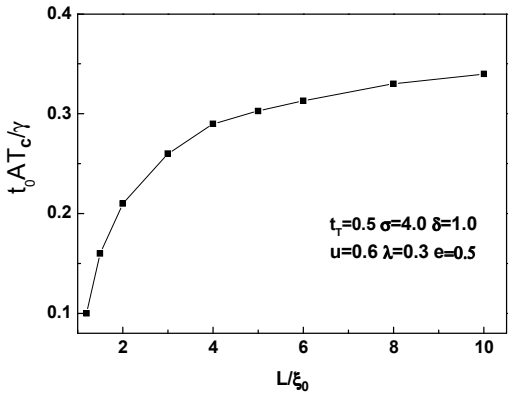

Fig. 4 Switching time as a function of the thickness of the ferroelectric thin film

Summary

In summary, we have discussed the influences of the film thickness and temperature on the polarization switching characteristics of a ferroelectric thin film with the surface transition layers using the Landau- Khalatnikov equation of motion for the first time. The results we obtained can be summarized as follows: (1) the existence of surface transition layer makes the time of polarization reversal of the film become shorter; (2) the coercive field and the switching time decrease as the thickness of the film reduces; (3) a critical thickness exists for coercive field of the film, and augments as the surface effects enhance; (4) a higher temperature can quicken the polarization switching of the film.

Keywords: diamond films; interlayer; copper substrate; SEM; hot filament chemical vapor deposition (HFCVD)

Abstract: Diamond films were grown by hot filament chemical deposition (HFCVD) on Cu metal substrate with two different buffer layers (SiC or $MoSi_2$) synthesized by using magnetron sputtering technique. The components of films were investigated using X-ray diffraction (XRD) and laser Raman spectrum, and the surface morphology and structure were observed with scanning electron microscopy (SEM). Film adherence was investigated by micro-indentation. The results showed that the diamond films were successfully grown on Cu metal substrate with two different buffer layers. There were cracks on diamond film grown on 3μm SiC buffer layer and some SiC crystal whiskers were observed. Dense diamond films with bad adhesion were observed on 22μm $MoSi_2$ buffered copper substrate. $MoSi_2$ made chemical reaction with CH_4 and produced MoC and Mo_5Si_3 on the process of HFCVD. Conclusion: the 3μm buffer layer of SiC can't help deposit no cracking diamond film; the 22μm buffer layer of $MoSi_2$ is helpful for depositing good diamond film, but can't effectively improve the bond strength between diamond film and copper substrate.

Introduction

Diamond has a unique set of excellent physical and chemical properties and is long recognized to be a precious material for many applications. It has the highest thermal conductivity, molar density, hardness and the lowest compressibility among all materials [1~5]. Despite the huge technological and commercial benefits that it presents, it is well known that to directly deposit diamond film on ferrous substrates is difficult. So many dissertations published in literature provided the information about diamond deposition on ferrous substrates [5~7]. To improve the poor adhesion and increase the low nucleation of CVD diamond film on copper substrate, the use of interlayer is a good way to overcome the diffusion between carbon and iron. There are three interlayer categories, (i) those that is easy to form carbides, such as Si, Ti or Cr; (ii) those do not form carbides but can dissolve carbon, such as Fe, Co or Ni; (iii) those that are difficult to form a carbide and don't dissolve carbon, such as Cu and Ag. In present, the radiator used in LED is made up with diamond and copper. Chromium

and titanium, the carbide firming metal, has been utilized as a planar structured interlayer to improve bond strength between substrate and diamond film due to the formation of strong carbide bond. But the thermal conductivity of titanium is bad (Ti: about 20.4W/mK); the thermal conductivity of chromium is good (Cr: about 93.7W/mK), but chromium is easy to make chemical reaction in the processes of HFCVD and produces Cr_3C_2 with low thermal conductivity in about 19.1W/mK. So it is important to find a higher thermal conductivity interlayer in order to decrease the thermal resistance. SiC and $MoSi_2$ with high thermal conductivity (SiC: about 54.4W/mK, $MoSi_2$: about 45W/mK) can be attempted to be used as a planar structured interlayer to deposit diamond film on those and improve the composite thermal conductivity [8].

Experimental

Disks with Φ50×20mm of red copper were used as substrates. The disks were cut into cube coppers which were in 8×8×2mm. The copper substrates were first mechanically polished to get smooth surface like a mirror. Afterwards, the two different intermediate layers, SiC and $MoSi_2$, were deposited on each red copper substrate using magnetron sputtering technology. sample1: depositing SiC; sample2: depositing $MoSi_2$.

Fabrications of two different transition layers were performed in magnetron sputtering reactor, and the experimental parameters were shown at table1.

Table1: Experimental parameters in magnetron sputtering

parameters	SiC	$MoSi_2$
temperature	180°C	180°C
substrates voltage	100V	100V
ions resources	1.0A,243V	1.0A,243V
current	3.0A	3.0A
total flow rate	150ml/min	150ml/min
pressure	0.36Pa	0.36Pa
growth time	2 hours	2 hours
Rotate speed	0	0

Then the two samples were ultrasonically abraded for 30min in a suspension of 5 g-diamond powder (3.5μm) in 15 ml of ethanol, which makes diamond powder inlay into each buffer layer and is benefit to improve nucleation.

Then the diamond growth was performed in a hot filament assisted reactor in the following condition: filament temperature: 2200~2300°C, substrate temperature: 830~850 °C, distance from filament to substrate: 6mm, total flow rate: 100 ml/min of 98.35%H_2/1.65% CH_4 mixture, pressure: 5040~5100Pa, growth time: 12h.

The two samples were characterized by using scanning electron microscopy (SEM), X-ray diffraction (XRD) and Raman spectroscopy (Argon laser, λ=514.5 nm) to examine the surface morphology, residual stress, films crystallinity and phase structure, respectively. Bonding strength between diamond film and copper substrate was tested by a Rockwell indentation experiment at 300 N, using a conical diamond indenter with an included angle of 60°.

Result and discussion

Fig.1 shows the micrograph of SiC surface and cross section. As showed in Fig.1 (a), there are some scratches on SiC layer surface, and the roughness of SiC surface is about 0.96μm in Ra. The thickness of SiC layer is about 3μm. Fig.2 shows the X-ray diffraction spectrum for sample 1 before and after 12 h CVD process. XRD patterns of the films before and after the CVD process shows diamond films grown on SiC-buffered copper substrates. Peaks at 44° and 75.3° can be clearly seen in the X-ray spectrum; these peaks correspond to diamond (111) and (220), respectively. Peaks at 44.1°, 64.4° and 77.4° can be clearly seen in the X-ray spectrum; these peaks correspond to SiC (200), (220) and (311), respectively. Thus, the X-ray diffraction spectrum reveals the formation of crystalline diamond on the copper substrates buffered with SiC layer. Furthermore, weak peaks in the pattern taken before the CVD process suggest the likelihood of the presence of SiC in amorphous state. After CVD process, the enhancement in SiC peaks implies that SiC in amorphous state happens crystallization, which will be confirmed in Fig.3 (d). Few SiC whiskers were observed in Fig.3 (d). It is because the process of CVD in about 800°C~900°C provides energy for amorphous SiC converting to crystalline state. We also observed the peaks of copper, which suggests that X-ray get into the copper substrate.

The surface morphology of the diamond film on SiC coated copper substrate after 12h deposition of hot filament CVD is shown in Fig.3 (a) and (b). A continuous and uniform diamond film with well faceted grains is grown. A broad size distribution (in the range of ~1-12 μm) of particles is evident, as minority were grown from the primary nucleating agents (homo-epitaxial growth of uncovered diamond grains) and most grains are secondary nucleated particles.

Fig.3 (c) shows the Laser Raman spectrum of the diamond film on the SiC interlayer coated Cu substrate. The strong and sharp peak at 1333 cm^{-1} demonstrates the good crystalline nature of diamond. However, because 1332.5 cm^{-1} is the normal peak position of unstressed diamond, the change in the diamond peak suggests that the diamond film is under little compressive stress. In the status of biaxial stress σ, the Raman curve of polycrystalline diamond generally was split into singlet and doublets. Because no splitting peaks are observed in Fig.3 (c), the peak at 1333 cm^{-1} is regarded as an overlap of singlet and doublets, and σ can be expressed in equation (1)

$$\sigma[\mathrm{GPa}] = -0.567/[\mathrm{GPa}/\ \mathrm{cm}^{-1}](\nu_m - \nu_o)\ [\mathrm{cm}^{-1}] \quad (1)$$

Where $\Delta\nu=\nu m-\nu o$ is the difference between the measured peak wavenumber (ν_m) and the unperturbed line center wavenumber (ν_o=1332.5cm^{-1}) [9~10]. So the film average internal stress is calculated about to -0.2835 GPa. This is a very small in-plane compressive stress, which is mabye remitted by cracks as clearly seen in the SEM picture of Fig.3 (a) and (b). The cracks are probably caused by the great different thermal expansion coefficient between Cu (0.167×10^{-4} m /°C) and SiC (4.7×10^{-6}m/°C), what's more, the thickness of SiC interlayer is about 3μm, which are not enough to remit the compressive stress in diamond film. A slight broad band at 1555 cm^{-1}~1570 cm^{-1} indicates the presence of non-diamond carbon in the film[11~12].

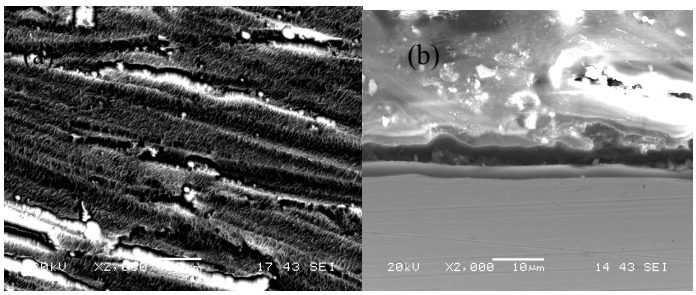

Fig.1 SEM micrograph of SiC surface (a) and cross section (b) on copper substrate

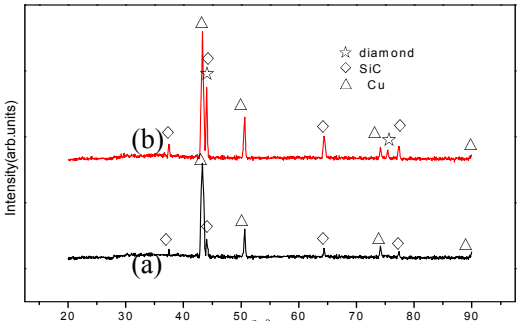

Fig.2 X-ray diffraction spectrum of sample 1 before (a) and after (b) 12 h CVD process

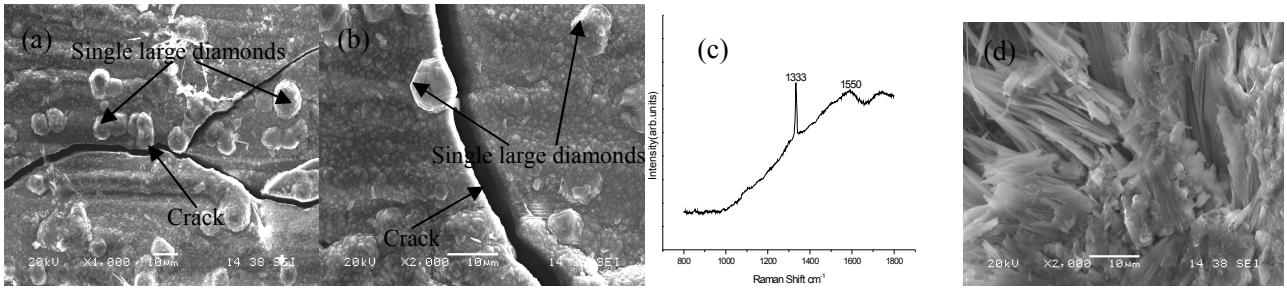

Fig.3 Surface morphology (a) (b), Raman spectrum (c) and SiC whiskers(d) of sample 1 after12 h CVD process

Fig.4 (a) and 4(b) show the micrograph of $MoSi_2$ surface and cross section respectively. As showed in Fig.4 (a), the surface roughness of $MoSi_2$ layer is about 0.72μm in Ra. The thickness of $MoSi_2$ layer is about 22μm, which is greater than the thickness of SiC layer in 2 hours. It can be explained that the bond of Si-C covalent bond is stronger than Si-Mo electrovalent bond. In same magnetron sputtering process, considering that to broke Si-Mo electrovalent bond needs less energy than Si-C covalent bond, the probability of breaking Si-Mo covalent bond is larger than Si-C. So the deposition speed $MoSi_2$ of is quicker. XRD spectrum of the film before and after the CVD process implies the continuity and crystalline in the diamond film, as showed in Fig.5. Peaks at 2θ diffraction angles of 44° and 75.3° are clearly evident, and respectively correspond to the (111) and (220) reflections of the cubic diamond structure. Furthermore, the absence of $MoSi_2$ peaks in the pattern taken before the CVD process suggests the likelihood of the presence of $MoSi_2$ in amorphous state. MoC and Mo_5Si_3 were detected after CVD process, which likely is because $MoSi_2$ is easy to make chemical reaction with CH_4 at about 800~900°C. The chemical equation can be expressed as follow:

$$MoSi_2 + CH_4 \longrightarrow MoC + Mo_5Si_3 + H_2\ (g) \qquad (2)$$

Fig.6 (b) shows Laser Raman spectrum for the diamond films deposited on $MoSi_2$-buffered copper substrates. The Raman spectrum shows a first-order Raman peak at 1339cm^{-1}, which are the sign of polycrystalline diamond and large existence of in-plane compressive stress. The spectrum contains a large band at about 1550cm^{-1}, which suggests a large number of existences of non-diamond carbon. The diamond crystals formed were highly crystalline seen in the SEM picture of Fig.6 (a). The diamonds were high dense and the diameter is in broad size distribution (in the range of ~2-12 μm). Few are grown from the primary nucleating agents and most are secondary nucleated particles. We can't observe any cracks in Fig.6 (a) despite the high compressive stress in diamond film that can be calculated to -3.86Gpa according to equation (1), which probably be explained by two reasons. Firstly, the thickness of $MoSi_2$ interlayer is about 22μm, which is sufficient to remit the inner stress in diamond film; secondly, the chemical products, MoC and Mo_5Si_3, maybe have strong bond to diamond, embed diamonds, causing a stronger combination among MoC, Mo_5Si_3 and diamonds.

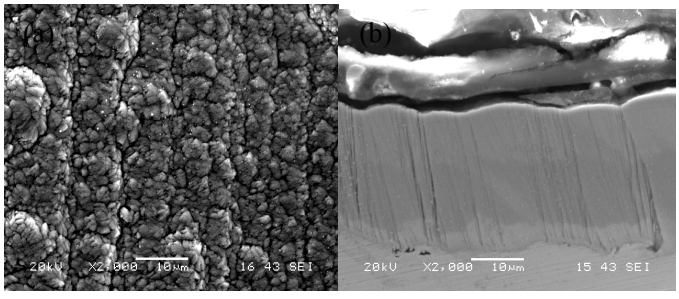

Fig.4 SEM micrograph of $MoSi_2$ surface (a) and cross section (b) on copper substrate

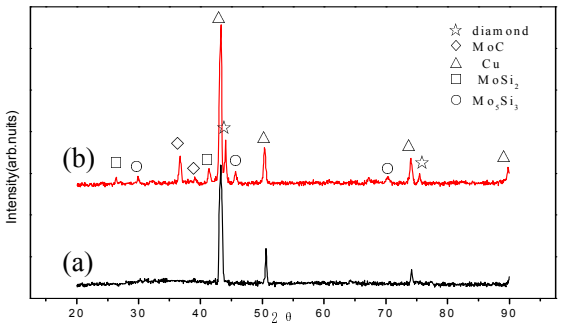

Fig.5 X-ray diffraction spectrum of sample 2 before (a) and after (b) 12 h CVD process

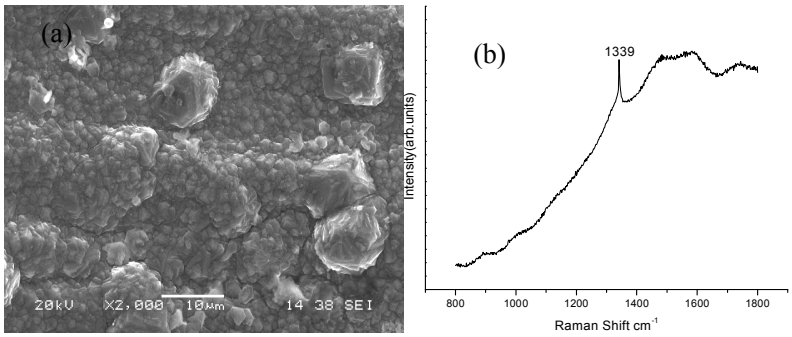

Fig.6. Surface morphology (a) and Raman spectrum (b) of the diamond films after 12 h CVD process

In order to further check the diamond film adhesion on $MoSi_2$ interlayer, Rockwell indentation experiment at 300N was carried on sample 2. Fig.7 shows the SEM image of the residual imprint of the indentation. The diameter of imprint is calculated about to 522 μm. If considering that the shape of residual imprint is same as the indenter with a half included angle of 60°, the imprint depth is calculated about to 166 μm. This imprint depth is much greater than the whole thickness of the diamond film and $MoSi_2$ interlayer (22μm), reckoning that the indenter pierced through the diamond film and the $MoSi_2$ interlayer to the copper substrate, resulting in major deformation of the residual imprint. The diamond film has been deformed and delaminated on the periphery of the indent as observed in Fig.7 (a). A magnification micrograph shows radial cracks evident on the surface of the diamond film around the indent shown in Fig.7 (b). Broken diamond grains and white small slices which are broken by the indenter during the indentation process are observed in Fig.7 (a), (c) and (d). The appearance of Radical crack and white mark surrounding the indentation spot in Fig.7 (a) shows that the adhesion strength between the diamond film and copper substrate is weak [13~14]. It suggests the 22μm buffer layer of $MoSi_2$ can't effectively improve the bond strength between diamond film and copper substrate even chemical products, MoC and Mo_5Si_3, probably causing a stronger combination among MoC, Mo_5Si_3 and diamonds.

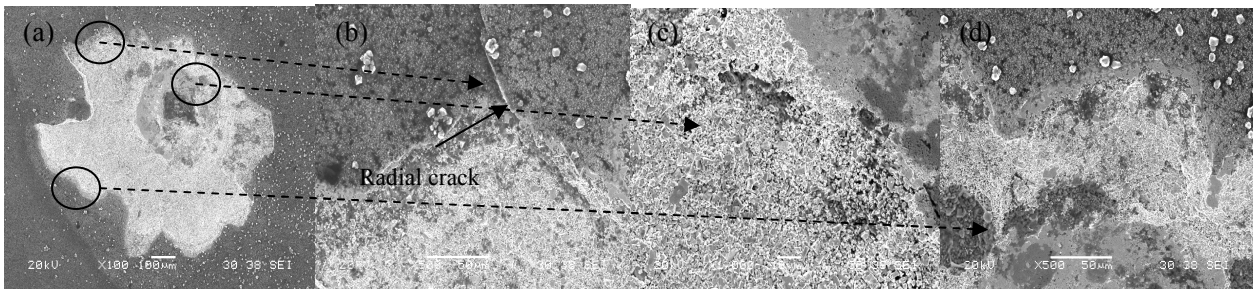

Fig.7 SEM micrographs of the indentation crater on sample2 (a) and periphery of the crater on sample2 (b), (c) and (d)

Conclusion

The present study shows that diamond films were successfully synthesized on copper substrates with two different buffer layers (SiC or $MoSi_2$) utilizing the hot filament chemical vapor deposition technique. It is demonstrated that the 3μm buffer layer of SiC can't help deposit no cracking diamond film. The 22μm buffer layer of $MoSi_2$ is helpful for depositing good diamond film, but can't effectively improve the bond strength between diamond film and copper substrate.

Keywords: perovskite; precious-metal; thin films; epitaxial growth; microstructure

Abstract: Single-crystalline, epitaxial $LaFeO_3$ films with 5 at. % substitution of Pd on the Fe site are grown on (100) $SrTiO_3$ substrate by pulsed-laser deposition technique. The epitaxial orientation relationships are $(110)[001]_{LFPO}||(100)[001]_{STO}$. X-ray diffraction and transmission electron microscopy reveal that the LFPO films have high structural quality and an atomically sharp LFPO/STO interface. After reduction treatments of as-grown LFPO films, very little Pd escaped the LFPO lattice onto the film surface, the formed Pd (100) particles are oriented epitaxially, and parallel to the LFPO films surface.

Introduction

Perovskite oxides based on $LaFeO_3$ and $CaTiO_3$ have recently attracted great attention. These materials, when doped with bivalent precious metal cations such Pd^{2+} or Pt^{2+}, exhibit appealing properties of precious-metal dissolving into/segregating out of the perovskite lattice and re-forming as small metallic particles upon the oxidizing and reducing conditions, respectively [1–5]. These properties make precious-metal-doped $LaFeO_3$ and $CaTiO_3$ as ideal candidates for application in automotive exhaust-gas catalyst and for studying metal/perovskite interaction, which are widely recognized but poorly characterized in heterogeneous catalysis.

Bulk $LaFeO_3$ has an orthorhombic structure (space group *Pbnm*) with the lattice parameters of a = 5.5570 Å, b = 5.5652 Å, c = 7.8542 Å [6], which can be described in terms of a pseudo-cubic lattice with a lattice constant of 3.923 Å. At here, Pd-doped $LaFeO_3$ single-crystal films will be grown, which is ideally suited to observe the precious metal migration in the perovskite lattice due to atomic running in single crystal is slower than polycrystal for much less grain boundary. Epitaxial single-crystal films of Pd-doped $LaFeO_3$, Pd-doping level is 5 at. % of the b-site cation sublattice, were deposited on $SrTiO_3$ substrate owing to their compatible structure and relatively small lattice mismatch. $SrTiO_3$ has a cubic perovskite structure with space group $Pm\bar{3}m$ and a lattice constant of 3.905 Å. The average lattice mismatch is ~0.46% between $LaFeO_3$ and $SrTiO_3$. Such small mismatch allows the epitaxial growth of thin films with high structural quality.

In this paper, we report on the results of Pd-doped lanthanum ferrite epitaxial single-crystal films deposited by pulsed-laser deposition technique, the films were characterized by x-ray diffractometer, x-ray photoelectron spectra and transmission electron microscope were used to investigate the structure transformation of the Pd-doped $LaFeO_3$ thin films before and after thermal treatment.

Experimental

The $LaFePdO_3$ (LFPO) thin films studied in this work were deposited on (100) $SrTiO_3$ (STO) substrate by the pulsed-laser deposition (PLD) technique using a KrF excimer laser (operating at 248 nm). The LFPO deposition target was fabricated via sol-gel method, which enables the mixing of the constituents at atomic levels. La_2O_3, $Fe(NO_3)_3{\cdot}9H_2O$, $Pd(NO_3)_2{\cdot}2H_2O$ and a dispersion agent were dissolved in dilute nitric acid to get transparent solutions. Evaporating the water in the solutions, the viscous gels were dried and then calcined at 800 °C for 1 h in the air to obtain perovskite powders containing homogeneously distributed precious metals. Then powders were pressed into pellet (about 3 cm in diameter and thickness 3 mm), which was finally sintered at 1300 °C for 12 h. The planar target was mounted on a holder and the set was then assembled into the deposition chamber. The base pressure achieved in the chamber prior to deposition was 4.0×10^{-6} Torr. A stoichiometric single phase LFPO target was ablated for 60 min at a laser power of 200 mJ and a repetition rate of 10 Hz onto (100) STO substrate at a fixed growth temperature of 600 °C and an oxygen partial pressure of 5.0×10^{-2} Torr. After growth, the films were processed under various conditions of temperature, atmosphere and duration.

The crystallinity and epitaxial orientation relationship of the LFPO films were investigated by x-ray diffraction (Rigaku MiniFlex X-ray diffractometer and Bede D1 high resolution X-ray diffractometer) θ–2θ scans, ω-rocking curve measurements, and ϕ scans with a CuK_α radiation. Cross-section TEM specimens were prepared from the LFPO films by standard methods (hand-lapping and polishing, followed by argon ion milling in a Gatan precision ion polishing system until electron transparent). Electron microscopy observations were performed with a JEOL JEM-3011 high resolution transmission electron microscope (HRTEM). X-ray photoelectron spectra (XPS) were obtained on a Kratos Axis Ultra spectrometer.

Results and Discussion

Fig. 1(a) shows a typical θ-2θ scan of LFPO films grown on (100) STO. The $h00_c/hh0$ peaks series belonging to the perovskite phase is clearly visible, where $h00$ peaks are marked by pseudo-cubic indices, denoted by subscript c, the cubic-to-orthorhombic transformation of the Miller indices are 100_c to 110, 200_c to 220, 300_c to 330, no extra LFPO or impurity peaks are detected, indicating that the LFPO films grown on (100) STO with an orientation relationship of $(110)_{LFPO}||(100)_{STO}$ at out-of-plane.

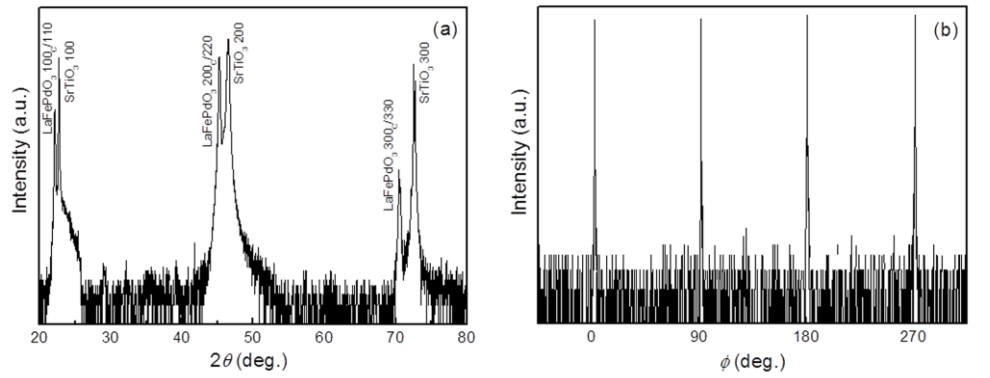

Fig. 1 (a) θ-2θ Xrd Pattern of a Lfpo Film Grown on (100) Sto Substrate, c Subscript Denotes the Pseudo-cubic Indices. (b) Xrd ϕ Scan of a Lfpo $(110)_c/200$ Peak.

Fig. 1(b) shows a ϕ scan of LFPO $110_c/200$ reflection, four sharp peaks are observed and located at the same azimuths with the STO 110 reflection, indicating that only the $100_c/110$-oriented LFPO single-crystallite was grown epitaxially on the top surface of (100) STO substrate, and in-plane orientation relationship is $[001]_{LFPO}||[001]_{STO}$. The ω-rocking curve full width at half maximum (FWHM) of $\Delta\omega = 0.05°$ for the LFPO $200_c/220$ peak indicates good crystallinity of the film.

Fig. 2(a) shows a typical low-magnification cross-sectional bright-field image of the LFPO films grown on (100) STO. It is apparent that the LFPO film has uniform thickness, both flat interface and top surface, no cracks in film. The film surface has a root-mean-square roughness of 2.69 Å measured by atomic force microscopy. The inset of (a) is the SAED pattern of film and substrate. High-resolution TEM image in Fig. 2(b) reveals an atomically sharp interface between the LFPO and STO layers, the long *c*-axis of the LFPO orthorhombic unit cell is oriented parallel to the interface and to the [001] axis of STO.

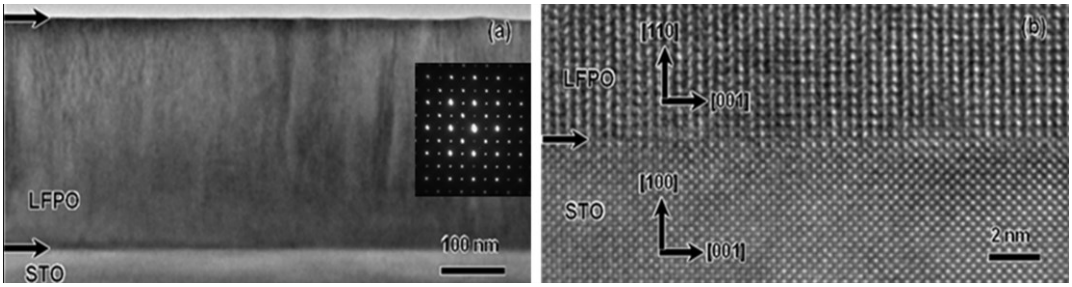

Fig. 2 (a) Cross-section TEM Image of a LFPO Film Grown on (100) STO. Arrows Denote the Top Film Surface and Film/Substrate Interface, Respectively. The Inset is the SAED Pattern of Film and Substrate. (b) HRTEM Image of the LFPO/STO Interface. The *c*-Axis of the LFPO Orthorhombic Unit Cell is Oriented Parallel to the Interface and to the [001] Axis of STO.

XPS results find the expected surface composition, Pd 3*d* spectrum shows two oxidized states of Pd ion, the signals are strong, but neither corresponding to the usual Pd^{2+} and Pd^{4+} states, and also unlike the results of Tanaka *et al* [3]. Here we think that Pd exists in the crystal of LFPO. Subsequently, the as-grown LFPO film is annealed at various thermal treatment conditions, changes in the surface compositions induced by thermal treatment are determined by XPS, results reveal that the peak position of Pd–O bonds shift toward lower binding energy for the sample as the annealing temperature and hydrogen concentration increase, and much of the Pd exist in metallic state at 800 °C in 10% H_2/N_2, as shown in Fig. 3.

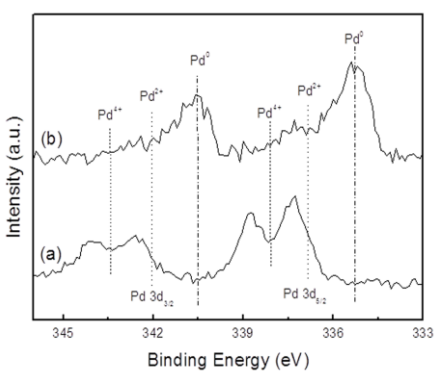

Fig. 3 XPS Scans in Pd 3d Region for LaFe0.95Pd0.05O3, (a) as-grown; (b) Reduced at 800 °C in 10% H2/N2. The Binding Energies were Corrected Based on Measured Values for C1s. Spectra Are Vertically Offset. Vertical Lines Indicate the Expected Peak Positions of the Pd Spin-orbitdoublets (3d5/2, 3d3/2) for Pd0, Pd2+, and Pd4+ [3].

Fig. 4 is HRTEM cross-sectional image of the LFPO as-grown film reduced at 800 °C in 10% H_2/N_2. It shows that the Pd in solid solution migrate to the surface region of the LFPO film, and lattice fringes of the formed Pd particles extend into the top surface of LFPO thin film, indicating that the formed Pd particles are oriented epitaxially, with Pd (100) parallel to the LFPO film surface. Maybe we can explain the above phenomena via classical nucleation model, i.e., the migration of Pd from interior toward the surface region of LFPO thin film is a thermally activated process, high heating temperature can provide a large thermal energy to overcome the high energy barrier of preventing the diffusion of Pd from interior toward surface of LFPO film, and oxygen vacancy formed under reduction atmosphere, which provide diffusion channels for Pd. Compared to out-of-plane diffusion of Pd from the interior to surface of LFPO thin film, in-plane Pd diffusion is easier. Nonstoichiometry appears in LFPO film for oxygen insufficiency during annealing, which inducing construction of new steps with high binding energy due to dangling or broken bond at the top surface of LFPO film, where the migrated Pd can be captured, and then be aggregated or coalesced into clusters or particles.

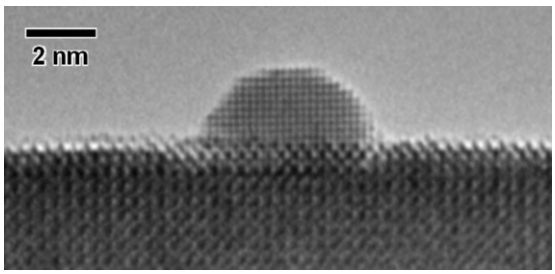

Fig. 4 HRTEM Image of a Typical Pd Particle Found on the LFPO Film Surface After Reduction.

Conclusions

Precious-metal-doped perovskite has structural and chemical transformations during annealing, and thin film materials are ideally suited to study the migration behavior of the precious-metal in the particular perovskite lattice.

Keywords: magnetron sputtering, ZnO thin films, structure, substrate temperature

Abstract. Zinc oxide (ZnO) films are prepared on n-Si substrates by means of radio frequency (RF) magnetron sputtering method. The influences of substrate temperature on the crystal orientation and crystalline structure of ZnO films are investigated by X-ray diffraction (XRD) and Raman spectroscopy. The surface morphologies are studied by scanning electron microscope (SEM). It is indicated that ZnO films with wurtzite structure were successfully prepared. When the substrate temperature reduced to 100 ^{o}C, the wurtzite structure with highly preferred orientation along the (002) plane of the ZnO film is prepared and the elliptical shape particles distributed uniformly on the ZnO film surface. The higher substrate temperature can offer more kinetic energy for mobility of particle on the surface to achieve other crystalline growth, resulting in the highly c-axis-oriented crystalline structure is destroyed.

Introduction

In recent years, wide bandgap semiconductors have attracted much attention. Zinc oxide (ZnO) is a typical wide bandgap (3.37 eV at 300 K) semiconductor with large exciton binding energy (60meV) [1], it has more excellent properties such as good chemical stability, high melting point, excellent mechanical strength, photoelectric properties and thermal conductivity, which can be used as field emitter [2], light emitting diodes (LED) [3], laser diodes [4], ultraviolet photo detectors [5], chemical sensors [6], and so on. However, these are some problems to hinder the application and development of ZnO such as the fabrication of stable and reliable p-type ZnO thin films and the growth mechanism [7]. Therefore, the studies of preparation, properties, growth mechanism and applications of ZnO films are important significance both in basic science and practical application.

The crystal and structural properties of ZnO thin films strongly depend on growth technique and growth condition. There are several methods to fabricate high quality ZnO films, such as chemical vapor deposition (CVD) [8], sol–gel [9], pulsed laser deposition [10], sputtering [11] hydrothermal method [12], and so on. Among all these methods, reactive magnetron sputtering has been most widely used as depositing the film because of its advantages of large scale production, high maneuverability and stoichiometry controllability. So many researches have been carried out on the dependence of film properties on sputtering parameters [13-15]. In this study, we prepared a series of ZnO films by radio frequency (RF) magnetron sputtering at different substrate temperature, and discussed the influences of substrate temperature on the structure of ZnO films.

Experimental

The ZnO films are deposited on n-Si (100) substrates using a high purity (99.99%) ZnO target using RF magnetron sputtering method. Argon and oxygen are used as the working gases. The distance between the target and substrate is fixed at 50 mm. The base pressure is below 5×10^{-4} Pa. Prior to the film deposition, the substrates are ultrasonically rinsed in acetone, ethanol and distilled water sequentially and dried with nitrogen. In order to improve the crystalline quality and reduce the impact of impurities, the target is pre-sputtered with high-power for about 10 minutes. Table 1 shows the detailed deposition parameters of the ZnO films deposited by RF magnetron sputtering. The crystal structure of the ZnO films is characterized by X-ray diffraction (XRD) with Cu Ka radiation (λ=0.1541nm). Raman spectra are taken by a Renishaw micro-Raman spectroscope. The surface morphologies are examined by scanning electron microscope (SEM).

TABLE 1. THE DEPOSITION PARAMETERS OF THE ZNO FILMS DEPOSITED BY RF MAGNETRON SPUTTERING

Substrate temperature[^{o}C]	Working pressure[Pa]	Sputtering power[W]	Ar:O2	Deposition time[min]
400,300,200,100	1	150	3:1	90

Results and discussion

Fig.1 shows the XRD patterns of ZnO thin films prepared at different substrate temperature. It is revealed that the ZnO thin films have the hexagonal wurtzite crystal structure with (002) preferred orientation, and no characteristic peaks due to other impurities are observed. It is generally known that the grains are more easily grown in the planes of lower the surface energy. For the ZnO films, the (002) orientation with the lowest surface energy would be more favorable, a preferential orientation along c-axis and the grains become uniformly perpendicular to the substrate surface then form a preferred c-axis orientation, other orientations would be restrained [16]. With the decreasing substrate temperature, other ZnO crystal directions, such as (100), (110) and (103) disappear, this may be because the trend that the adsorbed atoms gain extra thermal energy and tend to move to another preferred site is restrained with the decreasing substrate temperature. The high substrate temperature can offer more kinetic energy for mobility of particle on the surface to achieve other crystalline growth [17]. It demonstrates that the films more easily became polycrystalline in high substrate temperature.

The crystal grain size at (002) peaks of the ZnO films are calculated by Scherrer formula [18]:

$$D = k\lambda / \beta\cos\theta . \quad (1)$$

where D is the crystal grain size, k is the correction factor, λ is the wavelength of the incident beam, β is the full width at half maximum (FWHM) corresponding to Bragg diffraction angle. Here, k and λ values are taken as 0.9 and 0.1541 nm. And the lattice constant for the ZnO films are calculated by the following relation [19]:

$$\lambda = 2d_{hkl}\sin\theta . \quad (2)$$

$$\frac{1}{d_{hkl}^2}=\frac{4}{3}\left(\frac{h^2+hk+k^2}{a^2}\right)+\frac{l^2}{c^2}. \quad (3)$$

where d_{hkl} is the distance between adjacent planes in the set (hkl), λ is the wavelength of the X-ray, θ is the diffraction angle, a and c is the lattice parameter, and h, k and l are the indices of the planes. The crystal grain size and lattice constant of the ZnO films deposited at different substrate temperature are shown in the table 2. From the table 2, we can see that the films showed lattice distortion comparing with the bulk ZnO (a=0.32498 nm, c=0.52066 nm), this mainly is attributed to the residual stress developed in thin films [20].

The calculation of the film residual stress is based on the biaxial strain model. The strain in the c axis can be expressed by the following formula [21]:

$$\varepsilon=(c-c_0)/c_0. \quad (4)$$

where c and c_0 are the lattice constants of ZnO films and bulk ZnO, respectively. The residual stress parallel to the film surface can be given by the following formula [22]:

$$\sigma=\frac{2c_{13}^2-c_{33}(c_{11}+c_{12})}{2c_{13}}\bullet\varepsilon. \quad (5)$$

For the elastic constants, the following values for crystal ZnO are use: c_{13}=104.2 GPa, c_{33}=213.8 GPa, c_{11}=208.8 GPa, c_{12}=119.7 GPa [23]. The residual stress of the ZnO films deposited on different substrate temperature are shown in the table 2. The ZnO film deposited at the substrate temperature of 100 ^{o}C has the minimum residual stress, indicating that it has the best crystal quality. The residual stress of the film may include a thermal stress come from the thermal mismatch between the film and Si substrate and the intrinsic stress come from the crystal defects of the films [24].

Table 2. The crystal grain size, lattice constant and residual stress of the ZnO film deposited at different substrate temperature.

Substrate temperature[^{o}C]	crystal grain size [nm]	σ [GPa]	Lattice constant[nm]	
			a	*c*
400	19.3	1.942189	0.32427	0.51632
300	20.1	-0.27298	0.32506	0.52127
200	23.2	1.038221	0.32347	0.51834
100	18.0	-0.00895	0.32308	0.52068

In order to further investigate the structure of the ZnO films, the Raman spectra of the films is measured. The broadening of the Raman peak is the result of the phonon scattering caused by stress gradients, small grains, point defects and interfaces, and the intensity and the FWHM of Raman mode can describe the crystal quality of the films [25]. The ZnO is C6v-4 (P63mc) point group symmetry and has six Raman active optical phonon modes at the center of the Brillouin zone, the frequencies of the Raman modes in ZnO are E_2 (low) = 101 cm^{-1}, E_2 (high) = 437 cm^{-1}, A_1 (TO) = 380 cm^{-1}, A_1 (LO) = 574 cm^{-1}, E_1 (TO) = 407 cm^{-1} and E_1 (LO) = 583 cm^{-1} [26]. Fig.2 shows Raman spectra of the films grown at different substrate temperature. The films exhibit two peaks located at

about 436 cm^{-1} and 580 cm^{-1} which is related to E_2 (high) mode and E_1 (LO) mode , respectively. The peak at 520 cm^{-1} derives from the Si substrate [27]. The E_2 (high) mode is corresponding to band characteristics of the wurtzite phase [28]. The E_1 (LO) mode is related to oxygen vacancies [29]. Comparing with the bulk ZnO, the Raman frequency happens shift, the shift is probably due to the effect of the impurity or defect in the crystal, the tensile strain and laser irradiation heating [30]. The E_2 (high) mode peak of the film deposited at 100 °C has a good symmetrical spectral shape, in which the FWHM value is obviously smaller and the intensity is stronger than the films deposited on higher substrate temperature. It demonstrated that the crystal quality is worse with the increasing substrate temperature. This is consistent with measuring results from the XRD pattern.

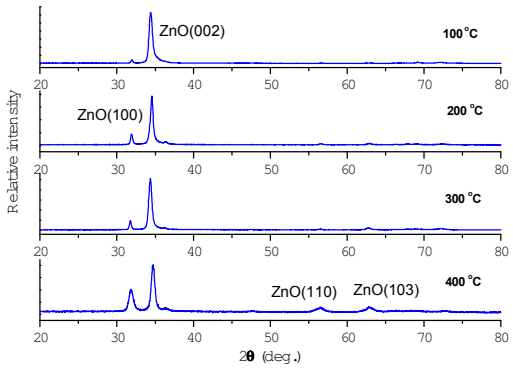

Fig. 1. XRD patterns of ZnO thin films prepared at different substrate temperature

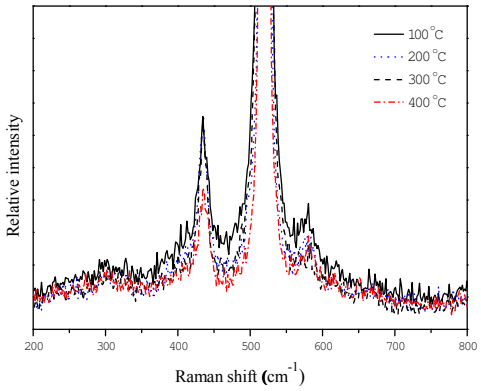

Fig. 2. The Raman spectra of the ZnO films sputtered at different substrate temperature.

In order to understand the surface features and size distribution of the deposited ZnO thin films, SEM analysis is carried out. Fig. 3 shows the surface and cross-section images of the ZnO film deposited at 100 °C, respectively. As shown in Fig. 3 (a), crystal particles with about 200 nm size and uniform top surfaces are found on the surface of the ZnO film. As shown in Fig.3 (b), the thickness of the ZnO layer is about 2.5 μm, and exhibits finer crystallinity and columnar structure with c-axis perpendicular to the Si substrate interface, which is consistent with the XRD result.

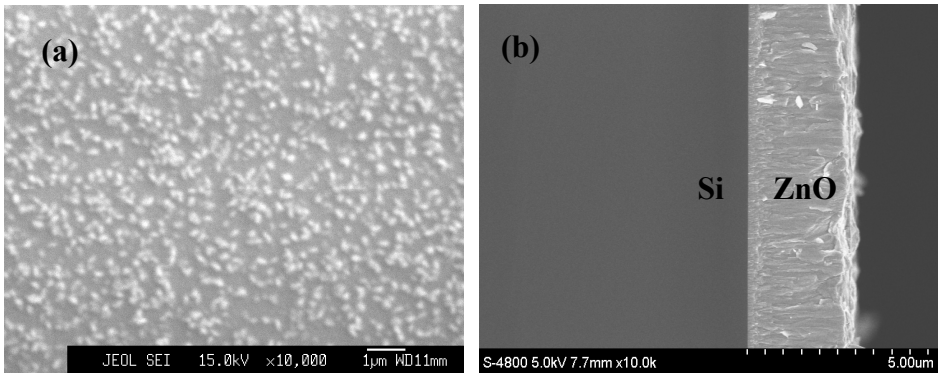

Fig. 3. The surface (a) and cross-section (b) SEM images of the ZnO film deposited at 100 °C.

Conclusions

In summary, the high crystalline quality of wurtzite structure ZnO films are prepared on n-Si substrates using RF magnetron sputtering method. The XRD shows that the films have a c-axial orientation along (002) plane and Raman spectrum measurement shows that high crystalline quality ZnO films have been obtained. In this study, highly c-axis-oriented crystalline structure is destroyed

by the increasing substrate temperature, indicating that the higher substrate temperature can offer more kinetic energy for mobility of particle on the surface to achieve other crystalline growth.

Keywords: HH-PDI, ZnS, nanocomposite, semiconducting property.

Abstract: A self-assembled film of an amphiphilic perylene tetracarboxylic diimide derivative (N-hexane-N'-(1-phenyl-4-aminoethanol)-1,7-di(4-tert-butylphenoxy)perylene-3,4;9,10-tetracarboxy late diimide, HH-PDI) has been used as the organic template to produce the first example of monodispersed nano-particles of HH-PDI/ZnS composites. The HH-PDI pure film and HH-PDI/ZnS nanocomposites were characterized by UV-vis absorption, X-ray diffraction (XRD), scanning electron microscopy (SEM) and current-voltage (I-V) measurements. Experimental results revealed the film crystallinity and general molecular order for HH-PDI molecules in the nanocomposites are improved effectively in comparison with those in the pure film due to the introduction of ZnS nanocrystals. The electrical conductivity of the HH-PDI/ZnS nanocomposites (6.6×10^{-5} S cm^{-1}) is more than ca. 2 order of magnitude higher than that of (3.6×10^{-7} S cm^{-1}). The present result provides an efficient way to improve the performance of organic semiconductors through introducing inorganic semiconducting nanocrystals.

Introduction

Semiconductor nanomaterials can often display unique optical, electronic, and magnetic properties, whereas these properties strongly depend on the size and shape of the nanoparticles [1]. As a result, synthetic control over the morphology, size, and crystallographic orientation of materials is highly desired [2]. Among the methods for the preparation of nanomaterials, growing of inorganic structures directly on an organic template has recently emerged as a powerful technique [3]. Perylenetetracarboxylic diimide (PDI) derivatives have been extensively and intensively investigated as advanced molecular materials [4]. In particular, because of their great potential application as organic semiconductors in different molecular electronic devices, the fabrication of ordered nanostructures of these functional molecular materials has become an attracting research area in the past decade [5]. The semiconducting PDI-based organic/inorganic composites in nanoscale should be highly desired for nano-optoelectronic materials due to the possibility of combining desired properties from both. In the present paper, we reported controlled preparation of ZnS nanoparticles in a self-assembled (SA) film of amphiphilic PDI derivative modified with distinctly different hydrophobic/hydrophilic side-chains, N-hexane-N'-(1-phenyl-4-aminoethanol)-1,7-di(4-tert-butylphenoxy)perylene-3,4;9,10-tetracarboxyl ate diimide (HH-PDI), Fig. 1. By using SA film of amphiphilic HH-PDI molecules as a template, the monodisperse HH-PDI/ZnS nanocomposites were prepared at the air–water interface. The enhanced semiconducting properties were observed for the hybrid nanocomposites relative to respective the pure HH-PDI film.

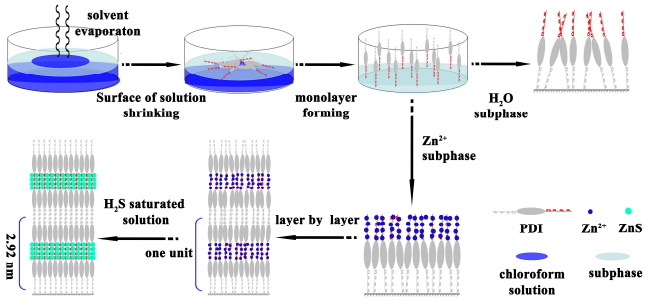

Fig. 2 Procedures for the fabrication of the HH-PDI and HH-PDI/ZnS nanocomposites.

Experimental Section

Chemicals

The sample of HH-PDI was synthesized according to previously published procedures [6]. All the chemicals are analytical reagents and used without further purification.

Preparation and characterization of the HH-PDI SA film and HH-PDI/ZnS nanocomposites

(Fig.2)**.** Prior to the deposition, substrates were successively sonicated in dichloromethane, methanol and distilled water and dried with argon gas. (i) HH-PDI (HH-PDI/Zn^{2+}) SA film: 5.0 mL of dichloroform solution (0.20 mg mL^{-1}) was put into a culture dish (diameter: 9 cm, height: 1.8 cm), then 50 mL water (or $ZnSO_4$ aqueous solution 0.081 mg mL^{-1}) was slowly added onto the surface of the solution. (caution: the amount of water added cannot cover completely the air/CH_2Cl_2 interface so as to keep the path for the evaporation of CH_2Cl_2 solvent). During solvent evaporation, HH-PDI molecules gradually assembled to form some fine nanostructures at the CH_2Cl_2-water interface. After complete evaporation of CH_2Cl_2, the densely packed film remained on the water surface. Then, the film can be easily transferred from the water surface onto a quartz or Si/SiO_2 substrate by horizontal lifting. This process was repeated to obtain the required number of layers. Residual water on the substrates, between transfer steps and after the final transfer, was removed with a stream of nitrogen. (ii) HH-PDI/ZnS nanocomposites: HH-PDI/Zn^{2+} nanocomposites were dipped to a H_2S saturated solution (~0.1 mol L^{-1} for 12 h). After being washed with water, the thin film was removed with a stream of nitrogen for SEM (Hitachi S-4300F), X-ray diffraction (Rigaku D/max-γB), UV-vis spectroscopy (Hitachi U-4100) measurements, respectively. The reactions were carried out at room temperature. The device for I-V measurements (Keithley 4200) were fabricated according to previously published procedures [7].

Results and discussion

UV-vis absorption spectra

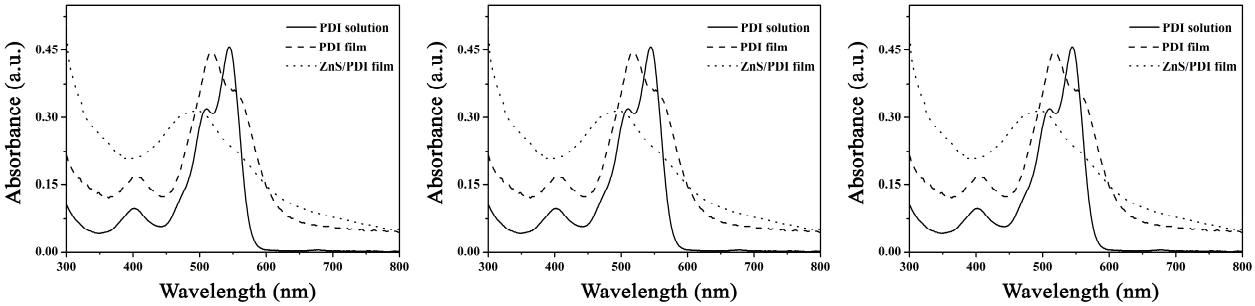

Fig. 3 UV-vis spetra of HH-PDI in dichloroform (solid line) and the HH-PDI pure film (dash line) and HH-PDI/ZnS nanocomposites (dot line). Fig. 4 The X-ray diffraction patterns of HH-PDI pure film (A) and HH-PDI/ZnS nanocomposites (B). The vertical lines show the ZnS powder diffraction pattern from the Joint Committee on Powder Diffraction Standards (JCPDS) Card No. 05-0566.

Fig. 3 displays the UV/Vis spectra of the HH-PDI pure film and HH-PDI/ZnS nanocomposites in comparison with that in the solution. As expected, HH-PDI in dichloroform showed typical feature of the non-aggregated diphenoxy-substituted PDI chromophores in the electronic absorption spectra [8]. The absorptions at about 545 and 514 nm can be attributed to the 0-0 and 0-1 vibronic band of the S_0-S_1 transition, respectively, while the observed absorption band around 402 nm is attributed to the electronic S_0-S_2 transition [6]. Note that the absorption of HH-PDI in the pure film and nanocomposites changed significantly in the ratio of the intensities of the 0-0/0-1 peaks, while peak positions of absorption maxima of HH-PDI remained almost unaltered in the pure film, and blue-shifted to ca.500 nm in the nanocomposites. Those kinds of changes implied the formation of face-to-face π stacks (H-aggregate) and stronger molecular stacking interaction between the PDI skeletons of HH-PDI in the nanocomposites than the pure film [8], which is able to provide the more efficient π stacking and in turn is responsible for the much larger carrier mobilities revealed for the devices fabricated from the former than the latter one(*vide infra*). Furthemore, by comparing the UV-vis spectra of HH-PDI pure film and HH-PDI/ZnS nanocomposites, we can find that the nanocomposites exhibits a higher absorption intensity in the wavelength region below 350 nm, which is very similar to the absorption of bulk ZnS nanoparticles [9], suggesting the ZnS nanostructures have been shaped in the nanocomposites.

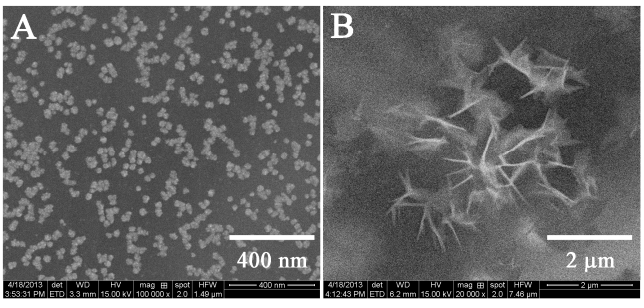

Fig. 5 SEM images of HH-PDI/ZnS nanocomposites (A) and HH-PDI pure film (B).

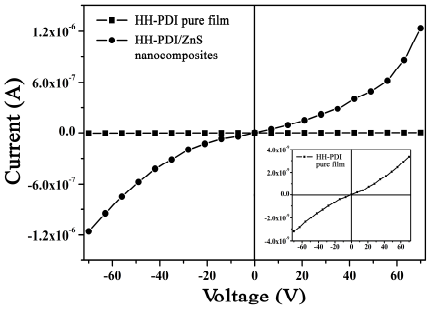

Fig. 6 The current-voltage (I-V) characteristics of the HH-PDI pure film (■), HH-PDI/ZnS nanocomposites (●).

X-ray diffraction (XRD) pattern

The XRD patterns for the HH-PDI pure film and HH-PDI/ZnS nanocomposites are shown in Fig. 4. In the nanocomposites, various diffraction peaks were observed, which were, according to JCPDS file No. 05-0566 (shown as vertical lines in Fig. 4), assigned to the (111), (220) and (311) planes of the cubic phase of zinc blende ZnS. XRD patterns in combination with UV-vis and SEM analysis (*vide infra*) of the samples provided exclusive evidence that ZnS nanoparticles formed exhibit a

highly crystalline structure. On the other hand, the XRD pattern of the HH-PDI pure film exhibits the (001) Bragg peak at 2θ = 4.48°, corresponding to a periodic spacing distance of 1.94 nm, Fig. 4A. Consequently, orientation angle of HH-PDI rings with respect to the substrate surface of ca. 59.4° are estimated for HH-PDI in pure film based on the length of HH-PDI (2.30 nm) taken from the energy-optimized structure. A slipped co-facial stacking mode with the molecular long-axis perpendicular to the substrate surface (H aggregate) was achieved for HH-PDI [10], which is in line with that UV-vis absorption. In addition, the appearance of a broad peak at 0.42 nm for the HH-PDI pure film suggested that there exists liquid-like ordered packing of long alkyl chains [6]. A sharper peak at 0.31 nm (2θ = 28.9°) obtained for the HH-PDI pure film is ascribed to π-π stacking distance of PDI rings between the adjacent molecule, implied a favorable molecular packing from co-facial conformation depending mainly on the π-π interaction between perylene rings in the HH-PDI film. However, in the HH-PDI/ZnS nanocomposites, as shown in Fig. 4B, the XRD diagram shows two well-defined low-angle diffraction peaks at 2θ = 3.01° and 6.07° (corresponding to a periodic spacing distance of 2.92 and 1.46 nm), which are ascribed to the diffractions from the (001) and (002) planes of HH-PDI, indicating the long range molecular ordering across the thickness of the nanocomposites. Due to the special asymmetric molecular structure of HH-PDI, the value of *d* (2.92 nm) in the nanocomposites is actually the thickness of the bilayer (Fig.2). Meanwhile, the diffraction at 0.42 nm disappeared, indicating that the long hydrophobic alkyl chain of HH-PDI in the nanocomposites might no longer take an extended conformation but a folded and tangled conformation instead. Consequently, a significant decreased monolayer thickness (1.46 nm) of HH-PDI obtained in the nanocomposites as compared to that in the HH-PDI pure film can be achieved. Therefore, ZnS crystals grown on HH-PDI organic template has a remarkable influence on the assemble structure of both hydrophobic and hydrophilic side-chains attached to HH-PDI in the nanocomposites.

Morphology of the HH-PDI pure film and HH-PDI/ZnS nanocomposites

As revealed by the scanning electron microscope (SEM), Fig. 5A, the unique nanoparticles were obtained with the average diameter of ca. 20 nm for HH-PDI/ZnS nanocomposites. This is in good contrast to the sheet-like microstructure with large gaps and cracks between aggregate domains observed for HH-PDI molecules in pure film, Fig. 5B, which will surely add negative effect on the electronic conductivity for the I-V devices fabricated.

Semiconducting properties

Fig. 6 shows the current-voltage (I-V) characteristics of the HH-PDI pure film and HH-PDI/ZnS nanocomposites. According to the equation reported in the literatures [7], the electronic conductivity, is calculated to be around 6.6×10^{-5} and 3.6×10^{-7} S cm^{-1} for the HH-PDI pure film and HH-PDI/ZnS nanocomposites, respectively. Comparing with the HH-PDI pure film, the improved conductivity for the nanocomposites might be attributed to readily π- stacks with adjacent planar molecules and the introduction of ZnS n-type semiconducting nanocrystal. The absence of traps or defects in these nanocomposites with more efficient π-π stacks should favour charge transport.

Summary

The well-defined HH-PDI/ZnS hybrid nanoparticles have been successfully prepared at the air-water interface by using SA film of amphiphilic HH-PDI molecules as a template. The significantly improved semiconducting properties are achieved for the resulting nanocomposites. The present result represents the first effort towards controlling the size and morphology of ZnS nanostructures via an amphiphilic asymmetric PDI derivate, which is helpful towards designing, preparing new nanomaterials and more complex nanostructures with tunable functionality.

Pt-TiO_2 Nanocomposites in Alginate for Enhancing Photocatalytic Activity

Yunrun Wang

Department of Physics, Renmin University of China, Beijing, 100872, China

yunrunwang@163.com

Keywords: Pt/TiO_2, nanocomposite, alginate, photocatalytic activity, phenol

Abstract: A new sol-gel method was employed to synthesize Pt-containing titania composite with varied dopant concentrations using alginate as an template for preventing inorganic materials' conglomeration. During the calcination process, the Pt nanoparticles, which had been loaded in alginate porous networks, were doped into the titania system. The morphology and crystallization behavior of titania were characterized. HAAD-STEM image and EDX spectroscopy of Pt/TiO_2 composites confirmed that Pt was well embodied into the TiO_2 mesoporous network. The UV-vis diffuse reflection spectra at room temperature shown that the Pt/TiO_2 composite exhibited a marked visible light adsorption compared with a pure TiO_2 sample. The photocatalytic activities were tested using phenol as the model compound, and the results demonstrated that higher photocatalytic activity was observed at higher levels of Pt added to the titania system. The optimum dopant concentration was found to be 0.37 mol % for Pt/TiO_2 sample.

Introduction

Photocatalysis has received a great deal of attention owing to its potential application in purifying water and air by thoroughly decomposing organic compounds [1]. Among the photocatalysis, TiO_2 is known as a relatively inexpensive semiconductor exhibiting substantial photocatalytic activity, stability in aqueous solution, and nontoxicity [2]. However, titania's low quantum efficiency because of a high rate of recombination between electrons and holes and large band gap of 3.2 eV (corresponding to a wavelength of shorter than 400 nm) limit its potential application. In order to increase the photocatalytic activity, modifications of titania are involved. Metallization of TiO_2 surface with noble metals is believed to decrease the band-gap energy, and further extend its solar-driven photocatalytic applications [3]. Several noble metals, such as Pt, Ag, and Au, have been shown to promote the separation of photogenerated charge carriers, and thus to improve its photoactivity [4]. Such an enhancement in the different studies has been explained that the electrons generated by UV irradiation of the TiO_2 semiconductor quickly transfer to the metal particles loaded on the TiO_2 surface. These metal particles generate effectively enhance to the charge separation of the electrons and holes, resulting in improving the photocatalytic performance. It must be noticed that the electronic properties of the metal-TiO_2 composite is size-dependent [5].

Besides the catalytic active species, the performance and stability of the catalysts also strongly depend on the dispersion of these species and the framework designed. The sol-gel method is an attractive method for low-temperature synthesis of TiO_2, and it is easier to realize metal doping. However, the particle size of TiO_2 prepared by the sol-gel method is not uniform and it is difficult to obtain nano-sized particles using this method due to calcination posttreatments. Template synthesis by surface functionalization/stabilization is widely accepted as a simple and effective method for controlling the microstructure of catalyst material. Encouraged by the development of green chemistry, the utilization of renewable natural materials has received considerable attention. Polysaccharides and other biomacromolecules have already been utilized as templates to prepare porous metal oxide structures [6].

This paper addresses the preparation of Pt-doped TiO_2 framework synthesized by a very simple and green method. In this work, alginate gel is used as a template to avoid particle conglomeration and

fabricate nano-sized TiO_2 particles, Pt nanoparticles are embedded into the tiamnia porous network in following calcination post-treatments. The UV-vis diffuse reflection spectrocopy at room temperature show that the Pt/TiO_2 composite exhibit a marked visible light adsorption compared with a pure TiO_2 sample. The enhanced ability to absorb visible light makes this composite a potential photocatalyst for solar-driven application. The enhanced photocatalytic activities of Pt/TiO_2 have been demonstrated using phenol as the model compound. Results of the photocatalytic evaluation demonstrated that higher photocatalytic activity was observed at higher levels of Pt added to the titania system.

Experimental

Materials

Sodium alginate was purchased from Alfa Aesar. Hexachlorophlatinic acid ($H_2PtCl_6 \cdot 6H_2O$), ethanol (AR), isopropanol (AR), phenol (AR) was purchased from the Beijing Reagent Company. $CaCl_2$ was supplied by the Beijing Chemical Company. The titanium isopropoxide (TIP, 98%) was purchased from Acros. All the reagents were used as received. Deionized water was used in all experiments.

Preparation of Pt/TiO_2 nanocomposites

In a standard experiment, the desired amount of $H_2PtCl_6 \cdot 6H_2O$ solution (0.1 mL 14.5 mM) was added into 2 mL of sodium alginate (SA) aqueous solution (3.0 wt%), and the mixture was then gently heated to 100℃in an oven for 2 h for the reduction of the metal precursor. In order to prepare Pt/SA beads, the stable Pt/SA suspension was added dropwise into a $CaCl_2$ aqueous solution (50 mM) without stirring, which was then kept in a $CaCl_2$ aqueous solution and cured for at least 12 h. The resultant Pt/SA beads were washed several times using deionized water, followed by dehydration with ethanol, and were finally placed into isopropanol. The as-prepared Pt/SA beads were then soaked in 70 wt% TIP isopropanol solution for 16 h, followed by hydrolysis for 24 h in a water/isopropanol (1:5 by volume) solution. The white hybrid amorphous titania/alginate beads were dried in air at room temperature for 36 h, and then placed in an oven at 60℃ for 5 h. Finally, the samples were calcined in an oven under flowing air at 450℃ for 10 h (heating ramp 3.5℃ min^{-1}) to remove the alginate template and induce crystallization of the inorganic components.

Characterization and measurement

HAADF images were obtained from FEI TECNAI F30 STEM, and accelerating voltage was 300 kV. UV-vis diffuse reflectance spectra (UV-vis DRS) of various doped TiO_2 catalysts were recorded on Hitachi UV-vis spectrophotometer (U2800) to observe visible light adsorption of the doped TiO_2 samples. The analysis wavelength ranges from 170 to 800 nm. UV-visible absorption investigation was determined by a TU-1201 model spectrophotometer.

The photodegradation reaction were carried out at 30 ˚C using a custom-built reactor that contains 250W UV lamps (characteristic wavelength = 365 nm) mounted 10 cm away from the reaction solution. Briefly, 0.1 g Pt/TiO2 sample was mixed with a 40 mL aqueous solution containing phenol (38 mg L^{-1}). The mixture was stirred vigorously in the dark for 30 min until reaching adsorption equilibrium. The catalytic degradation of phenol was initiated by irradiating the reactive mixture. Photodegradation was monitored by measuring the absorbance of the phenol at its maximum using UV-vis system.

Results and Discussion

The facile preparation of the Pt/TiO_2 samples has been reported in zhang' work [7]. The Pt/TiO_2 composites were prepared by soaking the cross-linked Pt-Alginate beads into TIP isopropanol solution, followed by hydrolysis, drying and calcination. The TEM image showed that the prepared sample has agglomerated to large particles; However, the image revealed that the sample was consist of agglomerates of particles with an average diameter of ca. 10 nm, which was in good agreement

with the crystallite size calculated from XRD pattern [7]. This indicated that the Pt/TiO_2 sample was composed of well-crystallized anatase. Crystallization of the TiO_2 mesoporous framework was a key factor for application of the sample in photocatalysis.

High angle annular dark field (HAADF) scanning transmission electron microscopy (HAAD-STEM) images and EDX spectroscopy of Pt/TiO_2 were shown in Fig. 1. The Pt phase was clearly seen as a bright spot with Pt/TiO_2 composites. The EDX spectroscopy analysis exhibited a clear Pt signal, indicating that the Pt particles were well dispersed in the TiO_2 network.

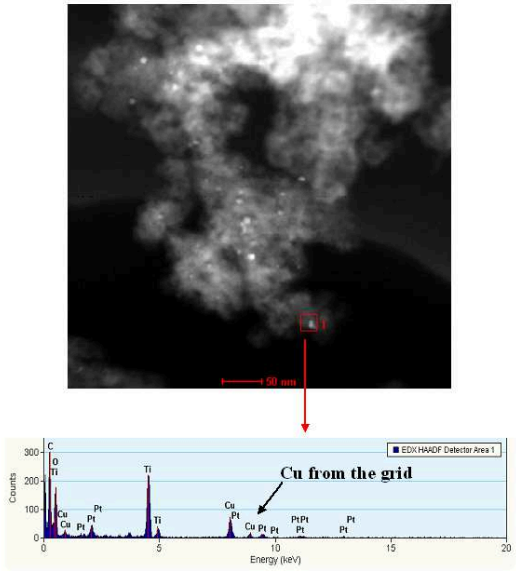

Figure 1 HAADF-STEM image and EDX spectroscopy of TiO_2 with embedded Pt nanoparticles

UV-vis DRS is useful to characterize the electronic structural property of the prepared titania nanoparticles. The UV-vis DRS of the mesoporous pure TiO_2 and Pt/TiO_2 samples were presented in Fig. 2. The spectra of the Pt-doped samples in Fig. 2 showed a red shift in the band-gap transition to longer wavelengths. The absorbance of the Pt-doped samples in the visible region was always higher than that of undoped TiO_2.

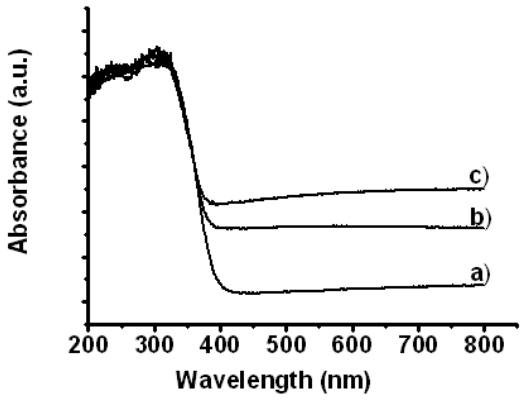

Figure 2 UV-vis diffuse reflectance spectra of (a) pure TiO_2, (b) Pt/TiO_2 (Pt: 0.18 mol-%), and (c) Pt/TiO_2 (Pt: 0.37 mol-%)

To evaluate and compare the photocatalytic performance of the mesoporous TiO_2 samples, the decomposition of phenol was used as a photoreaction probe. Results of the photocatalytic evaluation were summarized in Fig. 3. Addition of a low concentration of Pt into TiO_2 frame work could significantly improve the photocatalytic activity. The 0.37 mol % sample was found to have the

highest photocatalytic activity for the photodecomposition of phenol. The improvement of photocatalytic activity could not be expected as the Pt concentration increases further.

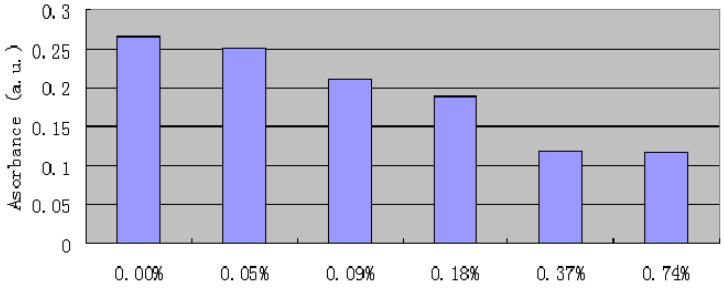

Figure 3 UV-vis absorption spectra of pure TiO_2 and different dopant (Pt) concentrations on TiO_2

Summary

A facile method was utilized to synthesize different Pt-doped TiO_2 with different dopant concentrations. Among these prepared samples, 0.37 mol % sample exhibit the highest photocatalytic activity over the degradation of phenol when 365 nm UV light was used for irradiation. The enhancement of the photoactivity can be attributed to its smallest particle size and large surface area, good dispersion of Pt over the surface of TiO_2, and suitable dopant concentration. In addition, the Pt/TiO_2 composite exhibit a marked visible light adsorption compared with a pure TiO_2 sample, which makes this composite a potential photocatalyst for solar-driven application.

Keywords: Carboxymethyl chitosan magnetic nanoparticles; Evodia rutaecarpa; Microwave reaction; Components separation

Abstract: Fe_3O_4 nanoparticles were prepared by coprecipitation method. Microwave synthesis method changed the property of the surface of chitosan, and the carboxymethyl chitosan was prepared. The carboxymethyl chitosan magnetic nanoparticle was prepared by microwave synthesis. Carboxymethyl chitosan magnetic nanoparticles were characterized by IR and SEM methods. The application conditions are discussed. Using this material to separate the alkaloid of Evodia rutaecarpa will greatly shorten the time than traditional separation method. The components will be more pure.

Introduction

Evodia rutaecarpa is the Rutaceae Evodia rutaecarpa(Juss．)Benth．dry nearly ripe fruit. This hot-natured herb was commonly used. Previous studies suggested [1] that hot-natured foundation for Evodia rutaecarpa is the N-butanol extract of Evodia rutaecarpa. This N-butanol extract mainly containing alkaloids, phenols and flavonoids components. In order to further confirm the category of hot-natured foundation for Evodia rutaecarpa, we must choose a fast, efficient and specific separation method, to separate the alkaloids of n-butanol fraction from Evodia rutaecarpa.

The conventional components separation methods of separating alkaloids of Evodia rutaecarpa have certain difficulties. It is easy to produce components cross by solvent extraction,and the Components may lossed. Small separation column is limited by capacity, so it is difficult to obtain the dose of pharmacological experiments needs.

Magnetic polymer microspheres has its unique advantages in chemical components separation like surface effect and superparamagnetism[2], it can be used for constant compositions separation, and also can be quickly and easily separated in the additional magnetic field. Functional groups on surface given by copolymerization and surface modification [3] make it adsorb some specific components. So, it is a kind of separating tool that low cost, good separated results, rapid separation, and strong selectivity.

This experiment changed the property of chitosan, and synthesized Carboxymethyl chitosan by microwave, and made Carboxymethyl chitosan magnetic nanoparticles. The alkaloids components were specific adsorbed by the carboxyl-methyl. The alkaloids from N-butanol extract of Evodia rutaecarpa was separated effectively.

Reagents and materials

Ferric chloride hexahydrate ($FeCl_3$•$6H_2O$), ferrous chloride tetrahydrate ($FeCl_2$•$4H_2O$), Tri-distilled water, the rest of the reagents are analytically pure.Chitosan, BR, Aladdin Chemistry Co. Ltd. Evodia rutaecarpa was bought in ZhangShu, appraised by teacher Liu Qinghua.G80F20CN2L-B8CRO microwave oven(Galanz appliances Co., Ltd.).Infrared spectra were measured with a VERTEX70 Fourier trans-form infrared spectrometer (Bruker, Germany). Absorption spectra were measured on a Unico UV spectrometer (St. Louis, USA). SEM were measured with a jsm6701f Scanning electron microscopy（The Japanese electronics company）.

Preparations

Preparation of Fe_30_4 nanoparticles

6.1g $FeCl_3$•$6H_2O$, 3g $FeCl_2$•$4H_2O$ were dissolved in 100ml Tri-distilled water which had been pre-degassed with nitrogen,and was heated up to 50℃. This mixed solution was added drop wise by NaOH solution ($1mol \cdot L^{-1}$) and was adjusted to pH 11, and 800 rpm mechanical stirring under nitrogen gas protection. This mixed solution was added by oleic acid 0.9g and 600 rpm mechanical stirring for 30min. This mixed solution was added by 50ml toluene, heating up to 80℃ and 600 rpm stirring for 2h. After 3minutes' standing, the toluene layer was divided and washed repetitive by tri-distilled water until it to neutral. The obtained Fe_3O_4 precipitates were separated from the reaction medium by a magnetic field, washed with ethanol and acetone five times, and then dried under vacuum at 50℃.

Preparation of Carboxymethyl chitosan

5g chitosan was swelled for 1 hour at 50℃ by isopropyl alcohol 100mL. Adding 30% sodium hydroxide solution 10mL, the mixture was stirred for 1 hour. The mixture was heated to 60℃ with microwave (800W). The mixture was reactied for 20min at 60℃ with microwave (80W) heating. The reaction product was completely dissolved in deionized water and adjusted pH value to acid with dilute hydrochloric acid solution. A white polymerization was precipitated and was filtrated with vacuum. The precipitation was washed by ethanol and acetone washing 2 times, and was dried in vacuum at 60℃.

Preparation of Carboxymethyl chitosan magnetic nanoparticles.

Carboxymethyl chitosan0.23g and 0.2g Fe_3O_4 was completely dissolved in deionized water and then an ultrasonic device is used to disperse the mixture for 20min. The mixture solution was added drop wise into the oil phase containing 35ml liquid paraffin and 0.6ml Span-80. Suspension system(W/O) was made under vigorous stirring(1000rpm) for 1 hours at room temperature. Adding 25% 4ml of glutaraldehyde,the suspension system reactied 26 min by microwave (80W) heating at 40℃. The carboxymethyl chitosan magnetic nanoparticles was separated by magnetic-iron and was washed with deionized water and ethanol 3 times, and was dewatered by Acetone. The carboxymethyl chitosan magnetic microspheres vacuum was dried 24h at 60℃.

Sample preparation

The solvent was recovered from N-butanol extract of evodia rutaecarpa. The residual was dissolved in 80% alcohol, the ethanol extract solution obtained. The mixed solution of this ethanol extract solution and 10ml 80% ethanol was adjusted to pH 5 by 0.1mol/L hydrochloric acid solution, and 0.2g carboxymethyl chitosan magnetic microspheres was added to this mixed solution. The microspheres had been dipped in 80% ethanol for 0.5 hours. Placed after 10 minutes, the mixture is placed in a magnet for 10 minutes. Carboxymethyl chitosan magnetic microspheres separated and 10ml ethanol was adjusted to pH 10 with 0.1mol/L sodium hydroxide solution. The alkaloids were eluted by ultrasound for 5 min. Separating carboxymethyl chitosan magnetic microspheres with a magnet, the alkaloid extract was obtained.

FTIR measurements

FTIR spectroscopic measurements were performed by KBr pellet method. The wave numbers of FTIR measurement range were controlled from 500 $cm^{-1}$to 4000cm^{-1}.

Determination of the content of alkaloids

The maximum absorption wavelength of evodiamine, rutaecarpine and total alkaloids of Evodia rutaecarpa were located at 361nm. And the maximum absorption wavelength of the negative solution was not in the 361nm. Therefore, the determination wavelength of alkaloid content in Evodia rutaecarpa was 360nm [4]. The 1mL test solution of Evodia rutaecarpa was diluted with ethanol into 10.00mL. Using ethanol as the blank, the absorbance of the test solution at 361nm was measured. The alkaloids amount in sample solutions was converted into rutaecarpine amount.

Static adsorption tests

Carboxymethyl chitosan magnetic nanoparticles (0.2g) were placed in a 250mL flask, and then added the alkaloid of Evodia rutaecarpa with the initial concentration ranging from 3mg/100mL to 18mg/100mL, adjusted to pH 5. The conical flasks were shaken by the oscillator for 30min and then separated carboxymethyl chitosan magnetic microspheres with a magnet. The free concentrations of alkaloid of Evodia rutaecarpa were determined by UV–visible spectrophotometer. And the acquired experimental data were analyzed by the Scatchard equation.

Identification of components

The 1ml alkaloids extract solution was removed by water bath. It showed positive reaction of alkaloid，that adding of iodine - bismuth iodide solution, the solution produced a large amount of precipitation. The results showed that the alkaloid could be successfully separated by carboxymethyl chitosan magnetic microspheres from Evodia rutaecarpa n-butanol fraction.

Adsorption time and desorption time

The n-butanol of Evodia rutaecarpa n-butanol fraction was removed by water bath. The residue was dissolved in ethanol. The ethanol solution was obtained.

The carboxymethyl chitosan magnetic microspheres 6 portions, each part 0.2g, were respectively added into 80% ethanol 20ml, and were stirred and were let stand for 20 min. The Carboxymethyl chitosan magnetic microspheres were separated by magnet. The 1mL ethanol extracts of Evodia rutaecarpa was respectively added to these Carboxymethyl chitosan magnetic microspheres, and were adjusted pH to 9, were respectively stirred for 5, 10, 15, 20, 25, 30min. The carboxymethyl chitosan magnetic microspheres after adsorption were separated from the mixture by magnet. Ethanol 20ml was respectively added into the magnetic microspheres. The mixtures were adjusted pH to 2, and were stirred, and were let stand for 20min. The carboxymethyl chitosan magnetic microspheres after desorption were separated from the mixture by magnet. The eluents were adjusted pH to neutral, and the absorbance at 361nm was measured.

Results and discussion

The characterization

Fig.1 displays the SEM image of Fe_3O_4, which illustrates the uniform size distribution of these nanoparticles. The diameter of Fe_3O_4 is in the range of 20 nm～30nm. Fig.2 displays the SEM image of Carboxymethyl chitosan magnetic microspheres, which illustrates the uniform size distribution of these nanoparticles. The diameter of Carboxymethyl chitosan magnetic microspheres is in the range of 50nm～60nm.

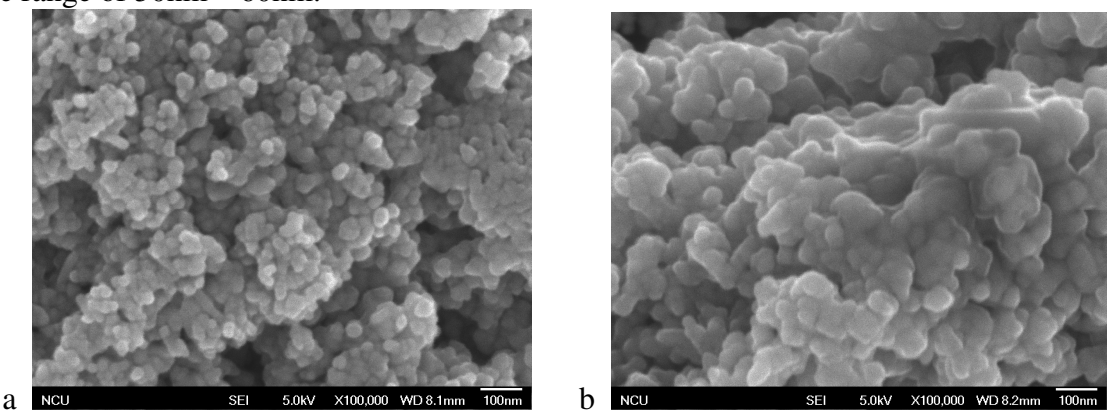

Fig1 SEM image of Fe_3O_4(a) and carboxymethyl chitosan magnetic microspheres(b)

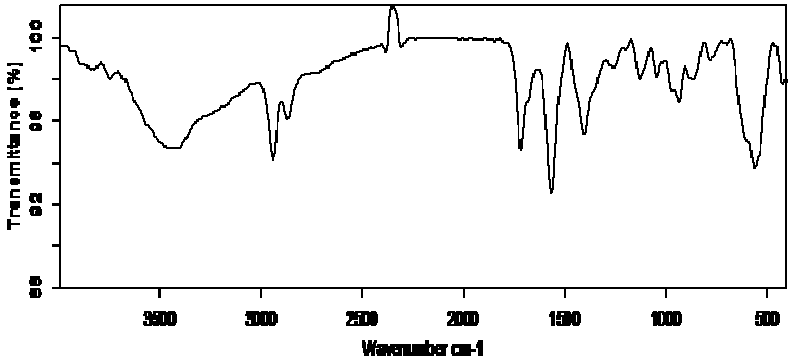

Fig.2 FTIR spectrum of Carboxymethyl chitosan magnetic nanoparticles

Fig. 2 shows FTIR spectrum of Carboxymethyl chitosan magnetic nanoparticles. Two strong O–H stretching vibration absorbance peaks in the molecule of Carboxymethyl chitosan magnetic nanoparticles are at 3300cm^{-1}~3500cm^{-1}. A stretching vibration peak of -CH_3 or -CH_2 is found at 2900- 2800cm^{-1}. A stretching vibration peak of C=O is found at 1758cm^{-1}. The absorbance peaks of —C=N— stretching, C- O or C-N stretching and Fe_3O_4 stretching are at 1566cm^{-1}, 1000-1100cm^{-1}, 580cm^{-1}, respectively. The results display that this Carboxymethyl chitosan magnetic nanoparticles was synthesized successfully.

Adsorption analysis of andrographolide

Fig. 3 describes the plot based on the Scatchard equations. The correlation coefficient (R) of regression analysis for the curve is 0.9968 for Carboxymethyl chitosan magnetic nanoparticles. It is noted that the Carboxymethyl chitosan magnetic nanoparticles has only one distinct section within the plot and inclined to a straight line, which presents that only the homogeneous affinity binding sites are formed in the polymers. From the slope ($-1/K_d$) and intercept (Q_{max}/K_d) of the Scatchard plot, the dissociation constants (K_d) and the maximum binding capacity (Q_{max}) of the Carboxymethyl chitosan magnetic nanoparticles are K_d = 2.495mg/g, Q_{max} = 34.15mg/g.

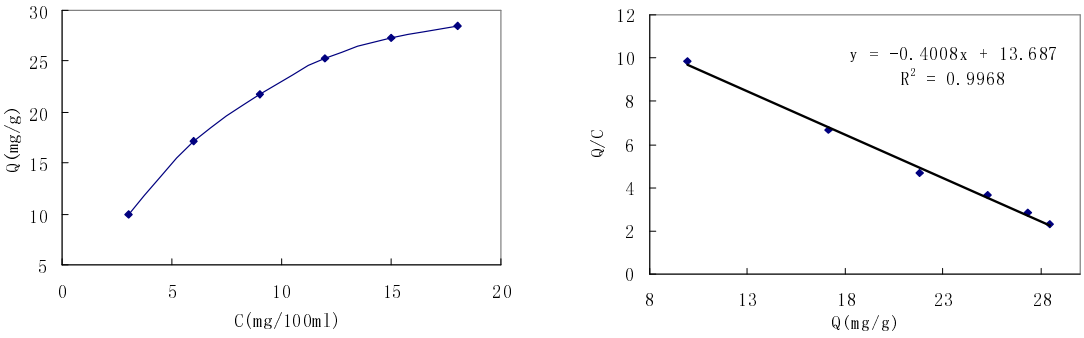

Fig. 3: Adsorption isotherm

Adsorption time and desorption time

The absorptions of each test solution of the adsorption time from 5 min to 30 min are no significant difference. These results suggest that under the experimental conditions, carboxymethyl chitosan magnetic microspheres can complete the adsorption of alkaloid components in the sample solution in 5 minutes. The desorptions of each test solution of the adsorption time from 5 min to 30 min are no significant difference. This results suggest that under the experimental conditions, carboxymethyl chitosan magnetic microspheres can complete desorption of alkaloid components in the magnetic microspheres in 5 minutes.

Adsorption pH and desorption pH

Fig. 4 and Fig.5 describes the experimental results of adsorption pH and desorption pH. When pH is 5, carboxymethyl chitosan magnetic microsphere adsorption effect is best. When pH is 10, the desorption effect is best.

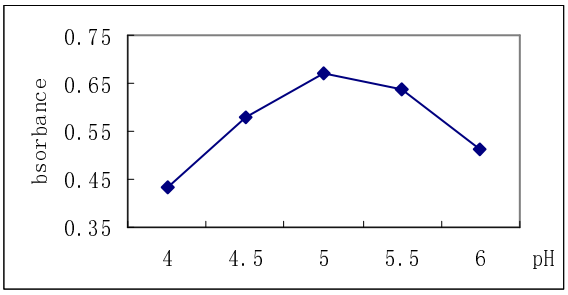

Fig. 4 Experimental results of adsorption pH

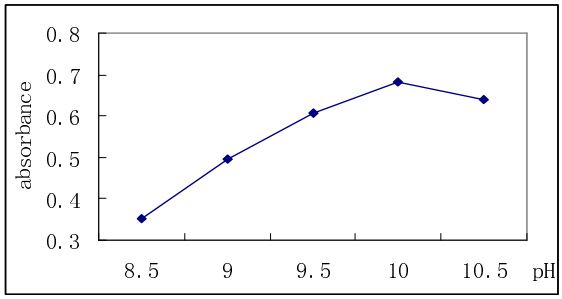

Fig.5 Experimental results of desorption pH

Discussion

In this experiment, we prepared the carboxymethyl chitosan and the carboxymethyl chitosan magnetic nanoparticles by microwave synthesis. By using this method, the reaction time is shortened about ten to twenty times than that by traditional synthesis method. According to literature references [5,6] that synthesized the carboxymethyl chitosan need 3 or 4 hours, but we just need 20 min. According to literature references [7] that synthetize the carboxymethyl chitosan magnetic nanoparticles need 7~10 hours, but we just need 26 min.

This kind of method is suitable for large doses of extraction and separation of alkaloids components in traditional chinese medicine. Comparing with acidity solvent extraction methods, new method showed advantages of short separation time, relatively pure extract, avoid cross of different solvent extraction and the broken of effective component.

Keywords: MWNTs, MWNTs-$HAuCl_4$, gas sensor, hydrogen sulfide

Abstract: The rapid and precise detection of hydrogen sulfide (H_2S) has great significance due to its high toxicity. In this work, the response properties of multiple-walled carbon nanotubes (MWNTs) and MWNTs-$HAuCl_4$ to H_2S at room temperature were compared. Scanning electron microscopy (SEM) technique was used to characterize MWNTs and MWNTs-HAuCl4 films. It was found that sensors with MWNTs- $HAuCl_4$ exhibited much higher response value. On the other hand, sensors with MWNTs were observed to have faster response time and better recovery properties.

Introduction

Hydrogen sulfide (H_2S) is known as a colorless, inflammable, corrosive, toxic and malodorous gas with smells like rotten eggs. When its concentration is higher than 250ppm, H_2S can be very dangerous to human health and even cause death [1]. Therefore, the rapid and sensitive detection and monitoring of hydrogen sulfide has great significance to both human daily life and industries. So far, much work on H_2S sensors has been done [2]. The majority of them are based on semiconductor sensitive membranes like WO_3 [3, 4], SnO_2 [5, 6], which exhibit good sensing properties at high working temperature.

Since the discovery by Iijima[7], carbon nanotubes (CNTs) have increasingly aroused attention as gas sensitive films. Now more experiments are focused on the methods to improve the sensing properties of CNTs through the modifications of CNTs by functionalizing, doping or coating with different materials [8].

In this paper, both MWNTs and MWNTs doped with $HAuCl_4$ (MWNTs-$HAuCl_4$) films were fabricated on the interdigitated electrodes (IDEs) through air spraying method. The results show us that sensors with MWNTs-$HAuCl_4$ exhibited much higher response, a slower response time.

Experimental

Preparation of sensitive films

In this work, pure MWNTs were purchased from Chengdu Institute of Organic, Chinese Academy of Sciences. The tube outer diameter is over 50nm, length 10～20nm, purity > 95%. The $HAuCl_4$ (99.9%-Au) was purchased from Strem Chemicals, Inc.

Fabrication of H_2S gas sensor

In this work, the structure of interdigitated electrodes is shown in Fig.1. The 0.2 ml pure MWNTs and MWNTs-$HAuCl_4$ uniform dispersion were sprayed onto the interdigitated electrodes by airbrushing method, respectively. The airbrush device is shown in Fig.2. The height from the nozzle to the sensor chip was approximately 20cm and the height was one of the influence factors on the film. Then the sensitive films were dried in a vacuum oven at 60℃ for almost 2 hours so that all the internal solvent could be volatilized.

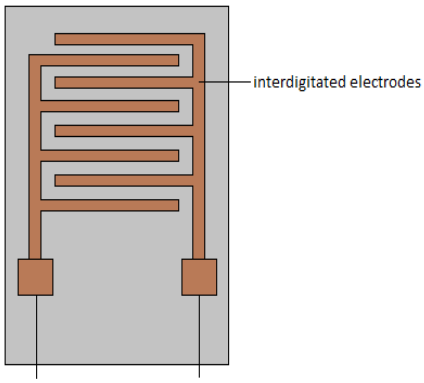

Fig. 1 Structure of interdigitated electrode

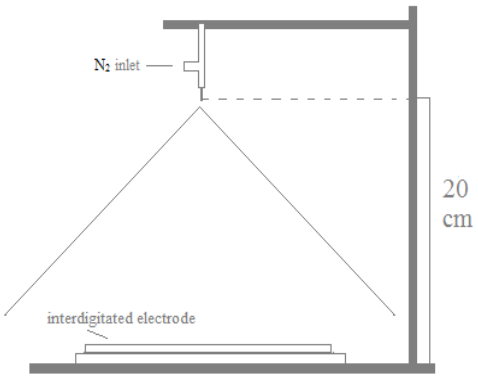

Fig. 2 Device of airbrushing

Measurement

In this work, MT50-4J flux indicator was used to produce the desired concentrations of gas mixture. The gas sensor was put into a sealed testing chamber. The electric resistance change of the sensor exposed to H_2S gas at different concentrations was monitored by keithley 2700 connected to a computer. All tests were operated at room temperature. The gas response is defined as below:

$$S=\frac{|Rg-R0|}{R0} \quad (1)$$

Where R_g and R_0 are the value of the resistance measured when the sensors were exposed to H_2S gas and N_2, respectively.

Results and discussion

Sensitivity testing

From Fig.3 and Fig.4, it's clear to see that at room temperature the sensor based on MWNTs-$HAuCl_4$ presented much higher response value than that based on pure MWNTs. When exposed to 120ppm H_2S, the response of the pure MWNTs and MWNTs-$HAuCl_4$ were 0.5% and 5%. And the response of both films when exposed to 600ppm H_2S were 2.5% and 25%, respectively. As a result, the response of MWNTs-$HAuCl_4$ film was 10 times more than that of pure MWNTs, which was a huge improvement in this regard.

The results show that both pure MWNTs and MWNTs-$HAuCl_4$ functioned as p-type semiconductor. After absorbing H_2S gas which is a kind of reducing gas, electrons transfer to the p-type materials from the gas itself. The probability that holes encounter and neutralize with electrons will increase. As a result, the conducting holes in the materials decreased which means the resistance of the films increased. When pure MWNTs were mixed with chloroaurate acid ($HAuCl_4$), the response was greatly improved. The function of $HAuCl_4$ is still not very clear.

The linearity is another important factor to characterize the static performances of a gas sensor. The linearity coefficient is used to estimate the linearity. And the closer to 1 the linearity coefficient is, the better linearity the gas sensor presents. As shown in Fig.5, the linearity coefficients of both MWNTs and MWNTs-$HAuCl_4$ films were 0.99 and 0.98, respectively. This meant that both films showed excellent linearity properties.

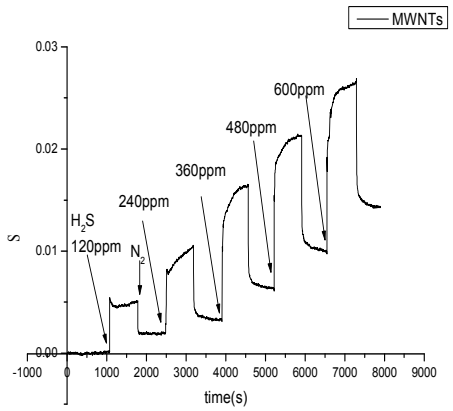

Fig. 3 The response of pure MWNTs

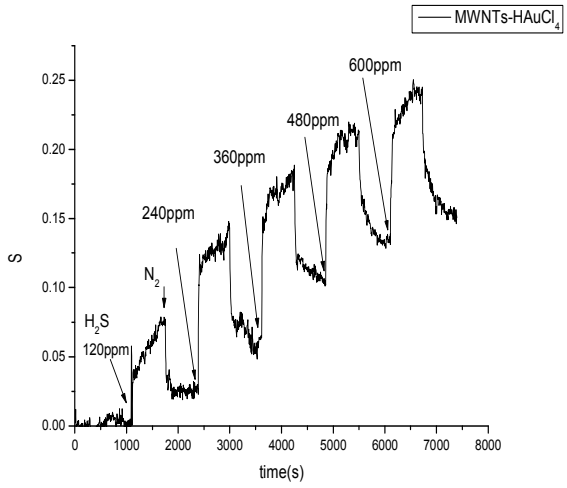

Fig. 4 The response of MWNTs-HAuCl4

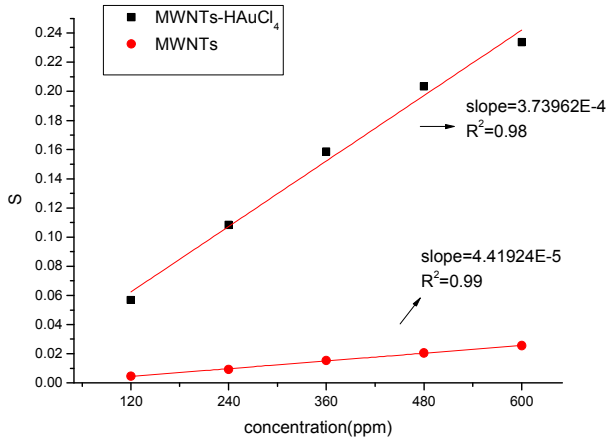

Fig. 5 The linearity of MWNTs and MWNTs-$HAuCl_4$ film

At last, the repeatability of MWNTs and MWNTs-$HAuCl_4$ films were also tested as shown in Fig.6 and Fig.7. Good repeatability is a very important property for a stable gas sensor. The cycle testing was performed at the same concentration of H_2S for five times. The original response value of MWNTs was 0.75% and the deviation of the next four test is within 0.002.It is shown that the resistance of the films could hardly return to the base line value in N_2. But it has been realized that the phenomenon is inevitable for the gas sensor. So both films were shown to present good repeatability.

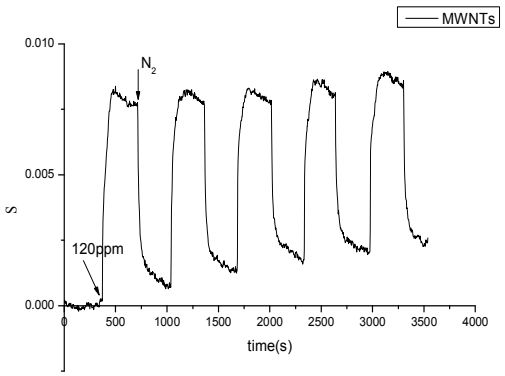

Fig. 6 The repeatability of MWNTs

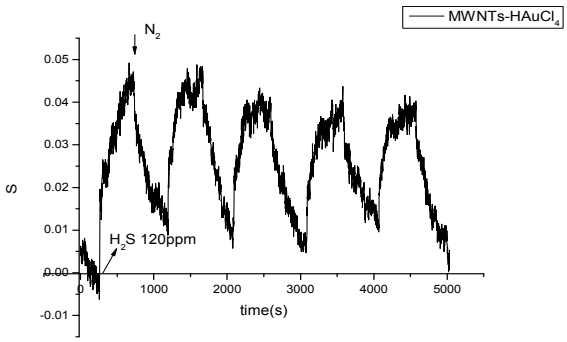

Fig. 7 The repeatability of MWNTs-$HAuCl_4$

Surface Morphology Images

In order to analyse the working mechanism of H_2S gas sensing, the surface morphology of both films were tested using SEM. It can be seen that pure MWNTs film is compact with higher density. And there are more and larger holes on the surface of MWNTs-$HAuCl_4$ film than that of pure MWNTs. The addition of holes to the surface may contribute to gas absorption. Thus more absorption sites are provided so that gas is much easier to get into the film. However, on the other hand, more holes are bad for gas desorption which leads to difficulty in the recovering of gas sensor. This result explains why MWNTs doped with $HAuCl_4$ enhanced the response to H_2S greatly, but degraded the recovering properties.

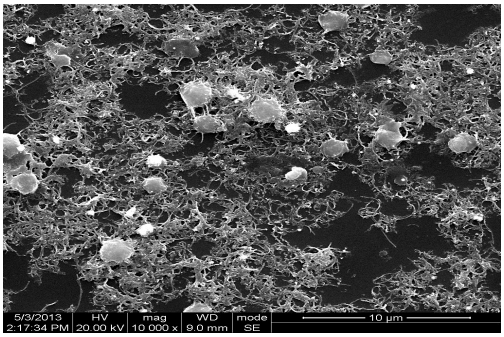

Fig. 8 The SEM images of MWNTs -$HAuCl_4$

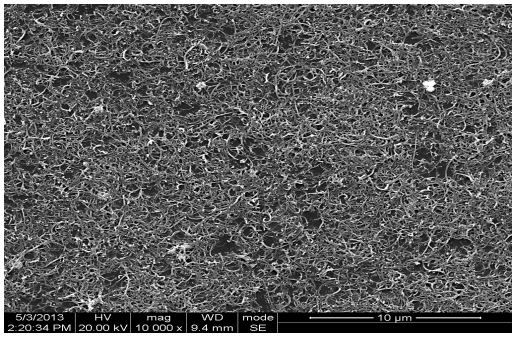

Fig. 9 The SEM images of pure MWNTs

Conclusions

In this paper, the sensing properties of MWNTs and MWNTs-$HAuCl_4$ films were compared. The results show that the response value of MWNTs-$HAuCl_4$ to H_2S was improved approximately 10 times. But on the other hand, the response and recovery times both increased. As shown in the paper, both films exhibited good linearity.

Keywords: SmCo film, co-doped, structure, coercivity, magnetic exchange bias

Abstract: Sm2Co17:Cu,Cr films growing on Cr buffer layer and Cu seed layer were prepared by pulsed laser deposition(PLD) method based on Si(100) substrate. The results showed that Cu and Cr co-doped in SmCo films made the refinement of crystal grain and the increase of coercivity of SmCo. Beside, the experiments found that the incorporation of Cu and Cr in SmCo films resulted in a positive effect of the exchange bias for SmCo-CuCr system. We suggested that the mechanism of the exchange bias origins from the interaction of ferromagnetic-antiferromagnetic state (FM-AFM, SmCo-CuCr). Meanwhile, the magnetic measurment of added magnetic field and zero-field-cooled (FC-ZFC) at temperature range of 10K~300K has further confirmed the critical value of FM-AFM tansform is about 80K, which is suggested that it was attributed to the coupling competition of FM phase and AFM phase.

Introduction

In recent years, advance rare earth permanence magnetic materials have been widely used in the communication technology, computer, medical, military and other fields. Its enormous potential has been highly concerned for researchers[1,2,3]. As a type of high coercivity material, SmCo alloy has a feature of high magnetocrystalline anisotropy, a high Curie temperature and excellent resistance to corrosion *et al*[4]. Recently, many researchers have synthesized SmCo thin films by physical and chemical methods, Junichi Sayama *et al*[5]. prepared SmCo films with perpendicular magnetic anisotropy on Cu layers by magnetron sputtering and they had investigated the influence of Cu underlayer thickness on the structure and magnetic properties of SmCo films. It is found that preparation parameters will have great impacts on the structure and magnetic properties of SmCo films[6,7]. L. N. Zhang *et al*. reported that a tantalum (Ta) seed layer can be used to decrease the Cu underlayer surface roughness, which enhanced the magnetic properties of SmCo films[8]. In this paper, Cr,Cu co-doped Sm_2Co_{17} films on Cr buffer layer and Cu seed layer were prepared by PLD, and found that Cr can restrain the grain growth of SmCo films and has great influence on the structure and propeties of SmCo films. The effects of co-doped on the structure and magnetic properties of SmCo/Cu/Cr thin films were further investigated.

Experiment

The (Sm2Co17Cux)/Cu/Cr and (Sm2Co17CuCry)/Cu(100nm)/Cr(3nm) films (x=1.5nm and 2.5nm, y = 1.6nm and 3.2nm) on Si substrates were prepared by PLD. The purity of Sm, Co, Cu and Cr metal targets are 99.99%, The background vacuum is better than 2.0 × 10-4Pa. Cr(3nm) buffer layer and Cu(100nm) seed layer are deposited on the Si (100) substrate in turn, then Sm2Co17Cux and Sm2Co17CuCry are grown on the seed layer. Beside incorporation of Cr, prepared Sm2Co17Cu(1.5nm)Cry/Cu/Cr films. The prepared samples are annealing at 680℃ under the vacuum of 10-4 Pa, holding time of 45 minutes. The structure and the surface morphology of samples are measured by X-ray diffraction(XRD) and scanning electron microscope (SEM). Magnetic properties are studied using vibrating sample magnetometer (VSM).

Results and Discussion

Structural Analysis

Figure 1 shows the XRD patterns of the Sm2Co17Cu (1.5nm) /Cu(100nm) / Cr(3nm) and Sm2Co17Cu(1.5nm)Cr(1.6nm) / Cu100nm / Cr(3nm) films. It can be observed the diffraction peaks of Sm2Co17(211) at 34.2° for fig.A and B and Sm2Co17(107) diffraction peak at 53.5° in the figure B. In addition, from the figure Cu(111) and Cr(110) diffraction peaks are also observed. To contrast figure A and B, it can also observe the Cr(110) diffraction peak of the figure A is slightly higher than the one of the figure B, which is mainly due to it contains the content of Cr (1.6nm) in SmCo. Figure 2 is the SEM spectra of the Sm2Co17Cu(1.5nm)/Cu100nm/Cr(3nm) and Sm2Co17Cu (1.5nm)Cr(1.6nm)/ Cu100nm/Cr(3nm) films. It can be seen that the fig.2(A) shows finer grain size and higher grain density as well as more uniform[9,10] than the fig.2(B) after added Cr 1.6nm, which exhibits that the small amount of doped Cr in SmCo may be helpful to refine crystal grain of film.

Magnetic and Exchange Bias Effect

Magnetic Properties

The figure 3 gives the hysteresis loops of $Sm_2Co_{17}Cu$ (1.5nm) /Cu100nm / Cr(3nm) and $Sm_2Co_{17}Cu$ (2.5nm) /Cu100nm / Cr(3nm) films. From the figure it can be found that the H_c (1731 Oe) of SmCo layer added 1.5nm Cu has slightly larger than one (1636Oe) of SmCo layer added 2.5nm Cu. Figure 4 is the SEM spectra of two samples. It can be seen that the surface of the sample added 1.5nm Cu is more smooth than one of adding 2.5nm Cu, and the average grain size is about 50nm and about 200nm, respectively. We suggested that the more amount of Cu is not helpful to the structure growth of films[11].

Figure 5 is the hysteresis loop of $Sm_2Co_{17}Cu$ (1.5nm) /Cu100nm / Cr(3nm), $Sm_2Co_{17}Cu$(Cu1.5nm/Cr1.6nm)/Cu100nm/Cr(3nm) and $Sm_2Co_{17}Cu$(Cu1.5nm/ Cr3.2nm) / Cu100nm / Cr(3nm) films. The H_c of the film added 1.6nm Cr is 2120 Oe and one of the added 3.2nm Cr is 2554 Oe, and the H_c of the film whit no-added Cr is 1731Oe. Figure 6 is the curve of coercivity H_c as a function of Cr content y. It can be found that the coercivity of film doped Cr has higher than that of no doped Cr, and the H_c increased as the increas of the Cr content. We suggested that it was attributed to the refining effect of Cr on film grains.

Fig.7 is the SEM spectra of $Sm_2Co_{17}Cu(1.5nm)Cr_y$/Cu100nm/Cr(3nm) films, y=0, 1.6nm, and 3.2nm. It can be seen that the average grain sizes are about 10nm, 15nm and 25nm for the film C, B and A, respectively. It illustrates that doping Cr can be helpful to reduce grain size and surface roughness, which is agreement to the reports of the literature[12,13,14].

Magnetic exchange bias

Figure 8 is the hysteresisloop of Sm2Co17Cu(Cu1.5nm)/Cu(100nm)/ Cr(3nm) and Sm2Co17Cu(Cu1.5nm)/Cu100nm/Cr(3nm) films. The shift of the hysteresis of A and B to right direction was seen from the figures. This indicates the appearance of the positive exchange bias effect in the SmCo-Cu system. Studies have shown that the exchange bias effect is mainly determined by the ferromagnetic-antiferromagnetic interactions in system and the coupling strength between the external field and the magnetic moment in magnetic interface. If the ferromagnetic-antiferromagnetic interaction in system shows a ferromagnetic state, exchange bias field is usually negative. If the interaction is antiferromagnetic, exchange bias field is usually positive. In a positive exchange bias system, the applied field is enough large to enable the magnetic moment in antiferromagnetic layer being arranged along the direction of the applied field, thereby the exchange bias field is positive. In the figure 8, there is a positive effect of the exchange bias, so we believe there is the competition result of ferromagnetic phase (SmCo) and anti-ferromagnetic phase (Cu) in the system[15,16,17].

The positive exchange bias effect was also found to the hysteresis loops of A, B, and C in figure 9, indicating that the exchange bias of ferromagnetic phase (SmCo) and antiferromagnetic phase (Cu,Cr) is also antiferromagnetic.

In order to confirm the above conclusions, we measured the ZFC-FC curves of the Sm2Co17Cu(Cu1.5nm/Cr3.2nm)/Cu100nm/Cr(3nm) film. Figure 10 shows the M-T curve of the sampe from 10K to 300K. It can be seen that the FC curve shows a downward trend at overall temperature range: a steep declined from 10K to 80 K, then the decline is gradual weaken after the 80K. For the ZFC curve, The magnetism decreased steeply till 80K, and there is a minimum value at about 80K, then it rises between 80 K to 260 K and has a maximum value at 260 K.

From 10 K to 80 K, FC and ZFC curves decrease monotonially, indicating the exchange interaction of film is ferromagnetic. This result is also confirmed by the figure 11, which is the hysteresis loop of the sample from fig.10 measued at 10K. From the fig.11, it can be clearly seen that the Hc changed from +450 to -583, illustrating it produced a negative magnetic bias. This approves further the exchange bias of film is ferromagnetic at low temperature. Because the thermal disturbance is weaken at low temperatures, a majority of magnetic moment in the magnetic domains is parallel, so,ferromagnetic phase has been main. On the other hand, the contents of Cr and Cu is less, so it results in the ferromagnetism being the main role.

At 80K, the ZFC curve has a minimum value, indicating the interaction of the sample transformed gradually from a ferromagnetic to an antiferromagnetc. This is due to the temperature increases and the thermal disturbance stronger. So the order arrange of magnetic moments are gradually destroyed, and the interaction is to reach equilibrium. After 80K, the ZFC curves begins rise, indicating the antiferromagnetic exchange bias begins to play a main role, which results in the hysteresis loops appears a positive exchange bias effect and the effect reaches a maximum. At 300K, the curves of FC and ZFC are to identical and is gradually to transform a paramagnetic state.

In addition, we can find that the FC and ZFC curves have a shoulder in about 50K, which may be due to the change of the exchange intensity between the ferromagnetic and the antiferromagnetic. Because the competitive of exchange interaction between ferromagnetic and antiferromagnetic is always in SmCo-Cr,Cu system. Once the antiferromagnetic is weakening, the ferromagnetic order is enhancing, and vice versa. Why the shoulder appears to 50K for our sample, we suggests that it may be related to the content of the ferromagnetic and the antiferromagnetic in the sample, the details needed to be studied further.

Conclusion

In summary, the (Sm2Co17Cux)/Cu/Cr and (Sm2Co17CuCry) /Cu(100nm)/ Cr(3nm) films (x=2.5nm, y=1.6nm and 3.2nm) on Si substrates were prepared by PLD. After Cr,Cu co-doping, the case of the refinement of crystal grain and the increase of coercivity of SmCo is observed, and the most interest behave that the exchange bias in the Sm2Co17: (Cr,Cu) system was found.The incorporation of Cu and Cr in SmCo films resulted in a positive effect of the exchange bias. We suggested that the mechanism of the exchange bias origins from the interaction between the ferromagnetic state and the antiferromagnetic state in the SmCo-CuCr system, and the change of the interaction intensity results from the competition between ferromagnetic phase (SmCo) and anti-ferromagnetic phase (Cu,Cr) in the system.

email :liyanhui@ciac.ac.cn

Keywords: porous silica nanoparticle, drug delivery and release, hyaluronic acid

Abstract : In this paper, we reported a facile strategy to synthesize hyaluronic acid (HA) conjugated porous silica nanoparticles ($pSiO_2$) as drug carrier. The $pSiO_2$ were prepared by solid nano-silica nanoparticles with "surface-protected etching". Morphologies of solid and porous silica nanoparticles were characterized by SEM and TEM. Amino groups were introduced on $pSiO_2$ to graft HA as cancer targeting ligand. Then rifampicin used as model drug was loaded in $pSiO_2$-HA. The results indicate that $pSiO_2$ can perform a certain degree of slow release. Overall, the system might open the door to a new generation of carrier system for site-selective, controlled-release delivery of anticancer drugs.

Introduction

Since the discovery of ordered mesoporous silica materials, much attention has been focused on the organic moiety functionalized mesoporous silica with different potential applications due to their large surface area, uniform pore size distributions and adjustable pore sizes over the range 1.5-30 nm. Several mesoporous silica nanoparticles-based controlled-release systems have been synthesized by using different kinds of capping agents[1-4] including nucleic acids, organic molecules, inorganic nanoparticles, polymers, and superamolecular assemblies. Gary-Bobo M[5] prepared Hyaluronic acid(HA)-functionalized mesoporous silica nanoparticles for efficient photodynamic therapy. Because HA is one of cancer cell selectivity ligand linked with two kinds of cancer receptors: CD44 and RHAMM[6].

In this paper, we explored the capability of the "surface-protected etching"[7] strategy and demonstrate a simple process for the synthesis of $pSiO_2$ for Rifampicin loading. HA was introduced on $pSiO_2$ and demonstrated great potential for cell-specific targeted and drug controlled release. We hope the products will be encapsulated different drugs into respective porous space, and showing that porous silica nanoparticles can be used in for imaging, catalyze and drug delivery vectors.

Materials and methods

Materials

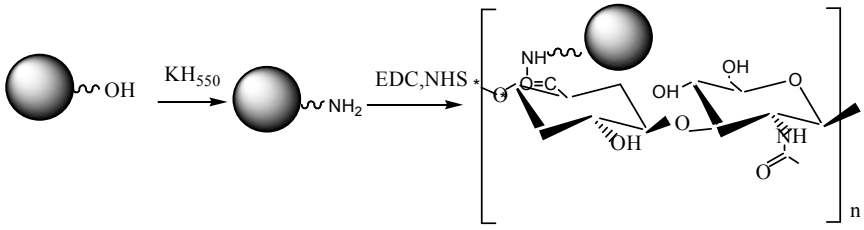
Tetraethyl silicate (TEOS), ammonia solution, isopropylalcohol (IPA) and Sodium hydroxide were obtained from Beijing Chemical Works with analytically pure. 3-aminoporopyl triethoxysilane (APTES), HA sodium salt, Polyvinylpyrrolidone(PVP), 1-ethyl-3-(3-dimethyl-aminopropyl) carbodiimide (EDC), N-Hydroxysuccinimde (NHS) were purchased from Aladdin Industria Corporation. Deionized water, phosphate buffer (PBS), 2-(N-morpholino) ethanesulfonic acid buffer (MES) were homemade.

Synthesis of SiO_2 Nanoparticles($sSiO_2$)

6 mL of TEOS and 20 mL of IPA were mixed in the beaker and added into the mixture of 9 mL of IPA, 20 mL of H_2O, and 8 mL of ammonia solution to stir until appeared white turbidity. Then

another stirring was continued for 15min, 3 mL of TEOS was added into the above mixture liquid, which was hydrolyzed and condensed for 4 h. Then, the products were centrifuged and washed with deionized water and ethanol several times then freeze-drying.

Synthesis of Porous SiO_2 Nanoparticles($pSiO_2$)



The as-prepared sSiO2 sample (200 mg) was dispersed in deionized water(20 mL) mixed mixed PVP(1.5g) at 100 ℃ for 3h. After cooling down to room temperature, NaOH aqueous solution (5 mL, 0.10 g/mL) was injected into the system to initiate etching[8]. After a defined time, the products were collected by centrifugation and washed several times by deionized water. Then the products were freeze-drying and calcined at 600℃ for 6h to get $pSiO_2$.

Amino modified Porous SiO_2 Nanoparticles(SiO_2-NH_2)

The solid and porous nano-SiO_2 microspheres were dispersed in deionized water, and then APTES was added under high-speed stirring with pH value of 10 to react at 100 ℃ for 24h. APTES and (APTES + SiO_2) molar ratio was 1:4. The products were collected by centrifugation and washed several times to freeze-dry to get SiO_2-NH_2.

HA modified porous silicon(SiO_2-NH_2-HA)

HA (30 mg) was hydrated in water overnight and then activated by EDC (6 mg) and NHS (12 mg) in MES buffer (pH=6.0) for 40 min[9]. 80 μL of PBS buffer (pH 7.4) was then added followed by the addition of 12 mg SiO_2-NH_2 at room temperature with continuous stirring for 20h. The unreacted HA was removed by centrifugation. After reaction, the products were freeze-drying to get SiO_2-NH_2-HA. The detailed process of $pSiO_2$-HA conjugates was shown as scheme 1.

Scheme 1. Synthesis of HA conjugate using amino-modified silica microspheres (SiO_2-NH_2).

Rifampicin Loading and release

The $pSiO_2$(20 mg) and Rifampicin(20 mg) were dispersed in PBS (80uL) to stir for 24h under dark conditions. The products were centrifuged and washed with PBS. Rifampicin concentration was measured by UV-vis measurements at 474 nm. Drug loading content and drug loading efficiency of Rifampicin can be calculated as follow [10]:

Drug loading content[wt.%]=(weight of loaded drug/weight of nanocomposites）×100%

Drug loading efficiency[%]=(weight of loaded drug/weight of drug in feed)×100%

The standard curve of Rifampicin was measured in the same PBS with R^2=0.9278, the equation was y=0.0044x-2.5006.

Characterization of materials

The morphologies of nanoparticles were observed through Transmission electron microscopy (TEM, JEM-2100F electron microscope) and scanning electron microscopy (SEM, JEOL JSM-6700F microscope). UV-vis spectra were recorded on a UV-3101PC Shimadzu spectroscope. The functional groups of products were emerged through infrared spectrum(8400S (Shimadzu)).

Results

Synthesis of SiO_2-NH_2 and $pSiO_2$-HA characterized by FTIR

SiO_2 and SiO_2-NH_2 were characterized by FTIR shown in fig.1. In figure 1b, the peaks at 1634 cm^{-1} and 3443cm^{-1} indicated SiO_2 surface active hydroxyl groups, the peaks at 798 cm^{-1}, 1097 cm^{-1}

and 470 cm^{-1} correspond to the Si-O-Si of antisymmetric stretching vibration, symmetric stretching vibration and bending vibration. Compared with the FTIR spectra of SiO_2 (Fig. 1b), new peaks of $pSiO_2$ were observed around 3164cm^{-1} and 1405 cm^{-1} assigned to the NH_2 vibration, the Si-CH_2 vibration. The results indicated that the SiO_2-NH_2 had been successfully prepared.

FTIR spectra of HA and $pSiO_2$-HA were shown in fig.2. The successful HA grafting was validated by the appearance more stronger absorption bands similar to HA emerged in $pSiO_2$-HA (Fig. 2a) at around 1633cm^{-1} similar to $pSiO_2$-HA(Fig. 2b), which assigned to amide C=O stretching of the carboxyl groups contained within the attached HA macromolecules.

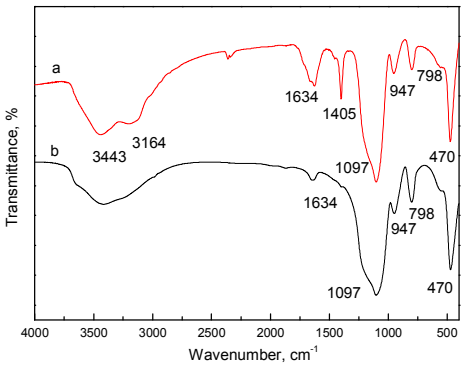


Fig. 1 FTIR spectrum of silica nanoparticles before (b) and after (a) aminaton reactiom

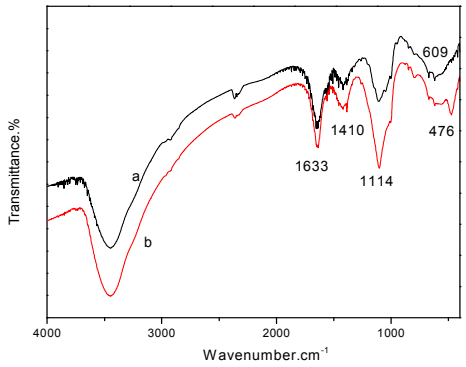

Fig. 2 FTIR spectra of HA (a), and $pSiO_2$-HA(b)

Morphologies

TEM and SEM images showed that $sSiO_2$ and $pSiO_2$ (surfactant not removed from $pSiO_2$) were of spherical morphology (Figure 3a,b), and $sSiO_2$ exhibit a smooth surface while $pSiO_2$ showed rough pore-like channels indicating the presence of pore structure.

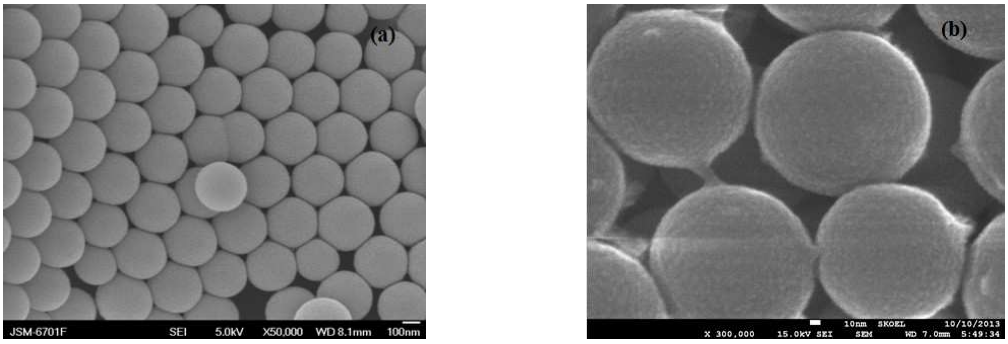

Fig. 3 SEM of $sSiO_2$ (a)(size 260nm) and $pSiO_2$(b)(size 200nm)

As seen in Fig.3, the size of $sSiO_2$ was about 240nm, while the size of $pSiO_2$was 200nm, the result indicated that the etching was successful.

Inner structure of solid and porous SiO_2 was observed by TEM as shown in fig.4.

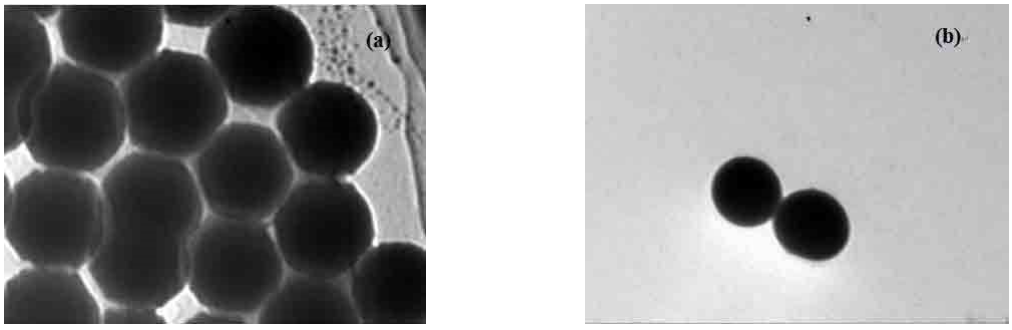

Fig. 4 TEM of $pSiO_2$ (a) and $sSiO_2$ (b)

As seen from the, there was a uniform structure in $sSiO_2$ with no difference between the internal and surface. While after NaOH dissolution, $pSiO_2$ had internal structure with the mesh from surface to inner seen from figure 4(b). In the first 70 min of reaction, the transmittance changed very slowly because the NaOH only attack the surface of silica layer which was protected by the PVP molecules. It also suggested that by controlling the reaction time the degree of etching can be controlled.

Figure 5a, b, were the SEM of nanoparticles packaged with PVP and grafted with HA, respectively.

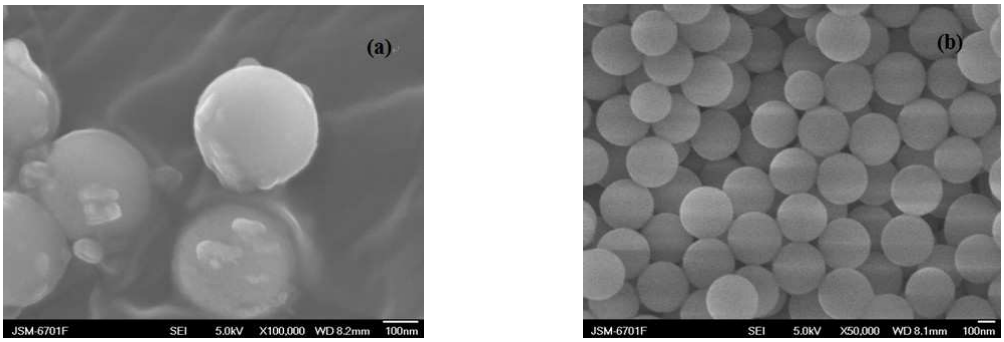

Fig. 5 SEM photos of PVP- SiO_2 nanoparticles(a) and HA-SiO_2 nanoparticles(b)

It can be seen that not only the spheres were still with the uniform size, but also possessed very good monodispersed.

Rifampicin loading and release

Drug loading content and loading efficiency of rifampicin in nanoparticles were listed in table 1.

TABLE 1 DRUG LOADING CONTENT AND DRUG LOADING EFFICIENCY

Sample	Drug loading content [wt.%]	Drug loading efficiency [%]
$sSiO_2$	20%	65%
$pSiO_2$	40%	80%

As can be seen from Table 1, rifampicin can be adsorbed in $pSiO_2$ with higher drug loading content and efficiency. The result indicated that more porous in $pSiO_2$ can load more drugs.

The experiment of Rifampicin released from $sSiO_2$ and $pSiO_2$ was performed in PBS, and the results were shown in Fig.6.

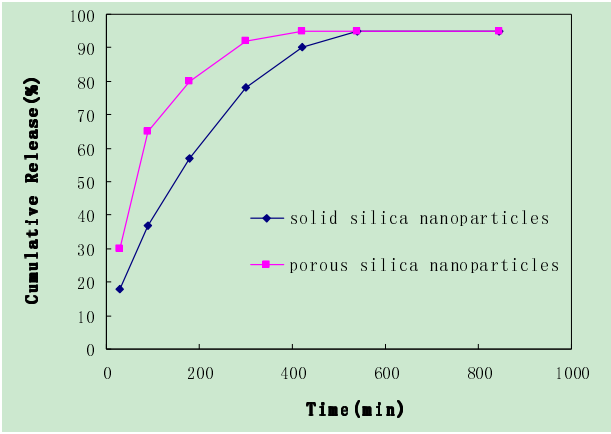

Fig. 6 Rifampicin release from solid and porous silica nanoparticles

As can be seen from Fig.6, rifampicin of solid and porous SiO_2 nanoparticles has burst release behavior, but comparatively speaking, the release rate of rifampin from $pSiO_2$ was significantly slower than $sSiO_2$. So $pSiO_2$ were more suitable for rifampicin loading and release.

Conclusion

This article prepared $sSiO_2$ by sol-gel with uniform size. Under the protection of PVP, NaOH was used to dissolute $sSiO_2$ to obtain $pSiO_2$. We can gain uniformly sized $pSiO_2$ through morphology observation in this method. But after dissolution treatment, the size of the silica sphere was slight decreased. Then HA was introduced on $pSiO_2$ to get targeting property. Based on $sSiO_2$ and $pSiO_2$, rifampicin was used as model drug to load in the paticles. The results indicated that $pSiO_2$ can load more rifampin, and release behavior has been improved. Compared with $sSiO_2$, the $pSiO_2$ was more suitable for using as drug carrier. Fortunately, we expected HA grafted on the surface of $pSiO_2$ will provide a suitable anticancer drug delivery for efficient cancer therapy.

Keywords: nanofiber; fibrillation; filtration

Abstract: The nanofiber, which diameter less than 1000 nm, has been discovered as advanced fiber material for high efficiency filtration. Tencel fiber is a new kind of regenerated fiber which can be easily fibrillated by a mechanical beating process to form nanofiber morphology. The present study shows the nanofiber morphology of Tencel fiber and investigates how the structure and properties of filter material change with the impact of fibrillated nanofiber. The results show a mass of nanofibril appeared after the Tencel fiber is intensively beat. At the same time, the air permeability and pore size of filter material is decreased with the decrease of fibrillated nanofiber content while the strength gets an opposite trend. What's more, the filtration efficiency of the filter material is significantly enhanced by fibrillated nanofiber which filtration rate achieves 6.3 for particles bigger than 4 μm at 20 wt%. This paper has shed some light on the application of fibrillated fibrillated nanofiber to enhance the efficiency of filter material effectively.

Introduction

The fibers with diameter less than 1 μm are generally defined as "nanofibers" in the filtration field [1]. Owing to the ultra small diameter, nanofibers have very high surface areas that are advantageous for fibrous filtration. As a result, nanofibers become a key component of many filter material. And the filter material which have at least some fraction of nanofibers are called "nanofibrous filter material" or "nanofiber material"[2]. Nanofiber material has proved as a promising material which can provide greater filtration efficiency and higher performance than conventional filtration material.

At present, electrospinning nanofibers, improved melt-blown nanofibers and micro glass fibers are most commonly used nanofibers. While they are effective for enhance the performance of filter material, it has drawbacks. For instance, they are hard to recycle and is fairly weak which can be easily damaged in the manufacture and service process.

Tencel fiber, which is spun from a solution of cellulose in N-methylmorpholine-N-oxide (NMMO) [3-6], is a fully biodegradable cellulose fiber has almost 100% conversion efficiency from woodpulp to the final fiber. It is easily fibrillated to form highly polydisperse nanofiber morphology by a mechanical beating process[7]. As those highly fibrillated nanofibers are polydisperse fibers with perfect hydrophilicity[8], it is possible to produce nanofibrous filter material by a wet-laid process through the usage of these fibers. This is a new nanofiber material. Therefore, how to investigate the properties of this material to form new technology is of great significance.

In this paper, the morphological changes of Tencel fiber after intensively beating are characterized and their SEM pictures are observed. Then, the effect of fibrillated Tencel nanofiber（58°SR） on the structure, basic properties and filtration properties of filter material are investigated. Some light was shed on the application of fibrillated Tencel nanofibers in the nanofibrous material field.

Experimental

Materials

Tencel fiber (Fineness: 1.7dex, Length:6mm)
Hardwood fibers

Equipment

PFI-refiner: Canada LABFECH
Sheet-forming apparatus: British ME-255
Beating degree meter: Yo-2-18, Sichuan, Changjiang Paper Instruments Ltd.
Fiber length tester: Kajaani Fiber Auto Analyzer FS-200
Permeability tester: YG461E, Ningbo Textile Instrument Factory
Burst strength tester: Code 180, Lorentzen & Wettre Ltd.
Thickness gauge: YG142, Ningbo Textile Instrument Factory
Scanning electronic microscope: S3700 scanning electronic microscope, Hitachi, Japan
Pore size tester: PMI permeameter, USA

Fiber Beating

The Tencel fiber was beaten by PFI refiner with 9000 revolutions.

Sample preparation and Scanning electron micrograph observations

Nanofiber material were made from the fibrillated Tencel nanofibers with Hardwood fibers, and basis weight was 105g/m^2. In order to protect samples without destructing the original three-dimensional structure, there was no press after formation. Subsequently, the structure of samples was studied by SEM. Lastly, the effect of fibrillated Tencel nanofiber（58°SR）on the basic properties and filtration properties of filter material were investigated. The filtration properties were tested by multi-pass test method, and the schematic of test system was showed in Figure 1.

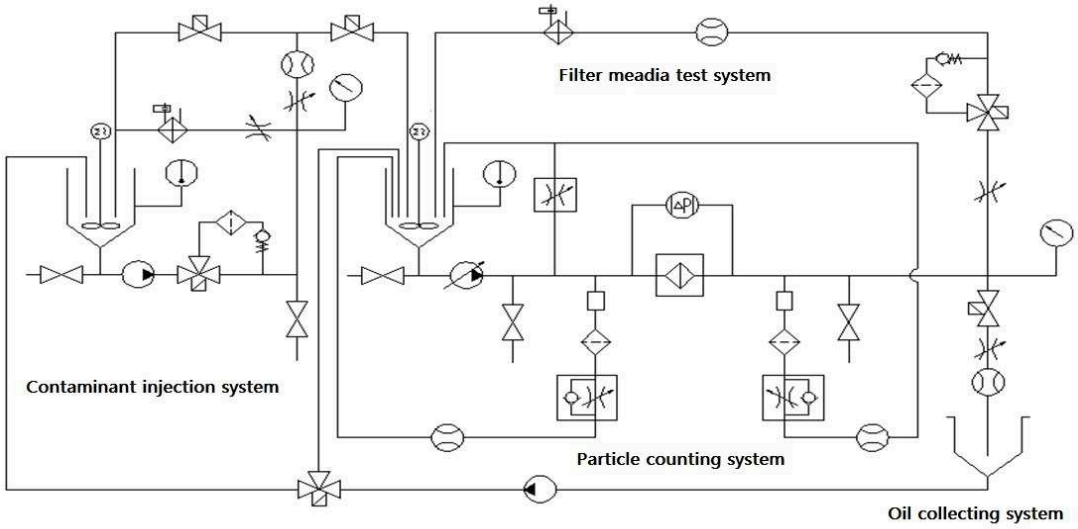

Fig. 1 The schematic of the multi-pass test method test system

Results and Discussion

Beating Properties of Tencel Fiber

After being beaten by PFI-refiner at 9000 rounds, the beating degree and the average length of Tencel fiber are listed in the following table and the un-beat fiber also listed to compare.

TABLE 1. THE EFFECT OF BEATING INTENSITY ON BEATING DEGREE AND AVERAGE LENGTH

Beating rounds	Beating degree [°SR]	The fiber's average length [mm]
0	12	6.00
9000	58	0.38

The values in the table 1 reveal that Tencel fibers are cut off instantly and their length decreases significantly after beating. Meanwhile, the beating degree is also rise obviously.

SEM Observation

Observation of Fibrillated Tencel Fibers

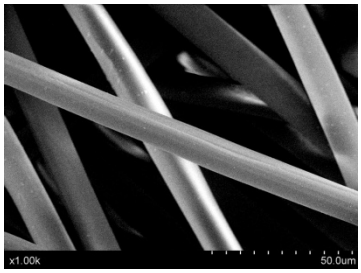

Fig. 2 Tencel fibers (×1000)

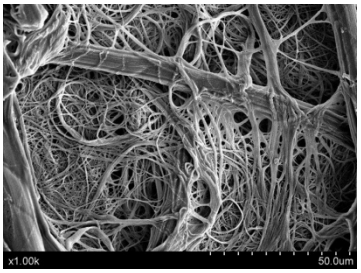

Fig. 3 Fibrillated fibers (×1000)

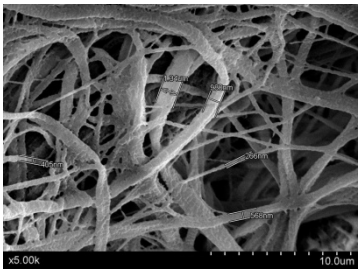

Fig. 4 Fibrillated nanofibers (×5000)

Fig.2 and fig.3 reveal the very change of morphology of Tencel fibers by beating process. Before beating (fig.2), Tencel fibers are smooth and the same size. But after beating, it can be found that a plenty of fibrils are peeled back or splintered from the trunk fiber. And from the enlarged SEM picture fig.4 with 5000 magnification, it shows the diameters of fibrils are smaller than 1 μm generally and some of them are as low as about 100 nm. They are nanofibers.

Observation of Fibrillated Nanofibrous Material

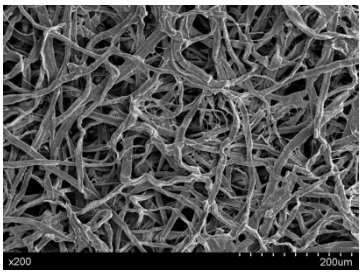

Fig. 5 5 wt% content (×200)

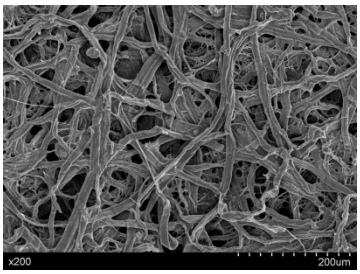

Fig. 6 10 wt% content (×200)

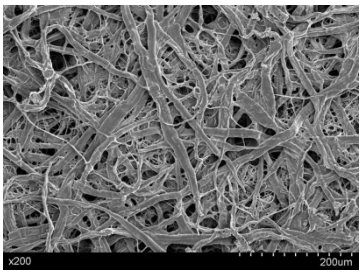

Fig. 7 20 wt% content (×200)

To understand the relationship between the properties of fibrillated nanofibrous material and its morphology, the material were studied by SEM. Fig.5 to fig.7 are the SEM pictures of fibrillated nanofibrous material. The fibrillated nanofibers content of the material are 5 wt% (fig.5), 10 wt% (fig.6) and 20 wt% (fig.7) respectively. From fig.5 to fig.7, it reveals that the fiber gaps are filled with fibrillated nanofibers quickly with the increasing of fibrillated nanofibers content. As a result, the fibrillated nanofibers make a great number of tiny pores in the material. This structure is beneficial to improve the filtration efficiency of material greatly. On the other hand, with the increasing of nanofibers' content, the bonding density of fibers in the material also increases remarkably and it might improve the strength of material effectively.

Fibrillated Nanofibrous Material Properties Test

To understand the effect of the fibrillated nanofibers on the filter material, the material properties are tested, including basic properties (burst strength, air permeability and pore size) and filtration properties (Initial pressure drop, dust retention capacity and filtration ratio). The results are listed in table 2 to table 4 respectively.

TABLE 2 BASIC PROPERTIES OF FIBRILLATED NANOFIBROUS MATERIAL

Content [wt%]	Burst Strength [Kpa]	Air Permeability [mm/s]	Max Pore Size [μm]	Mean Pore Size [μm]
0	152	114.3	24.5	9.1
5	228	62.8	17.1	6.3
10	269	48.3	16.6	5.4
20	336	29.3	13.9	3.8

From the table 2, it can be found that the properties of filter material vary a lot on the influence of fibrillated nanofibers. It means with the increase of fibrillated nanofibers' content, the air permeability and pore size decrease obviously, while the burst strength of filter material gets an opposite trend. Comparing with the material have no fibrillated nanofibers, only 5 wt% of fibrillated nanofibers have changed the performances of filter material significantly. When fibrillated nanofibers content comes to 20 wt%, the air permeability of material is quartered, pore size fells by almost half while burst strength is doubled. These results are consistent with the structure analysis above.

TABLE 3 INITIAL PRESSURE DROP AND DUST RETENTION CAPACITY OF FIBRILLATED NANOFIBROUS MATERIAL

Content [wt%]	Initial pressure drop[Kpa]	Dust retention capacity [mg/cm^2]
0	14	2.93
5	16	2.65
10	20	1.80
20	64	1.35

The results of table 3 shows with the increase of fibrillated nanofibers' content, the initial pressure drop of material is increasing while the dust retention capacity is decreasing. However, according to the test results of table 4, the filtration is radically increasing with the increase of nanofibers' content.

TABLE 4 FILTRATION RATIO OF FIBRILLATED NANOFIBROUS MATERIAL

Content [wt%]	>4μm(c)	>5μm(c)	>6μm(c)	>7μm(c)	>8μm(c)	>10μm(c)	>12μm(c)	>14μm(c)
0	/	/	/	3.91	6.04	16.00	47.54	126.24
5	/	/	/	6.44	10.55	30.84	93.87	205.51
10	/	/	7.73	14.70	29.11	106.39	294.58	/
20	6.30	18.34	41.09	82.90	146.51	/	/	/

Table 4 reveals the filtration ratio of material with different nanofibers' content. When nanofibers' content is 0%, the smallest size of detectable particle filtered by the material is 7μm, while the filtration ratio is 3.91. By contrast, when nanofibers' content reaches 20%, the filtration ratio of 7μm particles filtered by material is 80.90, 31 times as much as the material with no nanofiber. Meanwhile, when nanofibers' content reaches 20%, the smallest size of detectable particle filtered by material decreases to 4μm, while the filtration ratio is 6.3. It means the filtration efficiency of material toward to particles bigger than 4um reaches 84.12%. Fibrillated nanofiber enhances the filtration efficiency of filter material effectively.

Conclusions

The present study shows how the Tencel fiber morphology changed with intensively beating to become nanofiber and investigates the effect of this nanofiber on the structure and properties of filter material.

The results show a mass of nanofibril appeared after the Tencel fiber is intensively beat. And the fiber becomes to nanofiber. When these nanofibers are applied to filter material, the fibrillated nanofibers make a great number of tiny pores in the material. This structure is beneficial to improve the filtration efficiency of material greatly and also improve the strength of material effectively.

As a result, the test results reveal the filtration efficiency of the filter material is significantly enhanced by fibrillated nanofiber which filtration rate achieves 6.3 for particles bigger than 4 μm at 20 wt%. As to the burst strength, the filter material with 20 wt% fibrillated nanofibers is the double of non-nanofiber material.

This paper has revealed the fibrillated nanofiber is a right material to enhance the strength and filtration efficiency of filter material effectively.

Keywords: Pd-based nanoclusters catalysis, Physical vapor deposition, Formic acid oxidation

Abstract. Near-monodisperse Pd and PdCo nanoclusters were synthesized by physical vapor deposition using a plasma-gas-condensation cluster deposition system and tested for catalyzing formic acid oxidation. Under the condition of high vacuum and inert gas, NCs with clean surface and uniform size were obtained. The cyclic voltammetry tests revealed that the electrochemical surface area was increased from 49.7 $m^2 g^{-1}$ to 51.7 $m^2 g^{-1}$ and the peak current density of catalyzing FAO was raised from 0.115 mA cm^{-2} to 0.125 mA cm^{-2} when about 12*wt*. % Co element was added. Additionally, the tolerance to CO poisoning of Pd could also be improved by the addition of Co. The result indicated that this method offered a chemical-free way to prepare clean and efficient Pd-based nanoscale catalytics and encouraged deeper exploration for electrochemichal catalytic reactions.

Introduction

Nowadays, the interests in the energy-converting and energy-saving technology of direct formic acid fuel cell (DFAFC) are raised significantly, due to its higher theoretical electromotive potential and less fuel crossover comparing with those of direct methanol fuel cell (DMFC) [1]. Pt as its general catalyst was challenged on account of large cost, slow reaction kinetics and the intermediate CO poisoning [2]. So one of the key issues in practical applications was to explore less or non-platinum catalysts which also could catalyze more efficiently and tolerate CO poisoning better. Recent researches showed that Pd-based catalyst could be an effective alternative to Pt in this field, due to their lower cost and higher active surface area, besides, it almost could avoid CO poisoning more effectually by the direct 2-electron catalytic process which was different from the process with the nocuous oxidation product CO of Pt-catalysts [3]. Moreover, some authors have supported that PdCo bimetallic nanoparticles (NCs) could improve the Pd electrocatalytic activity and stability for formic acid oxidation (FAO), which could be attributed to the synergistic effects within the two parts [4-6]. At present, the most commonly method to prepare bimetallic NCs was liquid-phase synthesis [7-9], however, there were several limitations, such as bad size distribution, poor surface cleanness and weak attachment. Different from the traditional liquid-phase route, the physical vapor-phase deposition method (PVD) was carried out at a high vacuum and inert gas conditions which were allowed to avoid the surface pollution and oxidation efficiently.

In this paper, the plasma-gas-condensation cluster deposition (PGCCD, see Fig. 1) system developed according to PVD technique was used to prepare Pd and PdCo bimetallic NCs. The catalytic activity and utilization efficiency of Pd could be approved by the addition of Co element. The NCs assembled films prepared by PGCCD whose packing density (P) was only about 30 % of

the bulk one [10] had a narrow size distribution and good morphology consistency. In this device, the NCs were deposited onto the glassy carbon plate (GCP) directly, therefore, the preferable contact area and adhesive strength could be maintained even without any additives. Even more important, the catalytic performance of Pd NCs for FAO and the influences of Co on the structure, morphology and electrocatalytic properties of Pd NCs were also investigated systematically in this work.

Experimental

A PGCCD system (Fig. 1) was used to synthesize Pd and PdCo NCs, and the experiment principle has been described in detail in our earlier work [11]. High-purity Pd and Co (99.99%) metal targets were installed as 100 mm apart distance, and an Ar flow rate of 350 sccm adjusted by a fine mass flow controller was injected steadily into the Sputtering chamber. In the experiment process, the pressure of the Sputtering chamber and Assembling chamber was maintained at about 100 Pa and 5×10^{-3} Pa, respectively. The high concentration Pd or Pd/Co mixed atomic vapor was generated by dc sputtering with a power of 400 W. Vapor atoms lost their kinetic energy rapidly and nucleated by collision with insert gas molecules. Then the nucleated NCs were extracted into the Assembling chamber through the nozzle located in Filter region accompanied by the Ar gas flow under the pressure differential produced by the pumping system. The NCs obtained a drift rate for the isentropic and adiabatic expansion process and softly landing and assembling onto the GCP (S = 1 cm^2).

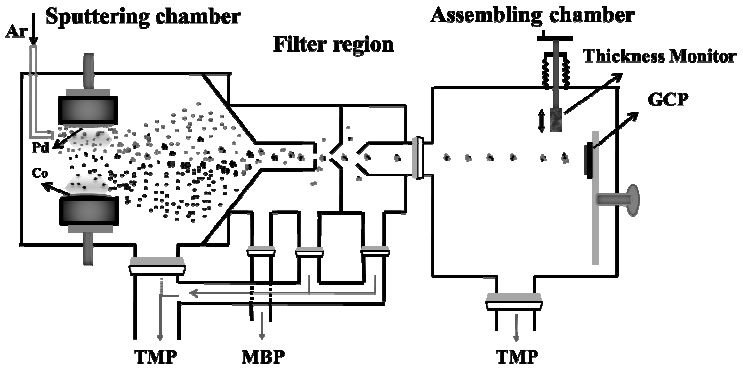

Fig. 1. Schematic Diagram of the Plasma-gas-condensation Clusters Deposition System (PGCCD)

The deposition rate of NCs was measured by a quartz oscillator-type thickness monitor located on the top of the Assembling chamber. The mass fraction of Co was measured by wavelength dispersive spectrometer (WDS, EPMA JEOL8100). The morphology and size distribution of NCs (with effect thickness of about 2.0 nm) loaded on the Cu micro grids were characterized by a transmission electron microscope (TEM, JEM2100HC). The surface morphology of the NCs assembled films (~100 nm) deposited on silicon wafers was observed though a scanning electron microscope (SEM, LEO-1530FE). Moreover, the crystalline structure of the as-prepared samples was analyzed by X-ray diffraction (XRD, Panalytical X'pert-PRO).

Electrochemical measurements were performed on an electrochemical workstation (Autolab PGSTAT302N). A standard three-electrode cell was used, which was consisted of a Pt net counter electrode, an Ag/AgCl (in saturated KCl) reference electrode and a GCP covered with 100 nm Pd or PdCo bimetallic NCs working electrode. Before deposition, the GCPs were polished with 0.3 μm alumina powder and then washed twice for 10 min each by ultrasonic in alcohol. The cyclic voltammograms (CVs) were measured in the electrolytes of 0.5 M H_2SO_4 and 0.5 M H_2SO_4 + 0.5 M HCOOH at -0.21 ~ +1.0 V with a scan rate of 50 mV s^{-1}. The potentials in electrochemical curves were reported with respect to Ag/AgCl (0.210 V vs. SHE).

Results and Discussion

The XRD patterns of the Pd and PdCo NCs assembled films were shown in Fig. 2. The main diffraction peaks located at 40.473° and 47.046° can be assigned to (111) and (200) planes of Pd_{fcc}, respectively. Besides, the additions of Co (the mass fraction was measured by WDS as 12%) didn't change the phase structure of Pd but made its crystallinity better. Fig. 3 shows the TEM and SEM images of Pd and PdCo bimetallic NCs. It can be seen form the TEM images that the Pd and PdCo NCs were spherical with small size and narrow size distribution. The particle size of PdCo NCs (6.44 nm) was larger than Pd NCs (5.15 nm), which was in accordance with the result of XRD. The SEM images show that the NCs were loosely packed on the surface of silicon wafers and formed porous films, which will be conducive to obtain large specific surface area.

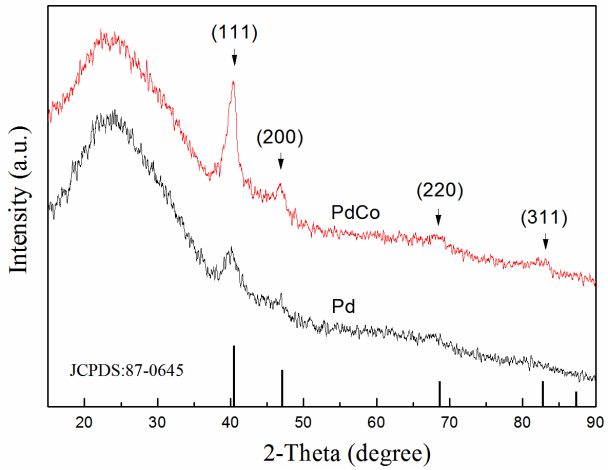

Fig. 2. XRD Patterns of Pd and PdCo NCs Synthesized by PGCCD

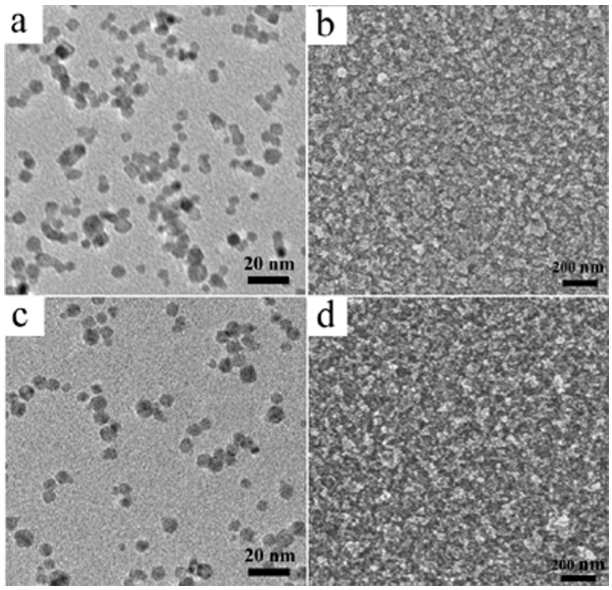

Fig. 3. TEM and SEM Images of Pd (a, b) and PdCo (c, d) NCs

Fig. 4a shows the stable CVs of Pd and PdCo NCs prepared by PGCCD and their current densities were normalized by the geometric area of catalysts. It could be found that two peaks current density (I_p) of hydrogen adsorption/desorption in the lower-potential region (-0.21 V~0.1 V). The electrochemical active area (ECSA) calculated from the integration value of the charge involved in hydrogen desorption area to reflect the real surface area of electrodes were 49.7 and 51.7 $m^2\ g^{-1}_{Pd}$ for Pd and PdCo, respectively [12]. Here, the catalysts assembled by NCs with big specific surface area and their unique spongy-network nature could enlarge the effective contact

area (ECA) and provide more active sites. On the other hand, in the anodic scan of the higher-potential region, the Pd surface oxidation could be seen at +0.55 V in forward scan and the reduction of Pd oxides (PdO) appeared at about +0.5 V in the reverse scan. It was noticed that PdCo NCs reduction peak potentials was shifted more positively than the Pd NCs, which indicated that the oxidized PdCo NCs was reduced more effortlessly. So the CVs results suggested that PdCo NCs showed a more "noble" metal character than Pd NCs.

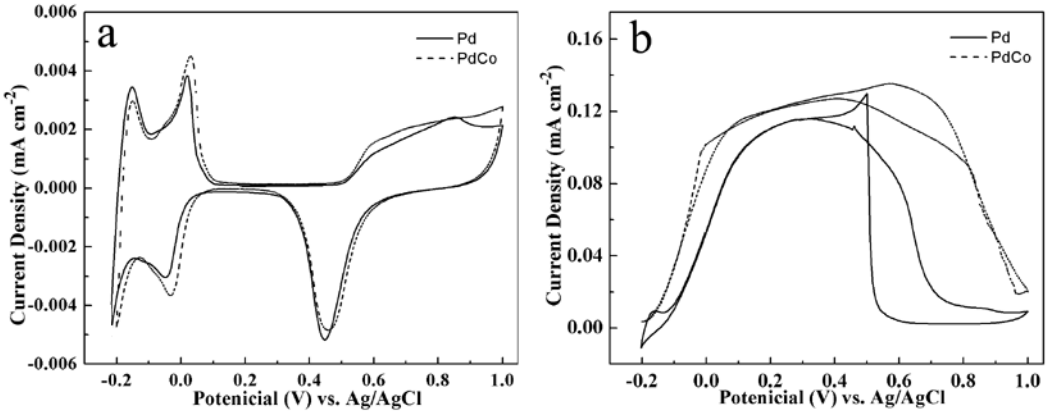

Fig. 4. CVs in N_2 Saturated 0.5 M H_2SO_4 (a) and Specific Activities (b) in 0.5 M H_2SO_4 + 0.5 M HCOOH of the As-prepared Pd and PdCo NCs

Fig. 4b reveals the responses of above-mentioned NCs catalyzing FAO and the current densities were obtained by normalizing the currents to the ECSAs (specific activities). It was observed that in the forward scan, there was a high I_p appeared near 0.3 V (the direct oxidation of formic acid to form CO_2) and a shoulder I_p near 0.6 V (the formation of intermediate CO generated from the dissociative adsorption step) [13]. The I_p of PdCo was 0.125 mA cm^{-2} which was higher than Pd (0.115 mA cm^{-2}), and its peak potential related appeared at -0.2V which was lower than Pd (-0.1V). The meaningful higher I_p of the first peak and much broader contour indicated the preferable catalytic activity to FAO and significant tolerance to CO poisoning [14]. So the PdCo NCs was capable of more rapid HCOOH absorption and activation which leaded to a kinetically faster catalytic reaction. The CVs in FAO indicated that Co doped into Pd could improve the electro-catalytic activities of Pd catalyst.

Conclusions

In this paper, a new physical vapor method to prepare Pd-based NCs catalysts was developed. By the addition of Co, the cost of Pd catalysts was reduced, and the electro-catalytic activities of Pd were improved. The ECSA was increased from 49.7 m^2 g^{-1} to 51.7 m^2 g^{-1} and the I_p of catalyzing FAO was raised from 0.115 mA cm^{-2} to 0.125 mA cm^{-2} when about 12wt. % Co element was added. Therefore, the PVD exhibits a broad application prospect in synthesizing metal NCs for applications of electrochemical catalysis.

Keywords: core-shell polymerization; silsesquioxanes; polyacrylate; nanocomposite.

Abstract: The core-shell nanocomposite particles were prepared from acrylate monomers and octavinyl polyhedral oligomeric silsesquioxane (V-POSS) by emulsion polymerization. The structure and properties of emulsion and latex film were characterized by FT-IR, dynamic mechanical analysis (DMA) and TEM and laser particle diameter analyzer (LPDA). The results showed that the V-POSS/polyacrylated (V-POSS/PMA) composite latexes was prepared and the diameter is about 36.1 nm when added 5wt% V-POSS. DMA results showed that the mechanical loss (tanδ) peak temperature (T_p) of the film enhance with increasing V-POSS content and had the best high T_p at 88.4^{o}C for added 7 wt% V-POSS, which increased 7.8 ^{o}C than had not V-POSS. Thermogravimetric analysis (TGA) showed that the addition of V-POSS can increase the thermal decomposition temperature and improved the thermal stability of polyacrylate.

Introduction

Organic-inorganic hybrid nanocomposite materials have been regarded as a new generation of high performance materials; they combine the advantages of both inorganic materials (rigidity, high thermal stability) and organic polymers (flexibility, electric insulation properties, ductility and processibility). Polyhedral oligomeric silsesquioxanes (POSS) are a relatively new type of organic-inorganic hybrid molecules. Polyhedral oligomeric silsesquioxane (POSS) are generally synthesized through the hydrolytic condensation of organotrialkoxysilanes, RSi(OR')3. POSS has a -Si-O-Si- nanostructured inorganic framework with diameters ranging between 1 and 3 nm as the core and reactive or non-reactive functional groups around the framework. The reactive functional groups on the POSS not only can further form homopolymers of the POSS, and can also be incorporated into copolymers via chemical reaction and physical blending [1-4].

Polymethacrylates are known as one of the most common commercial polymers, which had extensive applications in our daily life, for example latex coating. However, some shortcomings of these materials are relatively low glass transition temperature and poor thermal stabilities. In view of these considerations, a lot of effort has been dedicated to preparing the organic-inorganic hybrid materials with improved properties. Over the last decade, there are some reliable methods to synthesize POSS-PMMA composites to solve this problem [5,6].

In this paper, Octavinyl polyhedral oligomeric silsesquioxane (V-POSS) was synthesized through hydrolytic condensation of vinyltrimethoxysilane (CH_2=$CHSi(OCH_3)_3$), then the nano-dispersed V-POSS/PMA nanocomposite emulsion was prepared. The structure and thermal properties of emulsion and latex film were characterized through a variety of analysis methods.

Experimental section

Materials.

Vinyltrimethoxysilane was supplied by Shandong Qufu changing Chemical industry Co Ltd. 2,2,2-Trifluoroethyl Methacrylate (TFEMA) was supplied by Weihai New Era Chemical Co. Ltd. Tetramethylammonium, methyl methacrylate (MMA), methyl ethyl acrylate (EA), butyl acrylate (BA), and acrylic acid (AA), Potassium persulfate (KPS), sodium dodecyl benzene sulfonate (SDBS), isopropyl alcohol, methylbenzene, sodium chloride et al were all of analytical grade, and supplied by Tianjin Chemical Reagents Co. Octavinyl polyhedral oligoneric silsesquioxane (V-POSS) was synthesized according literature [7].

Synthesis of V-POSS.

Typically, 300 mL isopropyl alcohol, tetramethylammonium (1.053 g, 50% weight) and 10 mL deionized water were mixed in a four-necked flask, which was equipped with stirrer, dropping funnel, reflux condenser and thermometer, and then, the mixture of 30 g vinyltriethxoysilane and 50mL isopropyl alcohol was dropped slowly at 0~1 ^{o}C, he mixture was allowed to react for 24 hours at 18 ^{o}C and then isopropyl alcohol was evaporated, appropriate amount of methylbenzene was added in order to recrytallized the white power for another 4h and then cooled down to room temperature. The white crystallized power was filtered, washed with anhydrous ethanol, and vacuum dried. The yield was 82% and the epoxy value was 0.63 mol/100 g, which was closed to the theoretical value. ^{1}H-NMR (400 MHz, Bruker Co., Switzerland) and Liquid chromatography-mass spectrometry (LC/MS, Agilent 1100, Agilent Co. USA) was used for the determination of the components of the V-POSS and the detailed structure.

Synthesis of V-POSS/PMA nanocomposites emulsion.

The V-POSS/PMA latex was synthesized by using emulsion polymerization technique. The polymerization was carried out in a 100 mL four-necked glass flask fitted with a reflux condenser, stirrer, dropping funnel and thermometer. The synthesis of V-POSS/PMA which contain 1wt% V-POSS was synthesized as follow: deionized water (40 mL) and SDBS (0.471 g) were added into the flask with stirring. After the SDBS dissolved, the mixture of 0.260 g V-POSS and 10 g acrylate monomers were added with stirring quickly for 30 minutes. Then, the reaction vessel was heated to 75 ^{o}C, and then the KPS solution (0.021 g in deionized water 3 mL) as an initiator was added. The system was maintained at 75 ^{o}C for 1 h and then the rest mixture of acrylic ester monomers (MMA BA, EA and AA, total 15 g) was dropped in 1h, and adjusted to 8.0-8.5 pH with sodium carbonate, then the reaction system was heated to 80 ^{o}C and rested for another 1 h. After that, and the 5 g mixture of TFEMA and MMA was dropped in 1 h and reacted for 1 h again, then cooled down to room temperature. Finally, the fluorine-containing V-POSS/PMA nanocomposite emulsion was obtained. With the same method, the emulsion which contain 1, 3, 5, 7 and 9 wt% V-POSS was synthesized, and labeled as (b), (c), (d), (g) and (f), respectively. For comparison, the pure polyacrylate emulsion was synthesized and labeled as (a).

Testing and characterization.

Fourier transform infrared spectrometer (FTIR, FTS-40, BIO-RAD, USA) was used testing chemical reaction; Transmission electron microscope (TEM, JEM-100CX, JEOL, Japan) was used to determine the size and distribution of latex particle at 100 KV voltage and 0.14 nm resolution. The dynamic mechanical behavior of materials was characterized by dynamic mechanical analyzer (DMA, Q8000, Perkin-Elmer Co. USA). The particle diameter distribution of emulsion was determined by the laser particle diameter analyzer (LPDA, Delsa Nanoc, USA). Thermal stability of the specimens was characterized by thermogravimetric analysis (TGA, Pyris-6, Perkin-Elmer, USA) operated under 20 mL/min nitrogen flow rate. About 5mg powder of the specimens was introduced

into the thermobalance, and then heated from 30 to 500 ^{o}C at the heating rate of 5, 10, 15, 25 ^{o}C/min.

Results and discussion

Structure characterization of V-POSS and V-POSS/PMA.

Figure 1a shows the FTIR spectrum of V-POSS. In Fig. 1 (b) and (c), there is a strong absorption band at 1720 cm^{-1} which is attributed to the C=O stretching vibration, the C-H stretching vibration peak of vinyl group is located at 2941.65 cm^{-1}, the absorption band at 1118.94 cm^{-1} is the Si-O-Si stretching vibration band of POSS cage [8]. The FTIR spectra of all of the V-POSS/PMA composites are similar to that of the pure Polyacrylate, except that a symmetric absorption peak at 1118.94 cm^{-1}, which is the characteristic Si-O-Si stretching of silsesquioxane cages and the intensity increases with increasing POSS content.

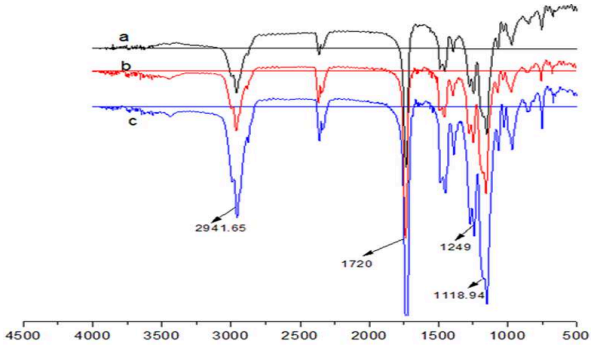

Fig.1 (a) FTIR spectra of pure PMA (b) 5 wt% V-POSS, (c) 9 wt% V-POSS

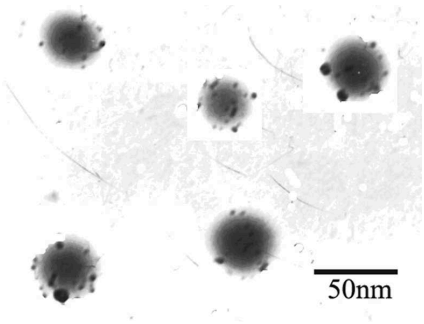

Fig. 2 TEM photograph of 5 wt% V-POSS/PMA

Figure 2 showed the TEM photograph of the 5% V-POSS/PMA latex, it can be seen that the particles are uniformly dispersed and with equirotal size of about 35 nm. Furthermore, the particles have core-shell morphology which was consisted with a copolymerized core of acrylate ester and V-POSS, and the fluorine-containing polymethacrylate shell was formed by copolymerization of TFEMA and MMA.

Particles diameter analysis of the emulsion

The effect of V-POSS/PMA on the average diameter and distribution of the composite latex particles is shown in Fig. 3. It can be seen that the diameter distribution of the composite latex with V-POSS is narrow as same as the emulsion No.0. The diameter of V-POSS/PMA and PMA is 36.1 nm and 32.9 nm respectively, the dispersing index of latex is 0.399 and 0.385, respectively. There is less difference of the average diameter between V-POSS/PMA and pure PMA. It is because that a core-shell synthesis procedure was carried out and V-POSS was packed in the core of the latex.

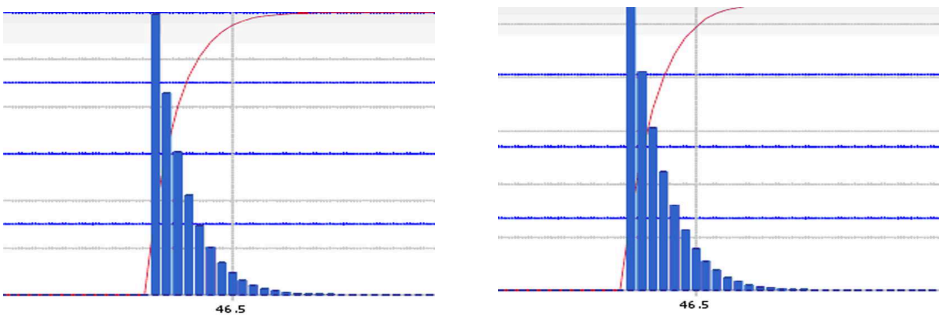

Fig.3 The diameter (nm) of composite latex particles. (a) pure PMA; (b) 5 % V-POSS/PMA

Dynamic mechanical analysis.

The glass transition temperature (T_g) may be used as a heat distortion parameter of the polymeric materials. Differential scanning calorimetry (DSC) is usually used to determine the T_g of polymers, but it is not the best method because the step in the DSC curve will be very little, inconspicuous and broadly at that time. Dynamic mechanical analysis (DMA) can be used to determine the maximal mechanical loss tanδ peak temperature (T_p) of polymers. The mechanical loss (tanδ) temperature values reflect the micro-Brownian movement of the macromolecular chain seqments. Generally, there is a one-to-one relationship between the T_g and the mechanical loss peak temperature, T_p, and the T_p is often designated as a T_g. The higher T_p, the higher T_g is, which depend on the molecular chain structure, cross-linking degree and material morphology [9].

Figure 4 shows the effect of different amount of V-POSS on the mechanical loss (tanδ) peak temperature (T_p) of coating film at a frequency of 1Hz. The Tp values of the copolymer with different V-POSS content is listed in Tab. 1. It can be observed that T_p of V-POSS/PMA increase with the increasing V-POSS content. When V-POSS content is 7 wt%, the T_p of coating film increase from 79.6 ^oC increase to 88.4 ^oC, and T_g reach the maximum value. This is because the vinyl group on the POSS reaction with acrylate monomers and increase the crosslink degree of Film. Therefore, the movement of molecular chain is blocked and become difficult, so the T_g increase. But T_g decrease with a further increase in the amount of V-POSS. The reasons are probably relative with the congregation of V-POSS and reaction one another when its content is higher than 7 wt%.

Tab.1 T_p values of polycrylate with various V-POSS content

V-POSS (wt%)	0 (a)	1 (b)	3 (c)	5 (d)	7 (e)	9 (f)
T_p(^oC)	79.6	83.4	86.8	86.7	88.4	84.5

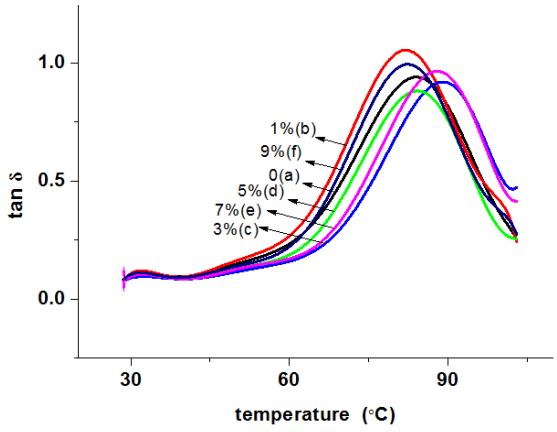

Fig. 4 DMA curves Of V-POSS/PMA

Thermal properties of V-POSS/PMA composites.

The thermal stability factors of the nanocomposites, including the initial decomposition temperature T_{id}, the temperature for mass loss of 50 wt% $T_{1/2}$, the temperature T_{md} of maximal weight loss rate. Figure 5 shows the TG curves of V-POSS/PMA composites and pure PMA with different mass samples which put in thermobalance. It can be seen from Fig. 5, all of the V-POSS/PMA nano-composites all display higher initial decomposition temperature T_{id} than the pure PMA. Figure 6 shows the initiative thermal decomposition T_{id} of the nano-composites for different V-POSS content. As seen from Fig. 6, the initiative thermal decomposition temperature T_{id} of the nano-composites is shifted to higher temperatures. When the content of V-POSS is 3 wt%, the T_{id} of the nano-composites increase about 5.5 ^oC than pure PMA; when the content of V-POSS is 9 wt%, the T_{id} increase about 19 ^oC than pure PMA. The results show that the addition of V-POSS can increase the initiative thermal decomposition temperature and improved the thermal stability of

polymethacrylate. This is because added V-POSS may increase the crosslinking density. The crosslinking density of the samples increases, the movement of molecular chain segment is limited, which is conducive to the glass transition temperature increase, and will reduce the diffusion of volatile components in the materials, so that it has also a higher thermal degradation than the pure PMA samples. The weight loss of samples at 200 to 400 ^{o}C is caused by the decomposition of polymethacrylate. The increase of residue rate after 400 ^{o}C is due to the presence of the V-POSS. The V-POSS contain the higher bond energy Si-O and Si-C bond and presence of inorganic structure similar to the SiO_2, under the high temperature it will form SiO_2 and SiC.

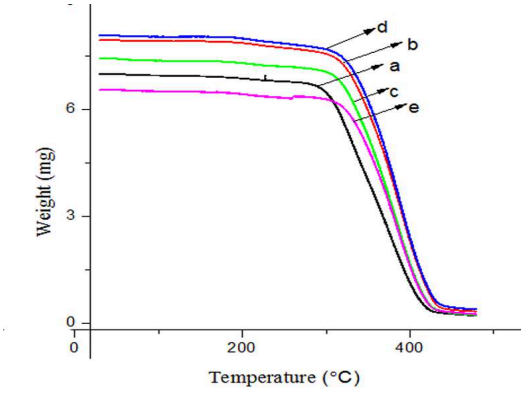

Fig.5 TGA thermograms of pure PMA (a),3~ 9% V-POSS/PMA composites (b,c,d,e)

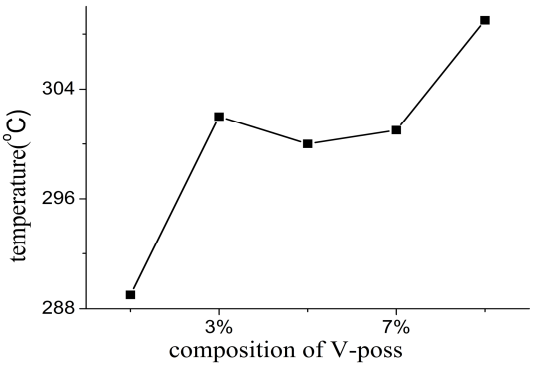

Fig.6 Initial thermal decomposition T_{id} of for the composites for different V-POSS content

Summary

The new fluorinated V-POSS/PMA core/shell nano-composite can be synthesized by using emulsion polymerization technique. The average particle diameter of core-shell latex for 5 wt% V-POSS content is bout 35nm and the dispersing index of latex is 0.399. The V-POSS can be increase the glass transition temperature (T_g) of the polyacrylates, when the content is 7 wt%, the T_g of the polyacrylate increase about 7.8 ^{o}C higher than pure polyarcylates. V-POSS can also increase the thermal decomposition temperature of the polyacrylates. When the content of V-POSS is 3 wt%, the T_{id} of the nano-composites increase about 5.5 ^{o}C than pure PMA; when the content of V-POSS is 9 wt%, the T_{id} increase about 19 ^{o}C than pure PMA.

Keywords: mesoporous zirconia, gold catalyst, azoxybenzene

Abstract. Gold nanoparticles supported on mesoporous ZrO_2 were prepared and their performance for the selective reductions of nitrobenzene to azoxybenzene was investigated. It was found that azoxybenzene could be successfully synthesized over these catalysts. Furthermore, the catalytic activity of catalysts is dependent on the pore size of catalyst. The catalyst Au/ZrO_2-PEG-1000 with pore size of 2.2 showed higher activity than Au/ZrO_2-PEG-600 with pore size of 1.9nm.

Introduction

Azoxybenzenes are important intermediates in industrial chemistry, which could be used in the production of dyes, indicators and liquid crystals. However, only very few methods have been reported for the selective reduction of nitroarenes to azoxy compounds. The most convenient method for their synthesis is the reduction of nitroarenes, which may also lead to hydroxylamine, hydrazine, azobenzene, and eventually, to aniline. Furthermore, the used reagents in most of these reactions have some shortcomings such as toxicity, complex preparation, difficult preservation and serious pollution [1-4]. Therefore, it is significant to develop a more simplified and green process to synthesis azoxybenzene.

Gold nanoparticles（Au-NPs）have many important properties, such as they can absorb visible light intensely because of so-called surface plasmon resonance (SPR) effect； and absorb ultraviolet（UV light）causing an interband excitation of electron in the Au-NPs. Zhu's group have realized to use the light adsorption of Au-NPs for driving chemical reactions, such as reduction of nitroaromatic compounds, deoxygenation of epoxide to alkenes, reduction of ketones to alcohols and hydrogenation of azobenzene to hydroazobenzene under visible or ultraviolet irradiation. They found that the light adsorption by the Au-NPs could activate the organic molecules then induce oxidation or reduction of the organic compounds. Therefore, these reactions on gold catalysts driven by light were realized at ambient temperature [5-8].

The mesoporous materials have attracted considerable attention because of their remarkably large surface areas and narrow pore size distribution, which make them ideal candidates for catalysts. It is anticipated that the use of a high surface area mesoporous ZrO_2 rather than a commercial low surface area ZrO_2 as support for gold catalysts might have some beneficial effect on the catalytic performance. Therefore, in this work, we present the study of azoxybenzene synthesis over Au-NPs supported on mesoporous ZrO_2.

Experimental

Preparation of Support

The ZrO_2 was prepared by the sol gel method with different surfactant, such as PEG-600 and PEG-1000 as structure template. The $ZrOCl_2$ solution was dropped into the surfactant solution under stirring with the final molar ratio of ZrO_2/PEG/H_2O =1/1/100. Then 1mol.L^{-1}NaOH was dropped into

the system to keep the pH of 8. After being dried at 90°C for 10h, the gel was obtained. The gel was washed with deionized water thoroughly, later dried at 80°C. Finally, the ZrO_2 was obtained after the calcination at 400°C for 2h. The ZrO_2 from different surfactant was denoted as ZrO_2-PEG-600 and ZrO_2-PEG-1000, respectively.

Preparation of Catalyst

Synthesis of catalysts was used reduction method. In the procedure of reduction method, a solution of 2.43×10^{-3}mol·L^{-1} $HAuCl_4\cdot3H_2O$ (80mL) was added to a suspension of 1.25g of the ZrO_2 supports in 50mL water, then Lysine (0.1 mol·L^{-1}, 20 mL) was added to the mixture with good stirring for 30 min. An aqueous solution of $NaBH_4$ (0.35 mol·L^{-1}, 10 mL) was added gradually within 10 min to the suspension, followed by hydrochloric acid (0.3 mol·L^{-1}, 15 mL). The mixture was left to stand for 24 h and then the solid was separated, washed with water and ethanol. After drying at 353K, 3 wt % Au/ ZrO_2 catalysts were obtained.

Catalyst Characterization

Specific surface area (BET) and pore structure were obtained on ASPA-2020 by American Micromeritics Company. The sample was vacuumed at 393K for 2h, and then began static nitrogen adsorption at 77K (liquid nitrogen). X-ray diffraction (XRD) was obtained on a Philips PW1830 diffractometer using Cu-Kα radiation (λ=0.15405 nm), operating at 40 kV and 40 mA. Profiles were recorded at 0.05°/s.

Catalytic Activity

The reactions were conducted in a one-mouth flask which contained 3 mmol of nitrobenzene, 30mL isopropyl alcohol, a solution of KOH in isopropyl alcohol (10mL, 0.1mol·L^{-1}), and 100mg catalysts. The reactions were conducted in an argon atmosphere at temperature of 333K and illuminated with incandescent light under stirring unless other specified. The resulting products were analyzed using Shimadzu GC-2014 GC with Rtx-5 column. The conversion of nitrobenzene, selectivity of azoxybenzene and azobenzene were determined by the following expressions:

$$C_{nitro} = \frac{amount\ of\ nitrobenzene\ consumed}{initial\ amount\ of\ nitrobenzene} . \quad (1)$$

$$S_{azoxy} = \frac{formation\ of\ azoxybenze\ ne}{total\ conversion\ of\ nitrobenze\ ne} . \quad (2)$$

$$S_{azo} = \frac{formation\ of\ azoxybenze\ ne}{total\ conversion\ of\ nitrobenze\ ne} . \quad (3)$$

Results and Discussion

Characterization Results

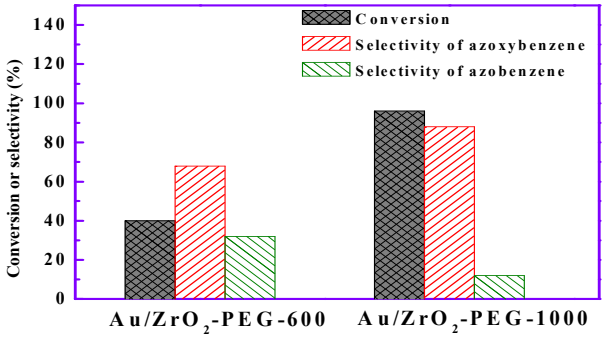

Figure 1 The Activity of Catalysts

The effect of support on the catalyst activity got at the reaction time of 3 h was presented in Fig. 1. Both ZrO_2-PEG-600 and ZrO_2-PEG-1000 supports showed imperceptible activity for the reduction in the comparison experiment. The addition of gold significantly increased the catalytic activity of the samples. From figure 1, it was observed that the property of support affected the performance of catalysts. Over the catalyst Au/ZrO_2-PEG-600, the conversion was 40% and the selectivity of azoxybenzene was about 68%. However, over Au/ZrO_2-PEG-1000, the selectivity of azoxybenzene reached 88% under the conversion of 96%. These results demonstrated that gold NPs supported on mesoporous ZrO_2 exhibited high activity for the synthesis of azoxybenzene under visible light irradiation.

TABLE.1.THE SURFACE AREA, PORE VOLUME AND PORE SIZE OF ZRO_2

support	BET surface S (m^2/g)	Pore Size nm	Catalysts	BET surface S (m^2/g)	Pore Size nm
ZrO_2-PEG-600	233	3.3	Au/ZrO_2-PEG-600	175	1.9
ZrO_2-PEG-1000	163	5.6	Au/ZrO_2-PEG-1000	115	2.2

In order to analysis the difference in the activity, the BET specific surface area, pore sizes and pore volumes based on the nitrogen adsorption/desorption isotherms were summarized in table 1. Both the ZrO_2 supports exhibited typical mesoporous structure. With the introducing of gold species, the decrease in surface area and pore diameter was observed. The pore size decreased from 5.6nm of ZrO_2-PEG-1000 to 2.2nm of Au/ZrO_2-PEG-1000 catalyst. This result indicated that part of gold particles existed inside the pore and the aggregation of gold particles could be hindered, which could result in the high performance of Au/ZrO_2-PEG-1000 catalyst.

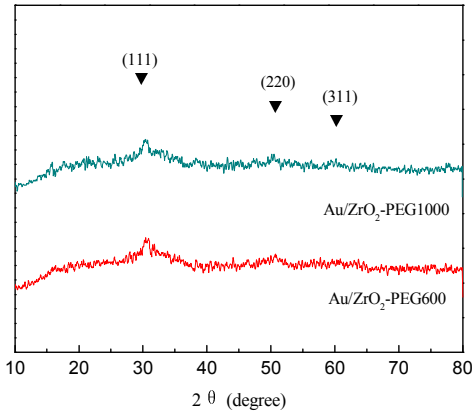

Figure 2 The XRD Patterns of Au/ZrO_2

The XRD patterns of Au/ZrO_2-PEG-1000 and Au/ZrO_2-PEG-600 were demonstrated in Fig. 2. The characteristic diffraction peaks at 30.16°, 50.60° and 66.26° verified that these supports existed in tetragonal phase. The absence of gold characteristic diffraction peak implied that the good dispersion of gold on the support.

Summary

Nanoparticle gold catalysts loaded on the ZrO_2 with different pore structure were prepared. The selective reductions of nitrobenzene to azoxybenzene were realized over these catalysts. The results demonstrated that pore size of support has effects on the activity of catalysts. Au/ZrO_2-PEG-1000 catalyst with 5 nm aperture on support prepared by non-ionic surface active agent PEG-1000 showed high activity for the reaction. The conversion of nitrobenzene reached 96% and the selectivity of azoxybenzene reached 88%.

Keywords: WO_3 nanoplates; hydrothermal synthesis; Photocatalytic activity; RhB

Abstract: The orthorhombic WO_3 nanoplates were fabricated *via* a hydrothermal process, using HBF_4 as the acid source. They were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), and UV-vis diffused reflectance spectroscopy (UV-Vis DRS), respectively. The WO_3 nanoplates exhibited nice UV-light driven photocatalytic performance in the degradation of Rhodamine B (RhB).

Introduction

Semiconductor photocatalysts play a significant role in the measures against energy shortage and environmental pollution. Nanostructure WO_3, with a band gap of 2.5-2.8 eV, mainly absorbed less than or equal to the wavelength of 443 nm and possesses a wide band of light absorption and light stability. Due to tungsten oxide is a versatile material, it has drawn considerable attention in these fields, such as gas sensing materials[1–3], photoluminescent[4,5] and photocatalysis[6,7]. Owing to the intriguing physiochemical properties and widespread potential applications, WO_3 has received much attention in the past few decades. Hence, people in climbing numbers pursue the synthesis of the tungsten oxide with different functions. Currently, there are many kinds of WO_3 nanomaterials. N. Le Houx showed that WO_3 nanoparticles in the 5-30 nm range have been prepared by solvothermal treatment of tungsten chloride in benzyl alcohol up to 210 ℃ followed by annealing in air[8]. Deliang Chen and Yoshiyuki Sugahara synthesized tungstate-based inorganic-organic hybrid nanobelts/nanotubes with lamellar mesostructures[9]. Jinmin Wang reported the synthesis of uniform crystalline WO_3 nanorods and their assembly without any surfactants [10].

In the present work, we report that a facile approach to synthesize WO_3 nanoplates. The obtained samples were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDX) and UV-visible diffuse reflectance spectra (UV-Vis DRS), respectively. The WO_3 nanoplates exhibited nice UV-light driven photocatalytic performance in the degradation of Rhodamine B (RhB).

Experimental

Photocatalyst preparation

All the chemicals were of analytical grade and used without further purification. A typical synthesis process for the WO_3 nanoplates were as follows: 0.005 mol $Na_2WO_4 \cdot 2H_2O$ was added into 32 mL 40% HBF_4 (0.5 M) aqueous solution while stirring. After further agitating for 1h, the yellow solution was migrated into a 50 mL Teflon-lined high-pressure reaction autoclave. The

autoclave was maintained at fixed temperature for several hours. Then the autoclave was naturally cooled to ambient temperature, and navy blue samples were collected after precipitation, washed several times with double-distilled water and absolute alcohol successively, and dried in an oven at 60 ℃ overnight.

Characterization

The XRD spectra was obtained with a Rigaku D/MAX-2000 diffractometer, using Cu Kr irradiation (λ=1.54056 Å) at 45 kV and 40 mA. The surface morphology of the samples was characterized by a JSM-7500F (JEOL Ltd, Japan) scanning electron microscope (SEM). In addition, UV-vis DRS was measured at room temperature with a UV-vis spectrometer (TU-1901; Beijing Purkinje General Instrument Co., Ltd, China).

Measurement of photocatalytic activities

The photocatalytic experiments were conducted to decompose RhB in photocatalyst aqueous suspension system, which were performed in an SGY-I photochemical reactor (Nanjing, Stonetech. EEC Ltd. Nanjing, China). A quartz cylinder (50 mm×450 mm) was placed inside the reactor and illuminated with a 300 W high-pressure mercury lamp. For each condition, WO_3 samples (0.200 g) were added into 200mL of RhB aqueous solution (10^{-5} mol·L^{-1}). Prior to irradiation, the solutions containing catalysts were stirred in the dark for 30 mins to ensure the establishment of an adsorption-desorption equilibrium between photocatalyst powders and RhB. The photocatalytic experiment was repeated under the identical reaction conditions to confirm the reproducibility. At given time intervals, 5 mL of aqueous suspension was taken from the quartz cylinder after specific intervals, centrifuged and filtered through 0.45 μm millipore filter to monitor the degradation of RhB dye. A UV spectrophotometer (UV-vis Cary50; Varian Co.) was used to monitor changes in the spectral intensity distribution of RhB.

Results and discussion

XRD analysis

XRD was used to investigate the phase and crystal structure of the products. And the XRD pattern for WO_3 prepared at different temperature is depicted in Fig. 1 (a). It was demonstrated that the crystal phase of all the products were orthorhombic. The curve a in Figure 1 (a) revealed that the crystal phase of WO_3 nanoparticles was orthorhombic structure with the diffraction peaks at about 2θ =23.1, 24.1, 28.8, 33.3, 34, 41.6, and 55.2°, which could be perfectly indexed to the (001), (200), (111), (021), (220) and (401) crystal faces of orthorhombic WO_3 (JCPDS No. 20-1324). No characteristic peaks for any other phases or impurities are observed, suggesting that the nanocrystal is composed of orthorhombic structure. It was worthwhile to note that the diffraction peaks of WO_3 at 160 ℃ in Fig. 1 (a) were sharp and intense, implying that the (001) diffraction peak of WO_3 at 160 ℃ possesses the maximum intensity and is in the best standard position (23.101°).

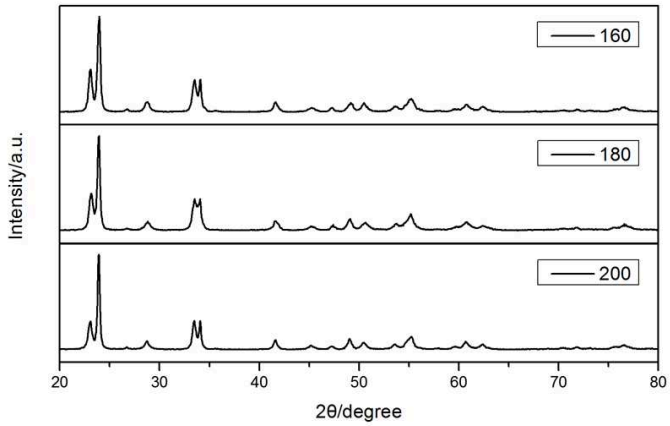

Fig. 1 (a) XRD patterns of the products synthesized at different temperature for 24 h

SEM analysis

The size and shape of the samples were further analyzed by SEM technique. The SEM images of WO_3 at different reaction conditions were exhibited in Fig. 2, which revealed the uniform nanosheets. The sizes of nanoplates decreased with the increase of the reaction temperature and increased with the increase of the reaction time. The illustration showed that the reaction time has a significant impact on controlling the growth and nucleation of tungsten oxide nanoplates. It is observed that the SEM images of specimen at 160 ℃ for 24 h existed the best morphology of cube sheets.

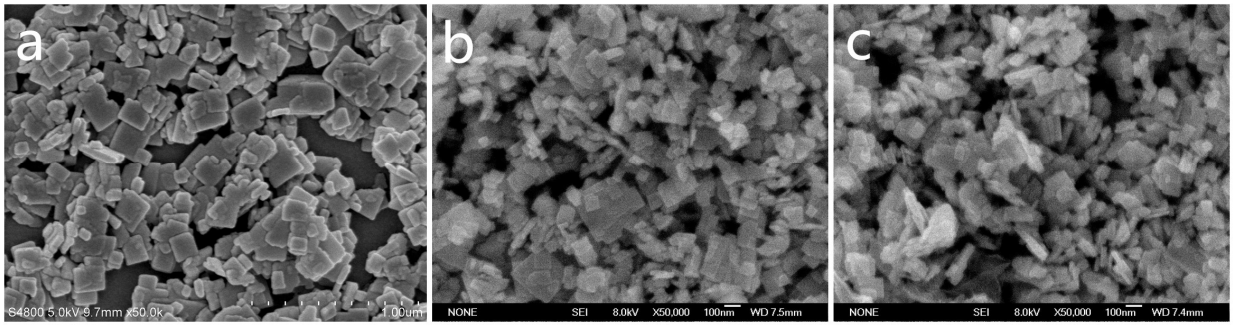

Fig. 2 SEM images of the products synthesized at reaction conditions: (a) 160 ℃ for 24 h, (b) 180 ℃ for 24 h, (c) 200 ℃ for 24 h.

UV-vis DRS analysis

The energy band structure has an influence on optical absorption property of a semiconductor. The photocatalytic activity of a semiconductor is up to this key factor. The optical absorption edge and the energy gap can be calculated via UV-Vis absorption spectrum. The UV/Vis diffuse reflectance spectra (DRS) were present in Figure 3. It indicated that the all the products exhibited strong photoabsorption in both UV and visible light area. The absorption edge can be got by the perpendicular to the abscissa axis from the point of intersection of the two tangent lines from the absorption spectrum. As it was seen in Fig. 3, WO_3 nanosheets at different conditions (160℃-24h, 180-24h and 200-24h ℃) had absorption edges at about 440 nm, 430 nm and 418 nm, which were all in the visible region (400 ~ 750 nm), and the absorption edges have shift to the long wavelength. However, it is contrary to energy gap. The E_g of the WO_3 semiconductor could be obtained by using the equation (Eq. 1):

$$\alpha hv = A(hv - E_g)^{n/2} \quad (1)$$

Where α is the absorption coefficient, hv is the discrete photon energy, and A is a constant relative to the material, and E_g is the absorption band gap, respectively. Assuming the absorption coefficient α is proportional to the Kubelka-Munk function $F(R)$, the E_g can be obtained from the plot of $[F(R)hv]^{1/n}$ *versus* hv, by extrapolation of the linear part near the onset of the absorption edge to intersect the energy axis. The energy gaps of the materials at different temperature (160, 180 and 200 ℃) for 24 hours were 2.81 eV, 2.88 eV and 2.96 eV, respectively. The band gap for WO_3 nanoplate at 160 ℃ for 24 hours was the smallest (2.81 eV). It is indicated that the photocatalyst WO_3 could exhibit photocatalytic activity under the solar light irradiation.

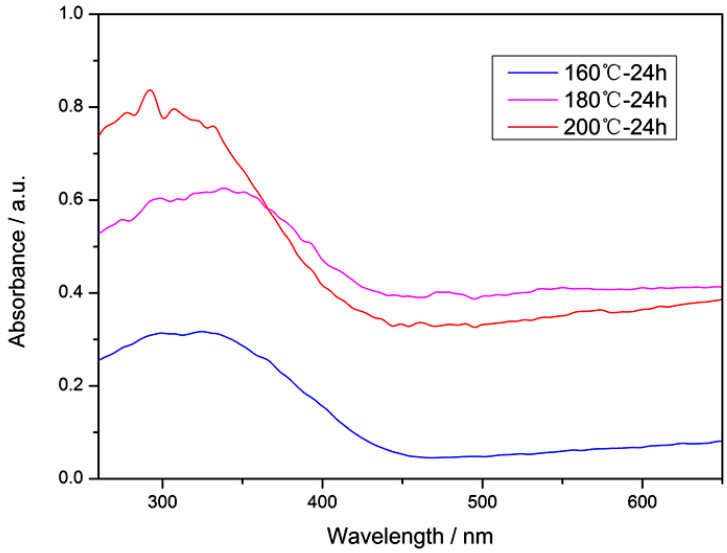

Fig. 3 UV-vis absorption spectra of the WO_3 nanocrystals

Photocatalytic activity

The photocatalytic activity of catalysts were evaluated by measuring the degradation on RhB under UV-light irradiation at room temperature. The photodegradation reaction with samples obtained from different experimental conditions. It indicated that there were obvious photocatalytic activities under irradiation for all specimens. There were evidently photocatalytic activities under UV-light irradiation for WO_3 photocatalyst. According to Fig. 4, the order of photocatalytic activity of the WO_3 nanocrystals was as following: 160-24 > 180-24 > 200-24.

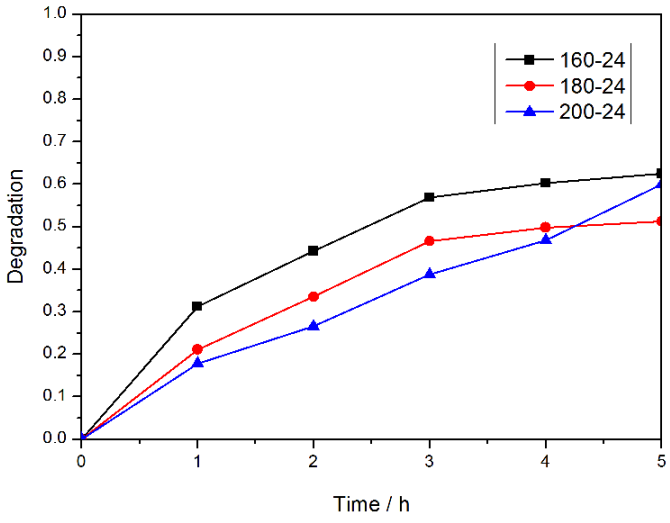

Fig. 4 Photocatalytic activity of Rhodamine B Photocatalysts under UV-light irradiation

Summary

In summary, a series of WO_3 nanoplates were prepared *via* a hydrothermal process, using HBF_4 as the acid source and structure-directing guiding agent. The products were characterized by XRD, SEM, DRS, respectively. The experimental photocatalytic degradation of RhB observations indicated that the as-prepared WO_3 photocatalysts exhibited powerful photocatalytic performance under UV-light irradiation.

Keywords: CeO_2, nanocatalysts, automotive exhaust clean-up, hydrothermal synthesis, transmission electron microscopy.

Abstract. We report a facile hydrothermal synthesis in base solution for shape/size-controlled ceria (CeO_2) nanocrystals and CeO_2-ZrO_2 solid solution. CeO_2 nanocrystals in the shape of nanorods, nanotubes, or nanocubes with reactive {110} and {200} faces can be produced using this hydrothermal method. We found that hydrothermal reaction temperature is a critical parameter to control the shape and size of ceria nanocrystals. Above 210 ^oC, high resolution transmission electron microscopy studies revealed that the CeO_2 nanocubes expose predominant {200} crystal planes. Microscopic investigation showed that the CeO_2-ZrO_2 solid solutions synthesized using this method had high crystallinity, and compositional homogeneity, and improved low-temperature reducibility.

Introduction

Synthesizing highly reactive and selective catalysts has been an intriguing and challenging goal in heterogeneous catalysis. Ceria (cerium oxide or CeO_2) along with a few other related oxides constitute an important class of catalysts that can rapidly pick up or release molecular oxygen ($2CeO_2 \leftrightarrow Ce_2O_3+1/2O_2$) under variable reducing and oxidizing conditions, mainly by way of a reversible change of the oxidation state of the cerium ions in combination with formation or elimination of oxygen vacancies [1-10].

As for all heterogeneous catalysis processes, surfaces play a crucial role for catalytic applications involving ceria as the active species. Several theoretical studies have investigated the structure and relative stability of the surfaces of CeO_2 crystals, and the results have indicated that the compact {111} surfaces are the most stable (and are therefore the least reactive), followed by {110}, {100}, and {211} [11-13]. It has recently been reported that materials with a 1 D-like morphology, specifically if they are prepared to predominantly expose {110} and {100} surfaces, have a higher catalytic activity in CO oxidation than conventionally prepared CeO_2 particles with exposed {111} surfaces [14-15]. The generation of nanostructured ceria particles in shapes other than octahedrons, such as e.g. nanorods, nanotubes, or nanocubes, may present an opportunity for the synthesis of low-temperature catalytically active materials with more reactive surfaces such as {110}, {100}, {211} etc. accessible on the crystal surface. In this report, we describe the preparation of shape/size controlled CeO_2 nanocrytals and compositionally homogeneous CeO_2-ZrO_2 solid solution using a facile hydrothermal method in base solution. Additionally, we discuss the thermal stability of as-synthesized CeO_2-ZrO_2 solution under reducing atmosphere.

Experimental Section

Pure CeO_2 and CeO_2-ZrO_2 nanopowders were prepared by hydrothermal method in a base solution. In a typical procedure, 0.1 M $Ce(NO_3)_3$ and 0.1 M $Zr(NO_3)_3$ solutions were prepared by dissolving $Ce(NO_3)_3 \cdot 6H_2O$ and $ZrO(NO_3)_2 \cdot xH_2O$, respectively, into 200 mL distilled water, while 6 M NaOH was prepared by dissolving 48 g of NaOH into 200 mL of distilled water. As far as pure CeO_2 is concerned, the reaction mixture containing 55 mL of 0.1M $Ce(NO_3)_3$ and 5 mL of 6 M NaOH

was prepared, after which the reaction mixture was stirred vigorously for 20 minutes before loading it into the autoclave. The sampele was hydrothermally treated at 150 ^{o}C for 48 hours. On the other hand, $Ce_{0.5}Zr_{0.5}O_2$ nanopowders were synthesized in the same manner as described above except that for each reaction setup, 22.5 mL of 0.1 M $Ce(NO_3)_3$ and 22.5 mL of 0.1 M $ZrO(NO_3)_2$ solutions were thoroughly mixed together first before 5 mL of 6 M NaOH were added to the mixtures. The reaction mixture was stirred vigorously for 40 minutes. The mixtures were then poured into sealed 100 mL Teflon lined autoclaves and hydrothermally treated at 50 ^{o}C and 150 °C for 48 hours, repectively. The vessels were then cooled to room temperature. Final precipitates were then filtered and thoroughly washed with 500 mL of distilled water and 200 mL of ethanol, then dried at 40 °C for 12 hours. High-temperature reduction treatment was carried out in a tube furnace at different temperatures (900^{o}C-1100^{o}C) for 3 hours with a carrier-gas of 4%H_2/96%He mixture.

Powder X-ray diffraction (XRD) analysis was done using the Rigaku Miniflex II Desktop X-ray Diffractometer applying a scanning range of 10 to 90^{o}. Transmission electron microscopy (TEM) was performed using a JEOL 2100 that was operated at 200 kV. For the electron energy loss spectroscopy (EELS) analysis, we used the Ce $M_{4,5}$ integrated white line at 883 and 901 eV to determine the Ce oxidation state in individual nanoparticles. To avoid the electron beam damage, weak-beam technique with wide spread beam and selected area aperture were used to get the EELS spectra from individual nanoparticles in diffraction mode. Isolated nanoparticles hanging in the vacuum without overlap were selected for EELS analysis. BET surface area analysis was performed on the dry nanopowders at -196 ^{o}C using liquid nitrogen. All the samples were pretreated for 1 hour at 110 ^{o}C using helium gas before surface area measurements were conducted. Hydrogen temperature programmed reduction (H_2-TPR) experiments were performed on the samples immediately after BET surface area analysis. Both H_2-TPR and BET surface area experiments were performed in a Micromeritics AutoChem^{TM} II 2920.

Results and Discussion

Synthesis of Pure CeO_2

Figure 1 shows the typical transmission electron microscopy (TEM) images of the particles collected after a hydrothermal reaction at different temperatures (a: 70^{o}C; b: 130^{o}C; c: 210^{o}C; d: 230^{o}C). A change of the nanoparticle morphology from nanorods to nanocubes with increasing temperature of the hydrothermal reaction is clearly evident. We found that hydrothermal reaction temperature is a critical parameter to control the shape and size of ceria nanocrystals in a base solution. Initially, OH^- was introduced in Ce^{3+} aqueous solution, reacted with Ce^{3+} and formed $Ce(OH)_3$. The separated colloidal $Ce(OH)_3$ clusters in solution will act as nuclei for the growth of nanostructure during the hydrothermal growth process. At low temperature, the anisotropic growth of $Ce(OH)_3$ is favored and rod-like morphology is obtained. As the hydrothermal reaction temperature increases, the $Ce(OH)_3$ becomes unstable and starts to oxidize into CeO_2. Fine CeO_2 nuclei form spontaneously nanocubes or nanocuboids in the aqueous solution.

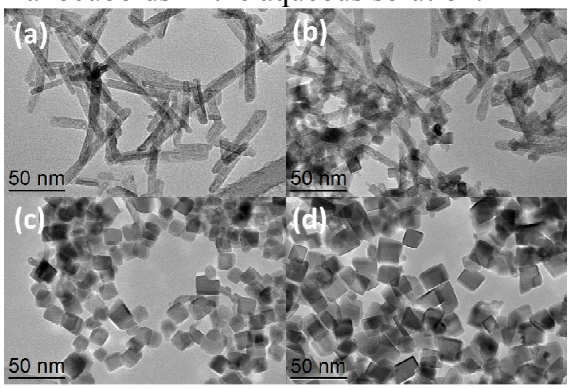

Fig 1. Some Typical Morphologies Of Ceo_2 Nanoparticles Prepared By A Facile Hydrothermal Method At Different Temperatures: (a): 70°C; (b): 130°C; (c): 210°C; (d): 230°C.

To have a better understanding of surface facets, a detailed high resolution transmission electron microscopy (HRTEM) characterization was carried out, shown in Figure 2, and HRTEM studies reveal that the CeO_2 nanocube exposes predominant {200} crystal planes.

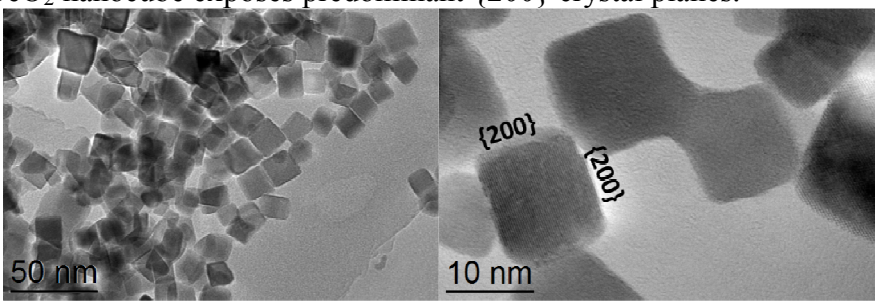

Fig 2. Low-magnification and Atomic-Level Tem Images Of Individual Ceria Nanocubes Prepared By Hydrothermal Method at 210 ^{o}C.

Synthesis of CeO_2-ZrO_2 Solid Solution

The strategy of hydrothermal synthesis was extended from pure CeO_2 to mixed cerium-based oxides as the mixed oxides present better low-temperature reducibility and superior thermal stability, compared to pure ceria [16]. In catalytic applications, a typical example of cerium-based mixed oxide is CeO_2-ZrO_2, used in commercial automotive three-way catalytic converters for its superior thermal stability and low-temperature oxygen storage capacity (OSC).

As shown in Figure 3, X-ray diffraction (XRD) data suggests that such mixed CeO_2-ZrO_2 oxides are solid solution, rather than composed of a mixture of CeO_2 and ZrO_2. For the $Ce_{0.5}Zr_{0.5}O_2$ solid solutions, the XRD lines are rather similar to those corresponding to pure ceria (face-centered cubic and fluorite structure, JCPDS 34-0394). It is clearly shown in Figure 3, that there is a shift of the XRD peaks toward higher angle for the $Ce_{0.5}Zr_{0.5}O_2$ solid solution samples. This is due to substitution of smaller Zr ion (ionic radius for Zr^{4+}: 0.84Å) for Ce (ionic radius for Ce^{4+}: 0.97Å) in the cubic ceria matrix. In addition, compared to ceria XRD peaks, the $Ce_{0.5}Zr_{0.5}O_2$ peaks are much broader. The peak widths for the sample prepared at 50 ^{o}C are broader than the sample prepared at 150 ^{o}C, indicating a better crystallinity for the sample synthesized at a higher hydrothermal reaction temperature. Since the peak widths are related to the crystalline size (without considering the strain effects) this data suggests that $Ce_{0.5}Zr_{0.5}O_2$ solid solution has a smaller crystalline size than that of pure ceria, and the $Ce_{0.5}Zr_{0.5}O_2$ sample prepared at 50 ^{o}C has a smaller crystalline szie compared with the sample prepared at 150 ^{o}C. This result is consistent with the observations of others. For examples, Sergent et al [17] found that the line widths increased with the Zr content to reach a maximum for the $Zr_{0.5}Ce_{0.5}O_2$ sample and subsequently decreased again. Their results are also in qualitative agreement with specific area data, where a maximum is obtained for the $Zr_{0.5}Ce_{0.5}O_2$ sample [17-18].

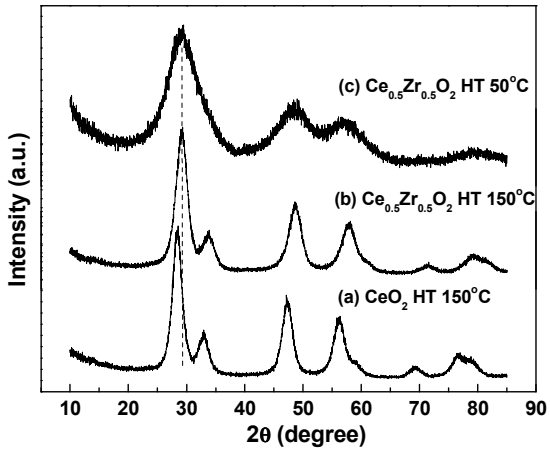

Fig3. XRD Patterns For As-Prepared Pure Ceo_2 At 150 ^{o}c And $Ce_{0.5}zr_{0.5}o_2$ Solid Solution Nanopowders Prepared At 50 ^{o}c and 150 ^{o}c using hydrothermal method. The dash line indicates the peak shift due to the doping of smaller zr ion (Zr^{4+}: 0.84 Å) In CeO_2 Lattice (Ce^{4+}: 0.97 Å).

For the catalytic redox application of cerium-based oxides, the oxygen exchange is restricted to the surface of the oxide nanoparticles. A high surface area of materials is a necessary requisite for catalyst application to maximize the gas-solid contact under reaction conditions. So we measured the BET surface areas of the CeO_2 and $Ce_{0.5}Zr_{0.5}O_2$ samples. The results are shown in Table 1. It is clear that $Ce_{0.5}Zr_{0.5}O_2$ samples have a higher surface area compared with the pure CeO_2 sample.

TABLE 1. COMPARISON OF BET SURFACE AREA OF THE CEO_2 AND $CE_{0.5}ZR_{0.5}O_2$ SAMPLES

Sample name	BET surface area
CeO_2 (150 ^oC)	111.0 m^2/g
$Ce_{0.5}Zr_{0.5}O_2$ (150 ^oC)	149.4 m^2/g
$Ce_{0.5}Zr_{0.5}O_2$ (50 ^oC)	159.8 m^2/g

Reactivity and Thermal Stability of CeO_2-ZrO_2 under Reducing Atmosphere

The reactivity of lattice oxygen in the CeO_2 and $Ce_{0.5}Zr_{0.5}O_2$ samples towards H_2 was investigated by temperature programmed reduction (TPR) technique, shown in Figure 4. The TPR profile of CeO_2 shows the "two/three-peak" pattern due to surface (low temperature peaks), and bulk reduction (high temperature peak), respectively. For the $Ce_{0.5}Zr_{0.5}O_2$ samples, only one peak is observed, in agreement with the promotion of the reduction in the bulk of mixed oxide upon doping zirconia [1-3]. This suggests that reduction of the bulk lattice oxygen must occur simultaneously with the reduction of surface oxygen.

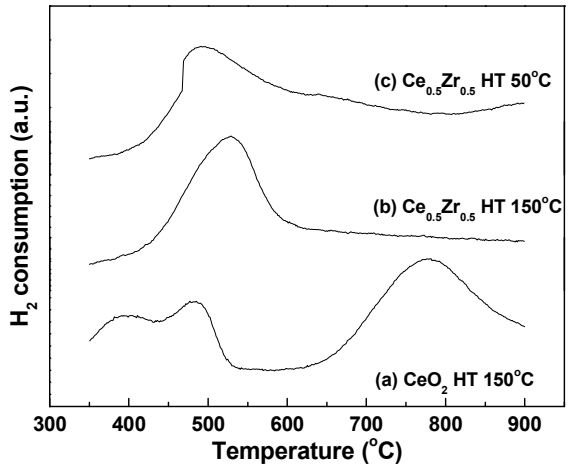

Fig 4. Temperature-programmed Redution (TPR) Profiles for Pure CeO_2 Prepared at 150 ^oC and $Ce_{0.5}Zr_{0.5}O_2$ Solid Solution Nanopowders Prepared at 50 ^oC and 150 ^oC Using Hydrothermal Method.

High temperature reduction treatments were found to favor the formation of highly active CeO_2-ZrO_2 materials [19-25]. However, there remain many questions about the role of compositional heterogeneity, cation ordering and oxygen vacancy ordering in the active component for redox reactions. Following powder synthesis, thermal treatments under reducing conditions were carried out to test the thermal stability of the CeO_2-ZrO_2 solid solution. Under a reducing atmosphere, we found that thermal treatments result in phase transformation, rather than phase separation, from fluorite structure (*Fm*3*m) to* cation-ordered pyrochlore-type superstructures (Fd-3m). Ordering of the Ce and Zr ions is clearly presented by the d-spacing doubling of the (111) peaks shown in the XRD patterns (Figure 5), which is consistent with our previous observation [9].

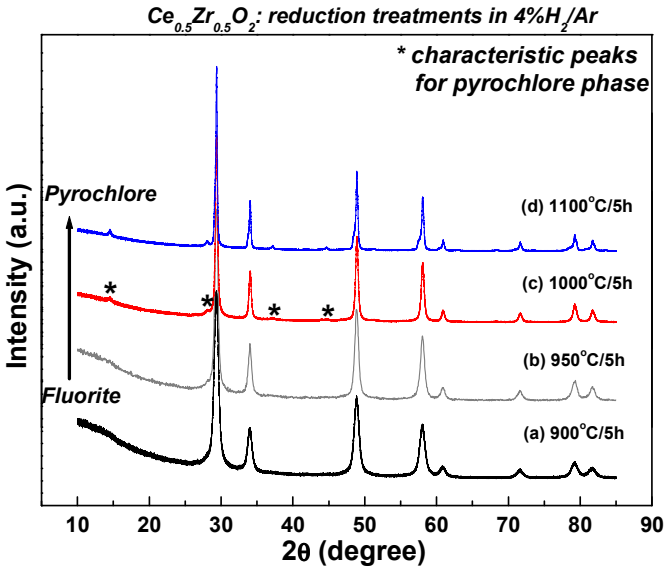

Fig 5. Phase Transformation From Fluorite To Pyrochlore Structure In Ce0.5zr0.5o2 During Thermal Treatments In Reduction Atmosphere.

Electron energy loss spectroscopy (EELS) was used to determine the Ce oxidation states for the $Ce_{0.5}Zr_{0.5}O_2$ nanoparticles in the samples before and after reduction treatments by analyzing the relative intensity of Ce $M_{4,5}$ edges. Analysis of Ce $M_{4,5}$ white line intensity ratio, obtained from EELS data indicates that the particles in raw materials is in +4 oxidation state and after reduction treatments the particles show a mixed +3/+4 oxidation states, showin in Figure 6. Statistical measurements obtained from at least 20 individual particles for each specimen. Figure 7 shows a schematic illustration of the structural transformation using $Ce_2Zr_2O_7$ unit cell and 2×2×2 CeO_2 super cell during the reduction treatment. The cation ordering along <110> is a distinguishing feature for the $Ce_2Zr_2O_7$ pyrochlore structure compared to the fluorite structure CeO_2 (Figure 7). This can be seen from the presence of pure Ce (blue), pure Zr (grey) and mixed Ce and Zr (blue/grey/blue/grey…) atom columns along <110> direction demonstrating that cation ordering is present.

Conclusions

In summary, we have developed a facile hydrothermal method in base solution to synthesiz CeO_2 and particularly CeO_2-ZrO_2 solid solution nanopowders, with a good control over particle shape and size. By controlling the crystallization process inspired from the formation of $Ce(OH)_3$ nanocrystals, the morphology could be tuned into different regular shapes such as nanorods, nanocuboids, and nanocubes. The compositionally homogeneous CeO_2-ZrO_2 solid solution nanopowders can also readily prepared. Reduction treatment of $Ce_{0.5}Zr_{0.5}O_2$ causes a phase transformation, instead of phase separation, from fluoride to pyrochlore structure, suggesting nanoscale compositionally homogeneity of particles. We envision that the synthesis process presented here can be extended to synthesize other cerium-based mixed oxides for use in low-temperature redox active materials in automobile catalytic converter, as well as for catalysis and sensor applications.

Key words: core/shell, magnetic, optical, composite, SiO_2 /$NaGdF_4$:Eu^{3+}

Abstract: The SiO_2/$NaGdF_4$:Eu^{3+} core/shell composite was prepared by a template -mediated method, making monodispersed SiO_2 as core and $NaGdF_4$:Eu colloids as shell, the morphology and the core-shell structure of the resulting particles were analyzed by SEM，X-ray diffraction, and the photo-luminescence and magnetic properties of the microspheres were investigated too. The results shows the composite have great potential to be used as homogeneous magnetic/optical bifunctional material.

Introdution

In recent years, there has been great interesting in developing nano/micro materials with controlled size, shape and structure.[1,2]It is well known that controlling the size, structure, and shape of inorganic nano/micro structures is of fundamental and technological importance because of the strong correlation between these parameters and their chemical/physical characteristics such as magnetic, luminescent and electronic properties.[3,4] Rare Earth (RE^{3+}) doped nano/micro materials have versatile utility in biological applications because of their unique electronic and optical properties based on the 4f electrons. They can be made either as luminescent, magetic or as dual model probe by selective doping lanthanide ions.[5]

$NaREF_4$, as a excellent down-conversion (DC) and up-conversion (UC) luminescent host material have aroused intensive research in the past decade owing to the very low phonon frequencies.[6,7] In particular, lanthanide ions (Ln^{3+}) doped Gd^{3+}-based rare earth fluorides are a category of multifunctional agents for multimodal bioimaging, because the optically active Ln^{3+} ions in the fluoride lattices contribute to luminescence(optical modality), and paramagnetic property of the Gd^{3+} can introduce magnetic resonance imaging (MRI) modality. Thus, some synthetic routes have been developed to prepare the nano/micro sized $NaGdF_4$, including thermal decomposition synthesis route[8], coprecipitation method[9], hydrothermal procedure[10] and so on. However, owing to the small size and the active surface of the $NaGdF_4$ nano/micro particles prepared without modification, they are unstable and easy to gather together. That will have serious impact on their application. In order to improve the stability of the $NaGdF_4$ particles, designing a

core-shell structure with spherical morphology is a efficient way.[11] Because of non-cytotoxic, chemically inert and optically transparent at visible wavelengths, silica-based materials have been the most general choice for preparing, modifying or functionalizing some desired objects and materials, but there are few reports on silica particles used as core.

In this work, core-shell $SiO_2/NaGdF_4:Eu^{3+}$ was prepared by coating of submicron SiO_2 spheres with $NaGdF_4:Eu^{3+}$ colloids and subsequent hydrothermal treatment. Stőber method[12] was selected to prepare silica submicrospheres because of their inexpensiveness, easiness to get spherical particles with narrow size distribution. Both magnetic and luminescent properties of the obtained $SiO_2/NaGdF_4:Eu^{3+}$ submicrospheres were investigated in detail.

Experimental

Equipment

The X-ray diffraction (XRD) of the powder samples was examined on a Rigaku-Dmax 2500 diffractometer using Cu Ka radiation (k = 0.15405 nm). The morphology of the product was measured by scanning electron microscopy(FEI Quanta200F), PL was examined with F4500 Fluorescent spectroscopy and Magnetic property measurements were carried out using a vibrating sample magnetometer (MPMS XL-7, -20 to 20kOe).

Materials

Gd_2O_3(99.99%), Eu_2O_3(99.99%), Citric acid (99.5%), tetraethyl orthosilicate (TEOS) (99.0 %), $RECl_3$ (RE=Gd and Eu) salts were freshly prepared by a reaction of RE_2O_3 with dilute hydrocholic acid. All other chemicals were analytical-grade reagents and used directly without further purification.

Synthesis of silica cores

The synthesis of highly monodisperse submicron SiO_2 spheres was carried out following the modified Stőber method, i.e. the hydrolysis of tetraethoxysilane (TEOS) in an ethanol solution containing water and ammonia. This method yielded the colloidal solution of silica particles with a narrow size distribution in the submicron range, and the particle size of silica depended on the relative concentration of the reactants. In a typical experiment, the mixture of 5 mL TEOS and 45 mL EtOH was poured into another mixture of 5 mL of NH_4OH (25 wt%) , 10ml deionized water and 35ml EtOH, then stirred at room temperature for 5 h, resulting in the formation of white silica colloidal suspension. The silica particles were centrifugally separated from the suspension and washed with ethanol for four times. In order to obtain SiO_2 sphere of different particle size, the amounts of used TEOS were changed, as shown in Table1.

Coating of SiO_2 Cores with $NaGdF_4:Eu^{3+}$Shells

SiO_2 core $NaGdF_4:Eu^{3+}$shell particles ($SiO_2/NaGdF_4:Eu^{3+}$) were prepared by the following process (Fig1). First of all, SiO_2 submicospheres were dispersed in $RECl_3$ (RE=Gd, Eu) solution, because of the -OH on the surface of the silica, the RE^{3+} ions were attracted onto the surface around of the silica core, then Sodium citrate solution as a chelating agent for the metal ions was added, the molar ratio of metal ions to citric acid was 1:2. After stirring for 30 minutes, NaF solution(10 times amount of the $LnCl_3$) was poured into the mixture, then this mixture was hydrothermal treated at 180℃ for 2h, and the core-shell particles were separated by centrifugation. For the purpose of comparison, the blank sample of $NaGdF_4:Eu^{3+}$ was prepared in a similar process.

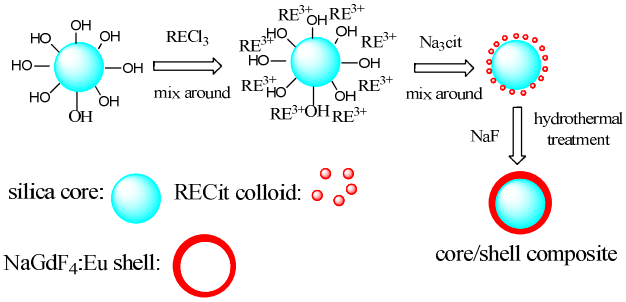

Fig.1. Formation process of $SiO_2/NaGdF_4:Eu^{3+}$

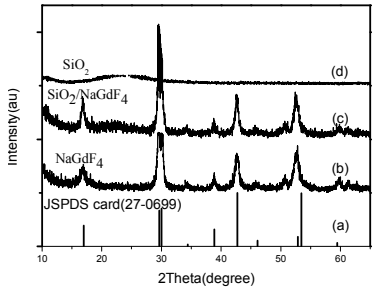

Fig.2. JSPDS card 27-0699 for β-$NaGdF_4$(a), core-shell particles and XRD patterns for pure $NaGdF_4$(b) core-shell $SiO_2/NaGdF_4$(c); pure SiO_2(d)

Results and discussion

XRD study

X-ray diffraction patterns of pure $NaGdF_4$(b), $SiO_2/NaGdF_4:Eu^{3+}$ core–shell samples (c), and bare silica spheres (d) are shown in Fig.2. In Fig.2a, the pure $NaGdF_4$ samples present several peaks that can be well indexed to hexagonal (β)-$NaGdF_4$ (JSPDS card no27-0699). For SiO_2 particles(Fig.2(d)), no diffraction peak is observed except for a broad band centered at 2θ=22.00°, which is the characteristic peak for amorphous SiO_2. For the $SiO_2/NaGdF_4:Eu^{3+}$ core–shell sample, the diffraction pattern (Fig.2(c)) consists of a broad band centered at 2θ= 22.00° and several sharp peaks, the former is due to part of amorphous SiO_2, and later is agreeing well with the XRD peaks of pure hexagonal (β)-$NaGdF_4$, no second phase was detected . The result shows that the $NaGdF_4:Eu^{3+}$ was successfully coated onto the surface of the SiO_2 core.

SEM measurements

Fig.3 shows the SEM images of the SiO_2 submicrospheres of different particle size which was obtained though changing the amount of TEOS and the SEM image of the $SiO_2/NaGdF_4:Eu^{3+}$ core/shell composite. It can be clearly observed that before coating, uniform and single-dispersed SiO_2 submicrospheres were formed, the size was changing with the amout of the TEOS which was shown in Tble 1. The diameter of the SiO_2 particles increased with the increase of the dosage of TEOS. In the Fig.3d there was obviously a thin lay onto the surface of the SiO_2 submicrospheres, that would be due to the coating of the $NaGdF_4:Eu^{3+}$ shell.

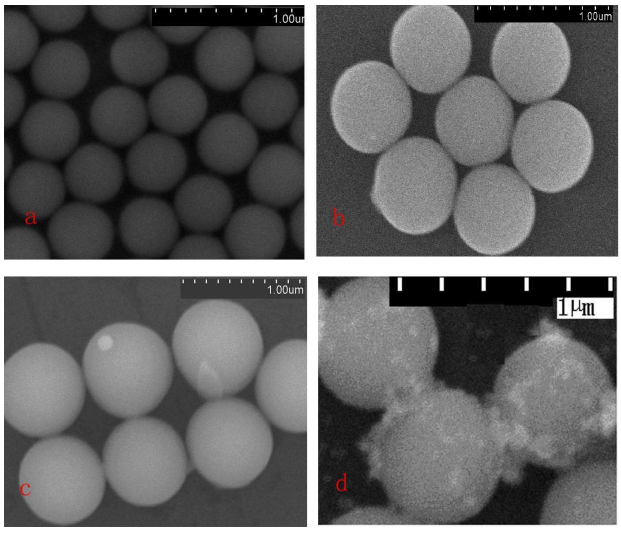

Fig.3 SEM images of SiO_2 submicrospheres of 400nm(a), 600nm(b), 680nm(c), and SEM image of the $SiO_2/NaGdF_4:Eu^{3+}$ core/shell composite (d).

TABLE 1. THE AMOUNTS OF USED TEOS CORRESPONDING TO THE DIFFERENT SIZE OF THE SIO_2

Solution A			Solution B		SEM image

10	35	5	3	47	Fig.3a(400nm)
10	35	5	5	45	Fig.3b(600nm)
10	35	5	6	44	Fig.3c(680nm)

Luminescence properties

Fig.4 shows the photoluminescent spectra of the $SiO_2/NaGdF_4:Eu^{3+}$ core/shell composite at room temperature. The excitation spectrum was obtained by monitoring $^5D_0$-$^7F_2$ transition of Eu^{3+} at 614 nm (Fig.4a).There were two strong peaks at 274nm and 395nm which can be ascribled to $^8S_{7/2}$-$^6I_{11/2}$ transition of Gd^{3+} and $^7F_0$-$^5L_6$ transition of Eu^{3+} respectively. The peak at 274nm has the highest absorption relative to the others. It indicates the occurrence of an energy transfer process from Gd^{3+} to Eu^{3+} ion. Upon excitation at 274nm, $SiO_2/NaGdF_4:Eu^{3+}$ core/shell particles showed emission peaks in the range of 550–750 nm, corresponding to the transitions of $^5D_0$-$^7F_{1-4}$(Fig.4b), The strongest emission was obtained at 614nm($^5D_0$-$^7F_2$), thus giving rise to the red emission for Eu^{3+}.

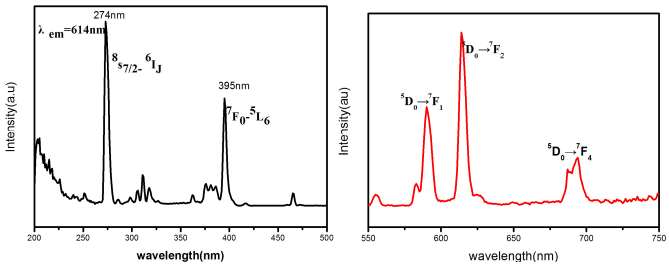

Fig.4 Excitation spectrum of $SiO_2/NaGdF_4:Eu^{3+}$ composite(a);
Emission spectrum of $SiO_2/NaGdF_4:Eu^{3+}$ composite under 274nm

Paramagnetic properties

Figure.5 shows magnetometry magnetization magnetic field (M-H) plots of $SiO_2/NaGdF_4:Eu^{3+}$ composite at 300 K. As the strength of the applied magnetic field increased, the ideal linear correlation between the magnetization and the applied magnetic field in the composite was obtained, indicating that composite possesses paramagnetism. The mass magnetic susceptibility value of the as-prepared $SiO_2/NaGdF_4:Eu^{3+}$ composite is determined to be $5.23*10^{-5}$ Oe. The paramagnetic property of the Gd^{3+} ions come from seven unpaired inner 4f electrons. $SiO_2/NaGdF_4:Eu^{3+}$ composite with paramagnetic property might be applied as MRI contrast agent.

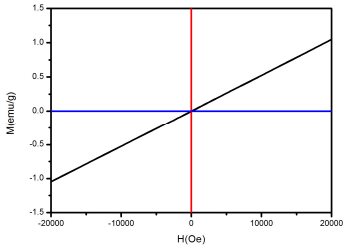

Fig.5 Magnetization versus applied magnetic field for $SiO_2/NaGdF_4:Eu^{3+}$ composite

Conclusions

$SiO_2/NaGdF_4:Eu^{3+}$ composite have been prepared by surface coating of $NaGdF_4:Eu^{3+}$ precursor on SiO_2 submicrospheres and subsequent hydrothermal treatment. The core/shell structure composite have a near perfect spherical shape with narrow size distribution, are not agglomerated. The Eu^{3+} shows a strong PL luminescence (dominated by $^5D_0$-$^7F_2$) red emission at 614 nm, and the composite shows paramagnetic property due to the 4f electron of Gd^{3+}. These properties makes it very promising for using as a dual-mode imaging nanoprobe for fluorescence and MRI analysises.

Keywords: Graphene nanosheets, Polyaniline, Supercapacitors, Electrochemical properties

Abstract. A graphene nanosheet/polyaniline (GNS/PANI) nanocomposite was synthesized using in situ polymerization. The morphology and microstructure of GNS/PANI nanocomposite were examined by transition electron microscopy (TEM) and X-ray diffraction (XRD). Electrochemical properties were characterized by cyclic voltammetry (CV) and galvanostatic charge/discharge. GNS as a support material could provide more active sites for nucleation of PANI as well as excellent electron transfer path. The GNS was homogeneously coated on both surfaces with PANI, and a high specific capacitance of 331 F g^{-1} was obtained at a current load of 0.02 A g^{-1}. The kinetics properties of GNS/PANI electrodes were investigated by AC impedance measurements. GNS/PANI electrode exhibited higher electrochemical activity and more favorable kinetic properties during charge and discharge process.

Introduction

With high requirement of energy storage systems for portable electronics, back-up power storage and hybrid electric vehicle applications, supercapacitors (also called electric double-layer capacitors) have gained an increasing attention, owing to their high power density and long cycle life compared with rechargeable batteries, and high energy density compared with conventional solid-state and electrolytic capacitors [1-3]. According to the double-layer energy-storage mechanism, the key to enhance the specific capacitance is to enlarge the specific surface area and control the pore size and distribution of the electrode material [4, 5].

Graphene is a two-dimensional carbon plane with one-atomic thickness. Since the paper on the freestanding graphene was published by Geim and co-workers [6], the preparation, structure and property of graphene have attracted great attention owing to its particular quantum Hall effect, sensitivity, mechanical hardness, electrical conductivity and so on [7–10]. These properties suggest wide applications, including field effect transistors, adsorbents, lithium-ion batteries and supercapacitors [7–11]. Recently, great effort has also been devoted to compounding graphene nanosheets (GNS) with polymers or inorganic particles. Among the conducting polymers, polyaniline (PANI) is the most investigated conducting polymer due to its low cost, easy synthesis, environmental stability, good electrical conductivity and controllable doping level [6–12]. However, it is very easy for PANI to be swelling and shrinkage in the charge–discharge process. In order to deal with this problem, it is a good methodology to compound PANI and carbon materials to increase the stability of PANI as well as to maximize the capacitance value. Among them, GNS brings many advantages that make it better than other carbon materials [13–15].

In this work, GNS/PANI nanocomposite was synthesized by in situ polymerization of aniline monomer in the presence of GNS suspension in HCl solution. The introduction of GNS into PANI could greatly enhance the electrochemical performances of the nanocomposite.

Materials and Methods

GNS was prepared in three steps: the oxidation of flake natural graphite via a modified Hummers' method, rapid heat treatment and ultrasonication. $KMnO_4$ was employed as the oxidant to obtain graphite oxide (GO). Firstly, 1 g of flake natural graphite powder with the mean diameter of 15 μm (provided by Dong Xing Electrical Carbon Co., Ltd. China) was added to 23 ml of cooled (0 ºC) concentrated H_2SO_4. Then 3 g of $KMnO_4$ was added gradually with stirring and cooling, so that the temperature of the mixture was maintained below 10 ºC. The mixture was then stirred at 35 ºC for 30 min. After this, 46 ml of distilled water was slowly added to cause an increase in temperature to 98 ºC and the mixture was maintained at that temperature for 15 min. The reaction was terminated by adding 140 ml of distilled water followed by 10 ml of 30% H_2O_2 solution. The solid product was separated by centrifugation, washed repeatedly with 5% HCl solution until sulphate could not be detected with $BaCl_2$, and then the resultant GO was dried at 65 ºC overnight. GO were quickly sent to a muffle furnace pre-heated to 1050 ºC in the air atmosphere to obtain expanded graphite. The expanded graphite was dispersed into ethanol and delaminated into GNS under a 600 W ultrasonic agitation for 15 h. The desired GNS was obtained after vacuum drying. Aniline was first distilled under vacuum to remove the oxidation impurities before using. The GNS/PANI nanocomposite was prepared by in situ polymerization. 200 mg of GNS was firstly dispersed in 100 mL of a 1 mol/L hydrochloric acid (HCl) aqueous solution and ultrasonicated for 30 min to form dispersed suspensions. The suspension was mixed with 200 mg (2.2 mmol) aniline monomer dissolved in 50 mL of a 1 mol/L HCl aqueous solution. After that, ammonium persulfate (APS, $(NH4)_2S_2O_8$) solution containing 50 mL of 1 mol/L HCl and 500 mg (2.2 mmol) of APS was added to the suspension dropwise with vigorous stirring to carry out the in situ polymerization at an ice-water bath for 24 h. The precipitated GNS/PANI nanocomposite was filtered and washed repeatedly with ethanol and de-ionized water.

The morphology and structure of the samples were observed by transmission electron microscope (TEM, Hitachi H-800). X-ray diffraction (XRD) analysis was conducted on a Rigaku D/max-2500B2+/PCX system using Cu/Kα radiation (λ = 1.5406 Å).

The electrochemical performances of GNS/PANI nanocomposite were measured with the coin-type cells. The supercapacitor electrodes were prepared by a coating method. A mixture of GNS/PANI nanocomposite, acetylene black (conductivity enhancing material) and polytetrafluoroethylene (10 wt.%, binder) with the mass ratio of 85:10:5 was dispersed in ethanol and coated on a piece of foam nickel, which was pressed under 10 MPa for 2 min and dried at 100 °C for 24 h. A two−electrode cell configuration was used to measure the performance of supercapacitors. The capacitor was constructed using a couple of electrodes face to face, with a separator inserted between these electrodes. The two identical (by weight and size) electrodes were assembled in a test cell, which consisted of two current collectors, two electrodes, and an ion-porous separator. The electrolyte was a 6 M KOH aqueous solution. Galvanostatic charge/discharge test was taken by CT2001A Battery Program Controlling Test System (China-Land Com. Ltd.) within the voltage range of 0−1 V, which was used to calculate the specific capacitance of GNS electrodes form the slope of discharge curves (dV/dt). The cyclic voltammetry and electrochemical impedance spectroscopy (EIS) were carried out on a VersaSTAT3 electrochemical working station. For the cyclic voltammetric measurements, the sweep rate ranged from 1 to 50 mV s^{-1} within a potential range of 0 to 1 V. For the EIS measurements, the frequency range was from 0.01Hz to 100 kHz.

Results and Discussion

The morphology of the obtained GNS/PANI nanocomposite was observed by TEM. Fig. 1 exhibits the TEM image of GNS/PANI nanocomposite, consisting of almost transparent carbon nanosheets with thin wrinkled structure that graphene owns intrinsically. GNS as a support material could supply a large number of active sites for nucleation of PANI, and homogeneous PANI coat on

the surfaces of GNS, which increases both the dispersion of PANI and the contact of PANI with electrolyte, and thus may be favorable for the enhancement of the electrochemical performance as an electrode for supercapacitors.

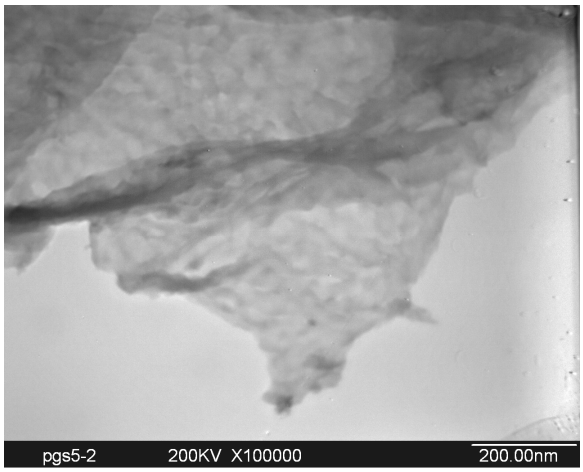

Fig. 1. TEM Images of GNS/PANI.

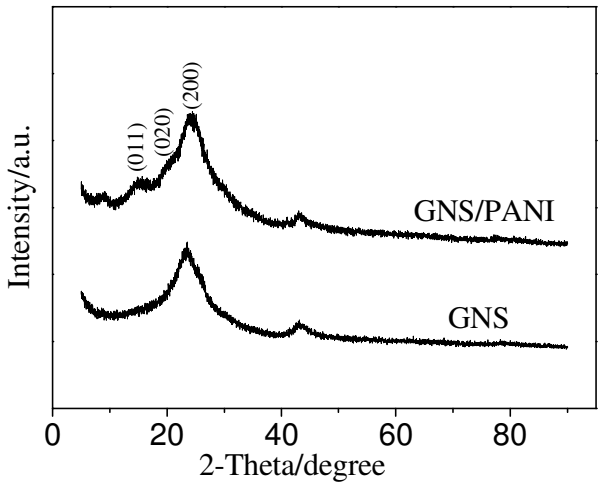

Fig. 2. XRD Patterns of GNS and GNS/PANI.

Fig. 2 shows the XRD patterns of GNS and GNS/PANI nanocomposite. For GNS, the diffraction peaks at 2θ = 24.5° and 42.8° can be attributed to the graphite-like structure (002) and (100), respectively. For GNS/PANI nanocomposite, the crystalline peaks appear at 2θ = 15.3°, 20.7° and 25.2°, corresponding to (011), (020) and (200) crystal planes of PANI in its emeraldine salt form, respectively.

Cyclic voltammetry measurements were carried out within the potential range of 0 to 1 V to analyze the electrochemical behavior of the supercapacitors. Fig. 3 presents the cyclic voltammograms of GNS/PANI electrode at scan rates varying from 1 to 20 mV s^{-1}. At low scan rates, the GNSs show typical rectangular curve without obvious oxygen and hydrogen evolution peaks, indicating good charge propagation within the electrodes. The CV curves for the GNSs still show rectangular shapes with small distortion at a scanning rate as high as 20 mV s^{-1}, suggesting that the GNS/PANI nanocomposite show a good power capability due to their uniform mesopore distribution. To investigate the electrochemical performance of GNS/PANI nanocomposite as electrodes for supercapacitors, galvanostatic charge/discharge cycling measurements were performed. Fig. 4 displays the capacitance versus cycle number curves of GNS/PANI under specific current of 0.1 A g^{-1}, and the electrode exhibits stable capacitances without fading after 500 cycles. The good cycle performances of GNS/PANI nanocomposite imply their stable energy–storage processes during long cycle charging/discharging. The electrochemical measurements show that the specific capacitance of the GNS/PANI nanocomposite maintained a stable specific capacitance of 230 F g^{-1} under specific current of 0.1 A g^{-1} for 500 cycles of charge/discharge.

To investigate the electrochemical performance of GNS/PANI nanocomposite as electrodes for supercapacitors, galvanostatic charge/discharge cycling measurements were performed. Fig. 5 shows the galvanostatic charge/discharge cycling curves for GNS/PANI nanocomposite at the current load of 0.02 A g^{-1}. From the well retained triangular-shaped curve, an apparent feature is that the electrode mainly exhibits a double–layer capacitor behavior resulted from the electrostatic attraction.

The galvanostatic charge/discharge curves of GNS/PANI nanocomposite at different specific currents are shown in Fig. 6. At 0.02 A g^{-1}, GNS/PANI nanocomposite electrodes show stable specific capacitances of 331 F g^{-1}. Higher specific capacitance values are obtained by GNS/PANI nanocomposite, which are in good accordance with its higher specific surface areas and the synergistic effect between GNS and PANI. As the specific current rises to 20 A g^{-1}, GNS/PANI electrodes show stable specific capacitances of 172 F g^{-1}, suggesting the high-rate cycle performance of GNS/PANI nanocomposite.

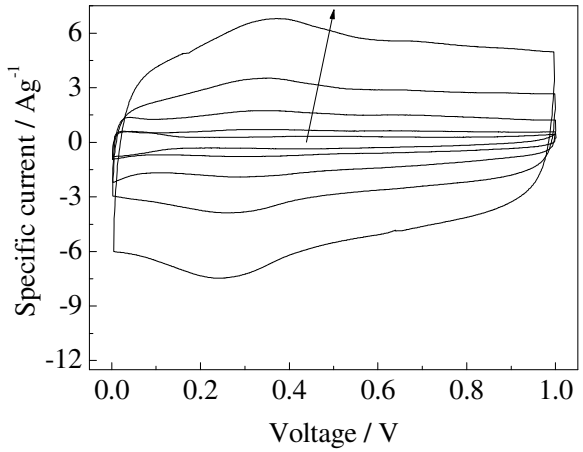

Fig. 3. Cyclic Voltammograms of GNS/PANI Electrodes at Different Sweep Rates (1, 2, 5, 10, 20 mV s−1, Direction of Arrow Shows that Sweep Rate Increases in Turn)

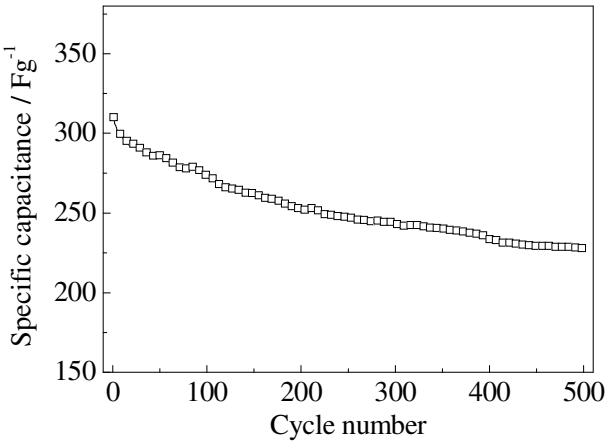

Fig. 4. The Capacitance Curve of GNSs under a Specific Current of 0.1 A g−1

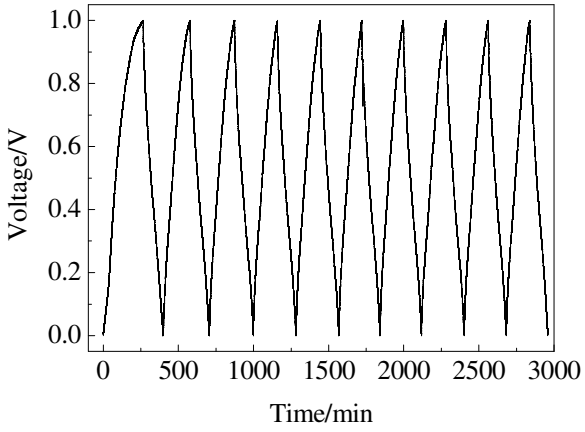

Fig. 5. Galvanostatic Charge/Discharge Cycling Curves for GNS/PANI at a Current Load of 0.02 A g -1.

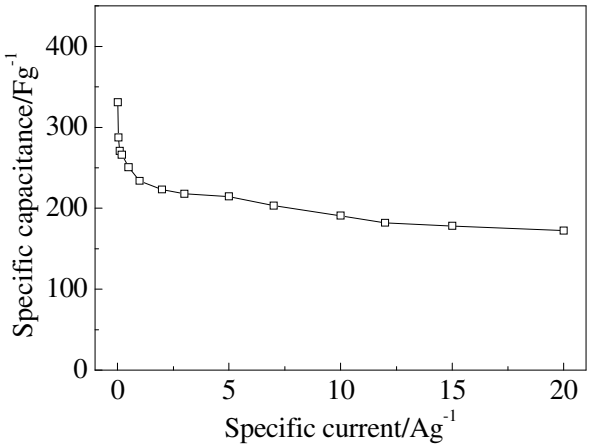

Fig. 6. The Specific Capacitances of GNS/PANI Electrodes at Various Specific Currents

Electrochemical impedance spectroscopy as a powerful technique was further employed to monitor the electrochemical behaviors of GNS/PANI nanocomposite electrodes. Impedance spectra for the electrodes are presented in Fig. 7a, where the real part (Z′) corresponds to the equivalent of ohmic resistance and the imaginary part (Z″) reflects the presence of non-resistive elements. The impedance behavior might be dominated by three major processes occurring in the high, medium and low frequency regions, respectively. The radius of semicircle in the high frequency region reflects the impedance on electrode/electrolyte interface. The slope of the 45° portion of the curve in medium frequency region is called the Warburg resistance and is a result of the frequency−dependent of ion diffusion/transport in the electrolyte. The radius of semicircle in GNS/PANI film is small, which indicates the polarization resistance of GNS/PANI nanocomposite is low. At low frequency the imaginary part of the impedance curves approaches a vertical line in GNS/PANI nanocomposite, indicating a capacitive−type behavior, in agreement with the CV results. Bode plots in Fig. 7b shows the frequency−dependent capacitance. A monotonous capacitance change is observed in the intermediate frequency region. GNS/PANI nanocomposite exhibits good frequency behavior in aqueous media, which coincide with the large volume of mesopores of GNS and the synergistic effect between GNS and PANI.

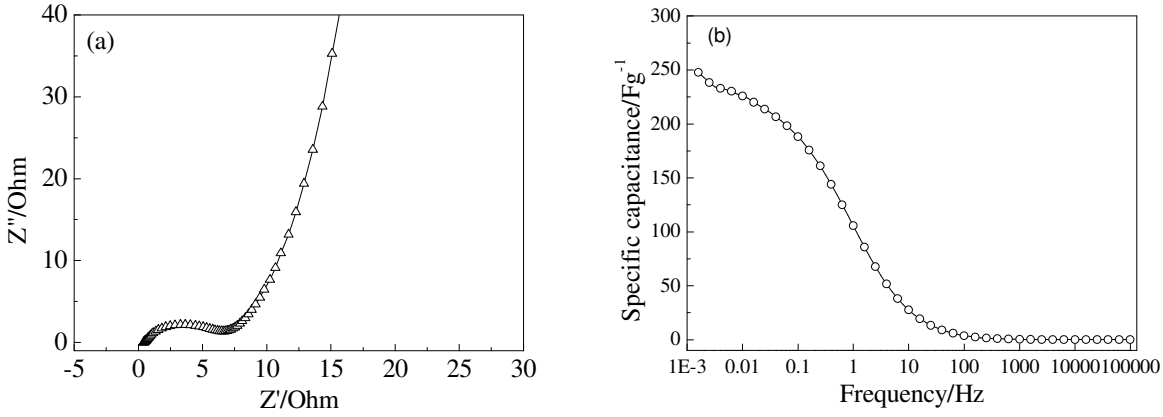

Fig. 7 Nyquist Impedance Plot for GNS Electrodes (a) and Frequency–dependent Capacitance Profile for GNS/PANI Electrodes (b).

Summary

The GNS/PANI nanocomposite was synthesized using in situ polymerization. The introduction of GNS in the nanocomposite provides high conductivity as well as a relatively large area on which to deposit the PANI, which could effectively reduce the kinetic difficulties for both charge transfer and ion transport throughout the electrode. GNS electrode maintained a stable specific capacitance of 230 F g^{-1} under specific current of 0.1 A g^{-1} for 500 cycles. The extraordinary electrochemical properties of the composites were attributed to the well designed structural advantages of binary nanocomposites and the good combination and synergistic effects between graphene and polyaniline.

Keywords: Graphene, Sulfur, Nanocomposite, Lithium-sulfur batteries

Abstract: The graphene/sulfur nanocomposite has been synthesized by heating a mixture of graphene sheets and elemental sulfur. The morphology, structure and electrochemical performance of graphene/sulfur nanocomposite as cathode material for lithium-sulfur batteries were systematically investigated by field-emission scanning electron microscope, X-ray diffraction and a variety of electrochemical testing techniques. The graphene/sulfur nanocomposite cathodes display a high reversible capacity of 800-1200 mAh g^{-1}, and stable cycling for more than 100 deep cycles at 0.1 C. The graphene sheets have good conductivity and an extremely high surface area, and provide a robust electron transport network. The graphene network also accommodates the volume change of the electrode during the Li-S electrochemical reaction.

Introduction

Lithium–sulfur batteries have been studied as one of the most promising systems for the next generation high-energy rechargeable lithium batteries because of their high theoretical specific capacity (~1680 mAh g^{-1}) and energy density (2600 Wh kg^{-1}) [1, 2]. Other advantages are that elemental sulfur is low cost, has low toxicity, and is an abundant resource. However, the practical application of lithium–sulfur batteries is greatly hampered by two major challenges including (i) high solubility of the reaction polysulfide products, which can shuttle between the anode and cathode, forming deposits of solid Li_2S_2 and Li_2S on the cathode, causing loss of the active material, which leads to low Coulombic efficiency, low utilization of the sulfur cathode, and a severe degradation of cycle life, and (ii) the low electrical conductivity of sulfur, the intermediate polysulfide products, and the final Li_2S, affecting the reaction rate of the battery [3-6].

Extensive studies have been carried out to improve the electrical conductivity of the sulfur electrode and to confine the sulfur and polysulfides in a carbon matrix. For example, ordered mesoporous carbon, hierarchical porous carbon, microporous carbon spheres, hollow carbon spheres, carbon nanotubes/nanofibers and graphene have been investigated as the confining/conductive medium and have shown improved cyclic stability. Among these carbonaceous materials, graphene has opened new possibilities and is promising as a two-dimensional conductive support because of its high electrical conductivity, superior mechanical flexibility, high surface functionality, and large surface area [3, 7-11]

In this work, we synthesized sulfur-coated graphene nanocomposite and investigated graphene sheets as a carbon matrix to improve the performance of sulfur cathodes for rechargeable lithium sulfur batteries, the electrochemical performances of the graphene/sulfur nanocomposite were investigated by a variety of electrochemical testing techniques on the basis of the morphology and structure of the graphene/sulfur nanocomposite.

Materials and Methods

The graphene sheets were synthesized by a modified Hummers' method through three steps: the oxidation of flake natural graphite powder, rapid heat treatment and ultrasonication [12]. In the experimental process, $KMnO_4$ was employed as the oxidant to obtain graphite oxide. Firstly, 1.5 g of sodium nitrate was added to 69 ml of cooled (0 ºC) concentrated H_2SO_4. Then 3 g of flake natural graphite with the mean diameter of 15 μm (provided by Dong Xing Electrical Carbon Co., Ltd. China) was added gradually under stirring for 15 min. At the same time, the temperature of the mixture was maintained below 10 ºC. Then 9.0 g $KMnO_4$ was added slowly to the solution and stirred for 20 min below 20 ºC. In the following 10 min, the experimental temperature was heated up to 35 ºC and kept for 1 h. Then 138 ml of distilled water was slowly added to cause an increase in temperature to 98 ºC and the mixture was maintained at that temperature for 15 min. The reaction was terminated by adding 420 ml of distilled water followed by 30 ml of 30% H_2O_2 solution. The solid product was separated by centrifugation, washed repeatedly with 5% HCl solution until sulphate could not be detected with $BaCl_2$, and then the resultant graphite oxide was dried at 65 ºC overnight. The graphite oxide was quickly sent to a muffle furnace pre-heated to 1050 ºC in the air atmosphere to obtain expanded graphite. The expanded graphite was dispersed into ethanol and delaminated into graphene sheets under a 600 W ultrasonic agitation for 15 h. The desired graphene sheets were obtained after vacuum drying. The graphene sheets were mixed with elemental sulfur S in the weight ratio of 1:1. Then, the mixture was held at 200 ºC for 6 h to allow the melted elemental sulfur to infiltrate into the layer of graphene. The temperature was increased to and held at 300 ºC for 3h, so that the vaporized sulfur was coated onto the graphene.

The morphologies and structures of graphene/sulfur nanocomposite were observed by field-emission scanning electron microscope (FESEM, Hitachi S-4700) and X-ray diffraction (XRD) analysis was conducted on a Rigaku D/max-2500B2+/PCX system using Cu/Kα radiation (λ =1.5406 Å).

The working electrodes were prepared as following: graphene/sulfur nanocomposite, acetylene black and poly(vinylidene fluoride) binder at the weight ratio of 80:10:10 were homogenously mixed and pasted on an aluminium foil, then dried at 80 °C for 10 h in a vacuum oven. The foil was pressed between twin rollers, shaped into a circular pellet with a diameter of 12 mm, and used as a cathode. The electrolyte was 1.0 M lithium bis-trifluoromethanesulfonylimide in 1,3-dioxolane and 1,2-dimethoxyethane (1:1 by volume) with 0.5 wt % $LiNO_3$ additive. A 2032 type stainless steel coin cell was used to assemble a test cell. A lithium metal foil was used as the anode, and a graphene/sulfur slice as the cathode. The Celgard 2325 microporous polypropylene film was used as separator. Electrochemical properties of the coin type cells were galvanostatically charged and discharged in the voltage range of 1.3-3.0 V vs. Li/Li^+ using LANDCT2001A. Cyclic voltammetry curves were measured at 0.1 mV s^{-1} within the range of 1.5-2.8 V using an electrochemical work station (VersaSTAT3). Electrochemical impedance studies of the coin cells were performed using an electrochemical work station (VersaSTAT3) by applying sine wave with amplitude of 10.0 mV in the frequency range of 100 kHz to 0.01 Hz.

Results and Discussion

The morphology and structure of graphene sheets and graphene/sulfur nanocomposite were characterized by FESEM and their images are shown in Fig. 1. Fig. 1a exhibits the SEM image image of graphene sheet agglomerate, consisting of almost transparent carbon nanosheets with thin wrinkled structure. The graphene sheets are entangled with each other and resemble crumpled papers. Moreover, the thin wrinkled structure represents a curled and corrugated structure that the graphene owns intrinsically. Fig. 1b exhibits the SEM image image of graphene/sulfur nanocomposite. After heat treatment of the mixture of S and graphene sheets, the microsized S particles were melted and covered the graphene nanosheets. The embedded sulfur exists in fine particles and a highly dispersed state, with the crystalline sulfur most likely converted to amorphous sulfur by the heat treatment. When the mixture of sulfur and graphene was thermally treated at 200

ºC, sulfur would be expected to melt and coat the graphene sheets. At the higher temperature of 300 ºC, sulfur existing on the external surface of the graphene sheets was sublimed. At the same time, sulfur gas could also diffuse into the pores of graphene [6]. Fig. 2 exhibits the XRD patterns of graphene, graphene/sulfur nanocomposite and sulfur.

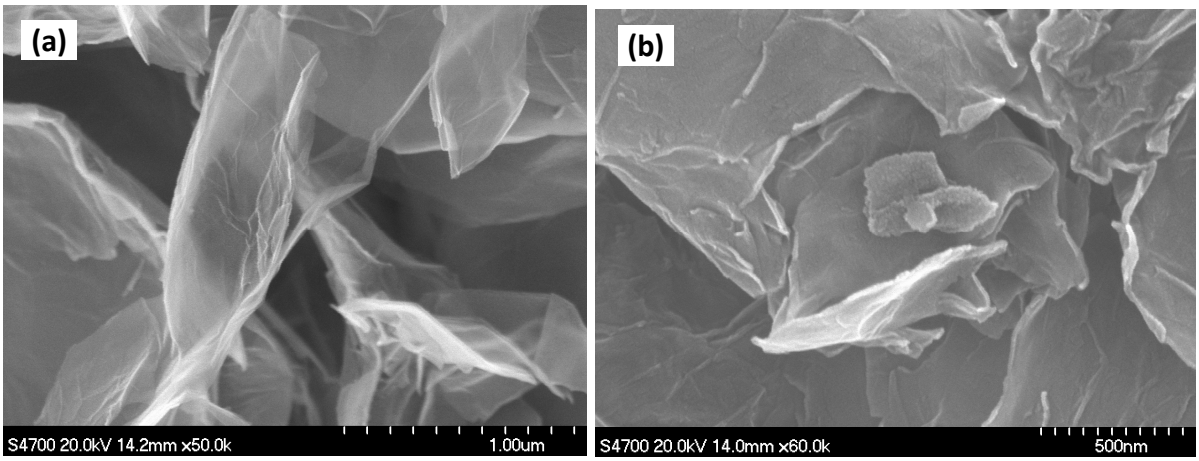

Fig. 1 SEM images of graphene (a) and graphene/sulfur nanocomposite (b).

Cyclic voltammetry (CV) was used to reveal the electrochemical reaction mechanism of the graphene/sulfur cathode measured between 1.5 and 2.8 V at a sweep rate of 0.1 mV s^{-1}, as shown in Fig. 3. During the first cathodic reduction process, three peaks at approximately 2.3, 2.0, and 1.8 V (vs Li/Li^+) were observed. The peak at 2.3 V corresponds to the reduction of sulfur to higher order polysulfides (Li_2Sx, $4<x<8$) [5]. The peaks at 2.0 and 1.8 V are related to the reduction of higher-order polysulfides to lower-order polysulfides (such as Li_2S_4, Li_2S_3, Li_2S_2) and Li_2S [3, 7]. In the subsequent anodic scan, one asymmetric oxidation peak (which can be divided into two peaks) is observed at about 2.5 V and is attributed to the conversion of lithium sulfides to polysulfides and sulfur. These results are in agreement with galvanostatic charge/discharge curves (Fig. 4) and similar to other reports [3]. From the second cycle, both the CV peak positions and areas remain almost unchanged, suggesting relatively good capacity retention.

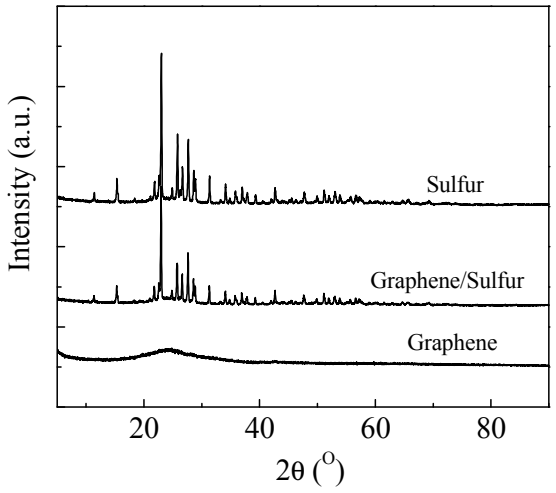

Fig. 2. XRD patterns of graphene sheets, graphene/sulfur nanocomposite and sulfur.

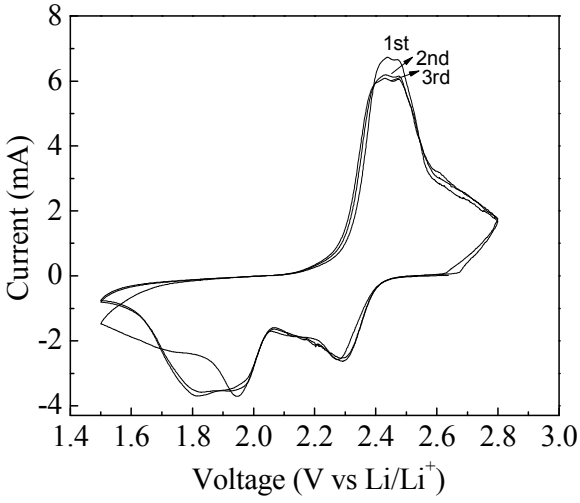

Fig. 3 CVs of the graphene/sulfur cathode at 0.1 mV s^{-1} in a potential window from 1.5 to 2.8 V vs Li/Li^+.

The electrochemical performance of the graphene/sulfur cathode electrode was examined by galvanostatic measurements. Fig.4 depicts the galvanostatic charge/discharge profiles of the graphene/sulfur cathode electrode at a current density of 0.1 C (1C=1675 mA g^{-1}) and the voltage rang 1.3-3.0 V, respectively. In the first cycle, an initial reversible discharge capacity of 1210 mA h g^{-1} is achieved. The characteristic voltage profiles are preserved during cycling, while a specific

capacity of 1189 and 1184 mA h g^{-1} is retained in the second and third cycle respectively, which indicates the good reversibility of the electrode materials. Fig. 5 shows charge/discharge capacity versus cycle number for cells made with the sulfur and graphene/sulfur electrodes. The initial capacity of the graphene/sulfur electrode is much higher than that of the pure sulfur electrode. Furthermore, the cycling stability of the graphene/sulfur nanocomposite is also improved. After more than 100 cycles at the same rate, the reversible capacity remains at 814 mAh g^{-1} (with a coulombic efficiency of about 97.8%), indicating very stable reversibility of the electrochemical reactions and excellent capacity retention. The graphene/sulfur electrode displays improved coulombic efficiencies compared to the pure sulfur electrode (Fig. 6). The improvement in the capacity and cycling stability of the cell with the graphene/sulfur nanocomposite electrode may be because the graphene in the nanocomposite can improve the conductivity of the electrode.

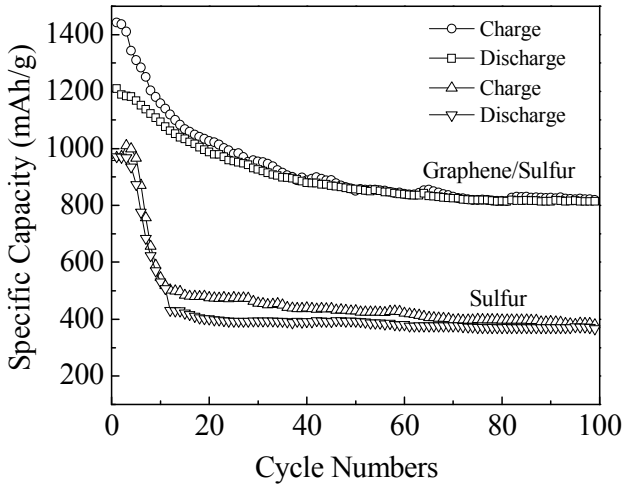

Fig. 5 Cyclic performance of graphene- sulfur cathode at 0.1 C for 100 cycles.

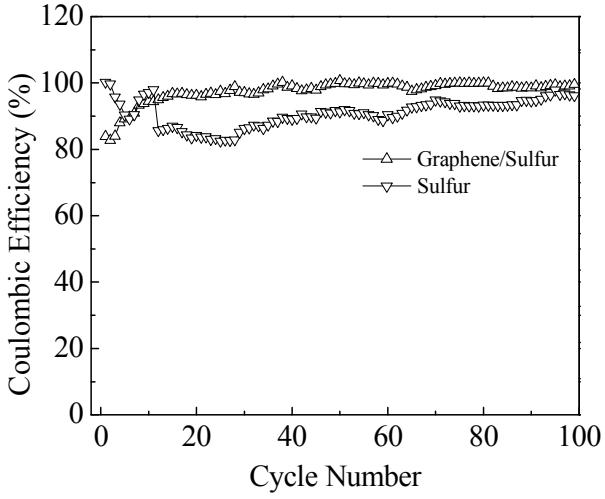

Fig. 6 Coulombic efficiency of sulfur and graphene/ sulfur cathode at 0.1C for 100 cycles.

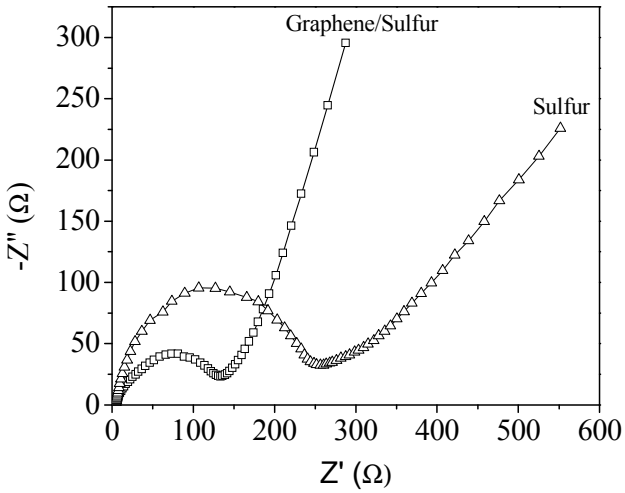

Fig. 7 Impedance plots for electrodes of sulfur and graphene/sulfur nanocomposite.

In order to verify that the graphene is responsible for the good performance of the cell with the graphene/sulfur electrode, electrochemical impedance spectroscopy measurements were performed on the pure sulfur and graphene/sulfur electrodes. Impedance spectra for the electrodes are presented in Fig. 7, where the real part (Z′) corresponds to the equivalent of ohmic resistance and the imaginary part (Z″) reflects the presence of non-resistive elements. The impedance behavior might be dominated by three major processes occurring in the high, medium and low frequency

regions, respectively. The radius of semicircle in the high frequency region reflects the impedance on electrode/electrolyte interface. The slope of the 45º portion of the curve in medium frequency region is called the Warburg resistance and is a result of the frequency−dependent of ion diffusion/transport in the electrolyte. At high frequencies, the impedance response exhibits a semicircular loop. The diameter of this semicircle gives the charge-transfer resistance, which is a measure of the charge transfer kinetics. The results show that the charge-transfer resistance of the cell with graphene/sulfur electrode is lower than for the cell made from pure sulfur electrode. This indicates that the nanocomposite of sulfur with graphene can improve the electrochemical kinetics of the sulfur in rechargeable lithium batteries.

Summary

In summary, the graphene/sulfur nanocomposite was synthesized by heating a mixture of elemental sulfur and graphene sheets. The graphene/sulfur nanocomposite shows a significantly improved capacity and cycle life compared to the bare sulfur electrode. The unique structure of the graphene/sulfur nanocomposite can improve the overall electrochemical performance when it is used as a cathode material for lithium-sulfur batteries. It can accommodate the significant volume changes of S as it is converted to Li_2S on discharge, and back to elemental S on recharge. In addition, the graphene with its large surface area along with ubiquitous cavities can establish more intimate electronic contact with S and avoid aggregation and loss of electrical contact with the current collector.

Keywords: magnesium oxide, aerogel, sol-gel.

Abstract: Magnesium-based aerogels were prepared by sol-gel technology and drying with supercritical fluid dry process in 245℃. The structure and properties of the magnesium-based aerogels were featured by TEM, XRD and BET. The densities of the prepared samples were about 0.34~0.59 g/m^3. The results show that the MgO aerogel has a high surface area.

Introduction

The extraordinary properties of aerogels including high surface areas, low refractive indices, low dielectric constants, low thermal loss coefficients and low sound velocities lead to potential applications such as: ultra-low dielectric constant interlayer dielectrics, sensors, and acoustic impedance matching.

The most outstanding feature of nano-sized MgO aerogel and other aerogel-prepared nanocrystalline metal oxides is their high efficiency in chemisorption of such toxic gases as NO_2, SO_2 , SO_3 , HCl, as well as chlorinated and phosphorous-containing compound. The interaction of such gases with the surface of the nanoparticles is referred to as destructive sorption as both the surface and the bulk chemical composition of the oxides are often subjected to significant changes during this process [1].MgO, an insulator, is traditionally used for the preparation of cement, medicines, insulators, desiccants, and optical materials. In recent decades, people have given attention to the synthesis of MgO nanomaterials with different morphologies—nanoparticles, nanotubes, and nanorods—which have been investigated for different purposes; MgO nanomaterials have been investigated as catalysts, adsorbents, and destructive adsorbents for toxins, including chemical warfare agents [2].

Method of precipitation is the most used technique to prepared Nano-sized MgO. Although Method of precipitation has a few merits such as cheap materials resource, simple process, the product of MgO powder's diameter was big and would distribute in a big range. Compared to the precipitation method, the sol-gel method could prepare MgO powder with tiny diameter and narrow the diameter distribution range.

There is considerable interest in the synthesis of nanoscale MgO and magnesium hydroxide $Mg(OH)_2$ particles via the magnesium alkoxide $Mg(OR)_2$ route. Generally, an alkoxide is hydrolyzed in an alcohol solvent to yield the hydroxide, which is followed by isolation and thermal dehydration. A modified autoclave hypercritical drying procedure has been developed to prepare nanoscale MgO particles. These nanoscale materials exhibit unusual surface chemistry and catalytic

properties and, compared to other MgO samples, are more chemically reactive. They have been extensively studied as destructive adsorbents for a variety of toxic substances [3].

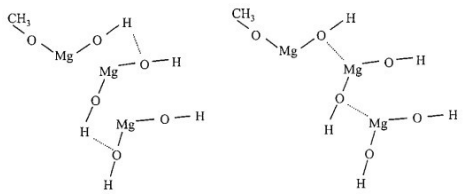
There are many reports about the preparation and properties of silica aerogels and carbon aerogels etc. However, there are relatively few reports about the preparation and characterization of magnesium oxide aerogels though the MgO aerogel have a plenty of great applications.

To prepare MgO aerogel which was made by sol-gel technology, methanol as solvent, water and magnesium methoxide were used in the experiment. Drying it with supercritical process in autoclave 245℃. Then Calcined at 500℃. It has a huge potential of application that could be found in further study.

Experimental

Preparation

$Mg(OCH_3)_2$ solution was prepared by the process as follows. First, immersing the Mg ribbon into the diluted hydrochloric acid to remove the MgO on the Mg ribbon's surface. Then, the treated Mg ribbon was dissolved in methanol to give $Mg(OCH_3)_2$.



$$Mg+CH_3OH \rightarrow Mg(OCH_3)_2+H_2 \quad (1)$$

The wet gels were prepared according to the following to the following steps. Appropriate amount of water and methanol were mixed in a beaker in 10 minutes. Then added the designed amount of $Mg(OCH_3)$ solution into the water-methanol solvent very quickly. The typical mole ratios were $Mg(OCH_3)_2:H_2O:CH_3OH=1:2:32$ and other ratios were tried too. The mixture would become transparent wet gel in less then 1minute.

$$Mg(OCH_3)_2+2H_2O \rightarrow Mg(OH)_2+2CH_3OH \quad (2)$$

The wet gels were conventionally aged for 48 hours followed by washing with methanol for 4 times (each 12 hours). To obtain dried gels, the nature evaporation process is unacceptable. Because it will destroy $Mg(OH)_2$ aerogel's porous structure. The wet gel was dried under a supercritical condition using ethanol as the drying agent.

To fit the required condition, the wet gel was placed in an autoclave that partially filled with ethanol and sealed. The ultra pure, dry nitrogen gas was flushed in the autoclave to have the oxygen free atmosphere and for safety precautions. Rising the temperature to 245℃ at the rate of 2℃/min while the pressure rose and was controlled at about 10MPa. When temperature reached the target limit, the autoclave was decompressed slowly at a rate of 40kPa/min. Finally, the system was cooled down to room temperature naturally and the aerogel was taken out. Then the samples were heated to 500℃ in Muffle furnace.

(1)hydrogen bonding (2)Mg-O bonding

Fig 1 Structure of interconnected gel molecules

Characterization

The bulk of density of the aerogels were determined by grinding the aerogel into powder and filling a small square container to measure its volume and mass. The nature of phases at the aerogels was analyzed by powder X-ray diffraction (XRD) in a Rigata/max-C diffractometer using the Cu-Kα radiation. The microstructures of the samples were characterized by a transmission election microscope (TEM). The pore size distribution and specific surface area of sample were tested by a N_2 adsorption analyzer (TriStar 3000, USA).

Result and Discussion

The combinations of $Mg(OCH_3)_2$ and H_2O happened in really short time . The longest gelling time was less than 10 seconds. In all cases, hydrolysis resulted in the formation of totally clear gels. The reason of gel that were turned to brown after supercritical drying process was that there were plenty of carbonaceous residuals linked to the network structure of the MgO aerogel. It shrunk more then 40% and turned into white and opaque after 500℃ heat treatment for 4 hour. The dried magnesium aerogel was transparent with the density about 0.34 to 0.59g/m^3.

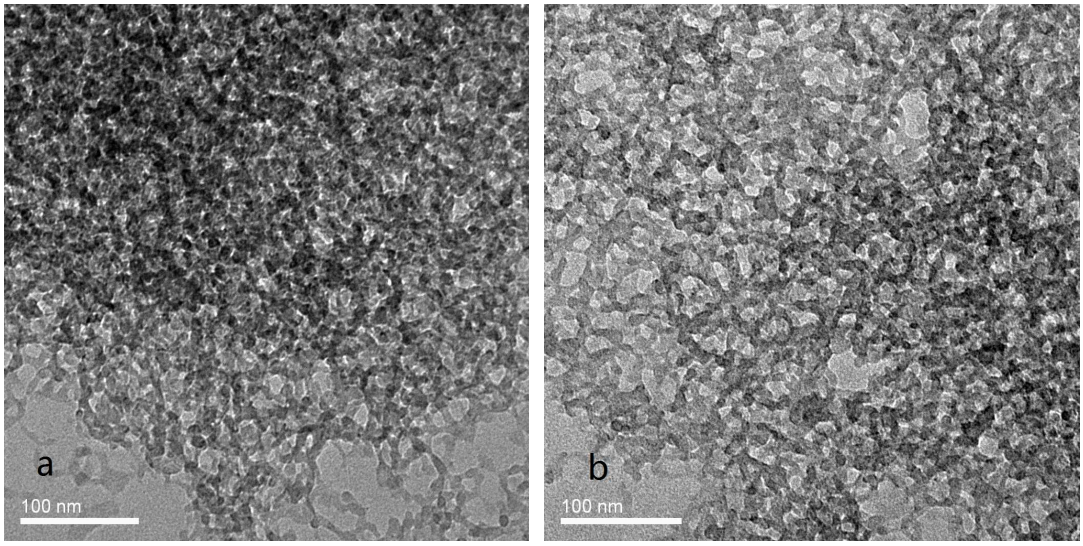


Fig 2 (a) The sample after supercritical drying process (b) sample calcined at 500℃

The TEM photographs of original and heated samples are showed in Fig 2. The micrographs suggest the existence of a polymer network which appears under the microscope as a multitude of thin strands to give a porous web-like matrix. It shows that the magnesium aerogel exhibits randomly interconnected networks consist of nanometer-sized fibrous particles with varying diameters ranging from 20 to 30nm. After 500℃ heat treatment by 4 hours, the magnesium aerogel remains its interconnected network structure. To get more information on the hydrolysis products, the wet gel was dried according to the previously mentioned drying procedure.

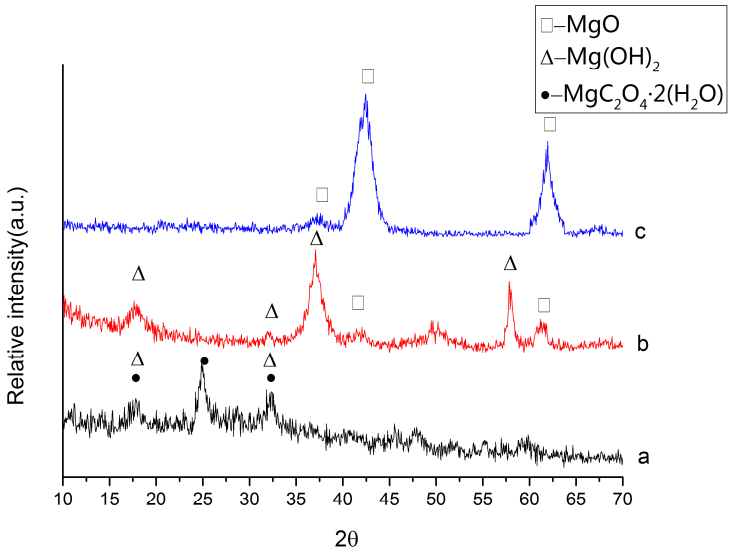

Fig 3. XRD sample of (a) the aerogel before calcination (b) aerogel calcined at 500℃ by 1hour (c) aerogel calcined at 500℃ by 4 hours

Figure 3 illustrates the XRD pattern of the dried gel and calcined gels respectively. From the Fig 3(a) the diffraction peak are largely fit the magnesium oxalate dihydrate and magnesium hydroxide ($Mg(OH)_2$) (JCPDS 86-0441) phase, it indicates that magnesium oxalate dehydrate and magnesium hydroxide are present in large amounts the aerogel before calcination. After 1 hour 500℃ heat treatment, the diffraction peaks which were showed in Fig 3(b) inferred that magnesium hydroxide and magnesium oxide's existence and the phase of magnesium oxalate dihydrate was dissapper. It prove that magnesium oxalate dehydrate was broke into magnesium hydroxide and magnesium oxide. After 4 hour heat treatment the XRD pattern from Fig 3(c) demonstrated that all the diffraction peaks of the samples were entirely consistent with the periclase structure (JCPDS 87-0653) which means that the rest of $Mg(OH)_2$ has been removed totally and there is magnesium oxide in aerogel calcined at 500℃ by 4hour .

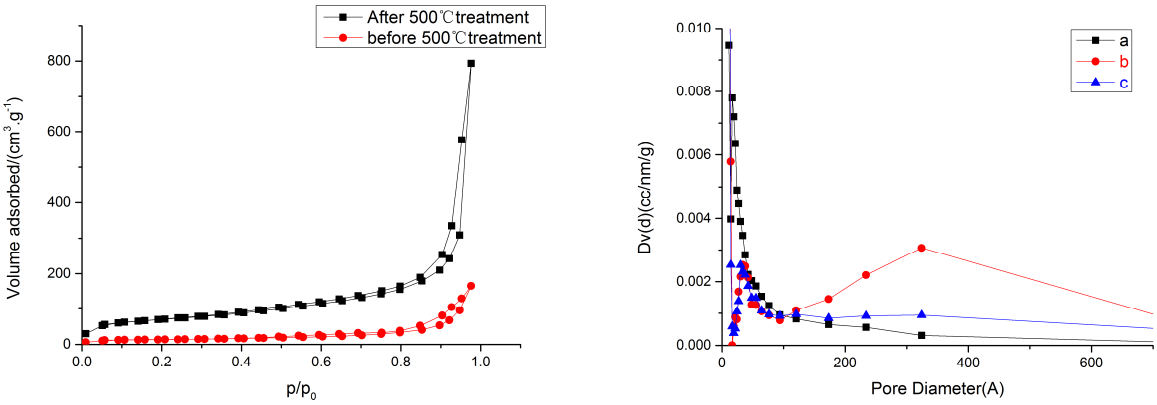

Fig 4. (A)N2 adsorption-desorption isotherms and (B)Pore size distribution for the samples (a) mole ratio Mg(OCH3)2:CH3OH=1:32 (b) Mg(OCH3)2:CH3OH=1:48 (c) Mg(OCH3)2:CH3OH=1:64

N_2 adsorption-desorption isotherms provide information about the microstructure of MgO aerogels before and after 500℃ hour heat treatment by 4hour. According to the IUPAC classification[4], the adsorption isotherms exhibit the H3 hysteresis loop to both MgO aerogels that before and after 500℃ heat treatment by 4hour, it inferred that the MgO aerogel is a fractured nanoporous magnesium material and has mesoporous structure and large pore size distribution. The

corresponding pore-size distributions were given in Fig 4(B), It's specific areas of the magnesium oxide aerogel are about to 220~291m^2/g. The main pore size are concentrated on the 30nm which are in good agreement with the trends discussed above. In those three sample, sample (b) has the most high surface areas 291 m^2/g. It means $Mg(OCH_3)_2$:CH_3OH=1:48 would be the best stoichiometry probably.

Conclusions

Magnesium aerogels were prepared by sol-gel method with the ethanol supercritical drying technique. This method afforded high surface area and transparent magnesium aerogel without the use of dangerous and complex agents. The aerogel possessed a web-like network microstructure consist with a high surface area of 291m^2/g. Since the technique of making magnesium aerogel was rarely reported, it has a huge potential of application that could be found in further study.

The project was supported by the National key Technology R&D Program of China (2013BAJ01B01), National Natural Science Foundation of China (U1230113), 863 Program of Ministry of Science and Technology of China, Shanghai Committee of Science and Technology (11nm0501600，12nm0503001) and Fundamental Research Funds for the Central Universities.

Keywords: ZnS, Nanomaterials, Microstructure, Field emission

Abstract: Large quantities of ZnS dentalation nanostructures were synthesized successfully at low temperature using a simple chemical vapor deposition method, and the microstructures and field emission properties of the dentalation structures were investigated. The results indicated that the stem of the dentalation structures is single-crystalline but the surfaces of the teeth are amorphous. The photoluminescence properties show a strong green emission at 520.89 nm due to S vacancy. Investigations on the field emission properties of the ZnS dentalation nanostructures imply that the turn-on field is about 5.56V/μm at an anode-cathode distance of 150μm, which should be attributed to the specific sharp tips and high aspect ratios of the present needle-shaped structure. The field emission behavior of the ZnS obeys Fowler-Nordheim relationship. The results could be valuable for using the ZnS nanostructure as cold-cathode field-emission materials.

Introduction

With a direct wide bandgap of 3.7~3.9 eV, which is higher than that of ZnO (3.37 eV), GaN (3.39 eV), and 4H-SiC (3.27 eV), ZnS is one of the most important II-VI semiconductors compounds, and exhibits the luminescence of short wave centered near 337 nm. Compared with the room-temperature thermal energy (25 eV), ZnS exhibits significantly large exciton binding of 40 eV, which makes the exciton's threshold much lower, so ZnS is an excellent candidate for efficient room-temperature exciton short-wave devices[1]. Latest achievements have shown ZnS has remarkable fundamental properties versatility and a promise for novel diverse applications [2-5], including field emitters, field effect transistors (FETs), light-emitting diodes (LEDs), UV-light and chemical sensors and biosensors, etc.

Although the structure and most properties of ZnS are comparable to more popular and widely known ZnO, certain properties pertaining to ZnS are unique and advantageous. However, the nanostructures of ZnS have not been investigated in much detail relative to ZnO nanostructures. Recently various morphologies of ZnS nanostructures have been fabricated while the ZnS dentalation nanostructures have been reported rarely[6-12], and the fabrication temperature of one-dimensional ZnS nanostructures is usually very high. Moore et al succeeded in the synthesis of nanoteeth-shaped ZnS by direct evaporation of ZnS powder at relatively high temperature of 1000℃[13-14].

With respect to field emission applications, it is also well known that the needle-shaped tips can significantly enhance the material field emission properties. The synthesis of microstructures with sharp tips is always the center of field emission research and application. In recent years, much attention has been paid to explore the prospects of inorganic semiconductor nanostructures including CNTs, ZnO, SiC etc, as field emitters due to their low work functions, high aspect ratios,

high mechanical stability, and high conductivity [15-19]. But few studies on the field emission properties of ZnS nanostructures has been reported [20,21], and it is still a question whether it is possible to make excellent field emitters out of various ZnS nanostructures by some facile routes. Chang et al investigated the field emission property of ZnS nanowire but a relatively high turn-on field of 12V/μm was achieved [22].

In this letter, Compared with the traditional thermal evaporation techniques (above 1000℃), ZnS dentalation nanostructures have been synthesized in a large scale by simple thermal evaporation method at lower temperature (800℃) with Au as catalyst, the microstructure and the field emission property of the product have been analyzed.

Experimental Section

The ZnS nanowires were synthesized by hydrogen-assistant thermal evaporation method through the direct reaction of Zn vapor with S vapor in a furnace with a horizontal quartz tube. First, Zn powder and S powder with the molar ratio of Zn : S= 1:2 were thoroughly grinded into a mixture before being loaded into a quartz boat. Then, the Si substrate with 10 nm Au catalyst with the polished side facing powder was fixed upon the boat, and the boat with the mixture was placed at the center of the furnace. A carrier gas of high-purity argon premixed with 3% hydrogen was kept flowing through the tube at a high flow rate (>400 sccm) (standard cubic centimeters per minute) for 1 h. The process was carried out at 800°C for 1 h with Ar flow rate of 50 sccm. After the reaction was completed, the product was collected from the Si substrate.

The morphologies and structures of the synthesized product were characterized using X-ray diffraction (XRD) (Rigaku DMAX-RB, Japan), field emission scanning electron microscopy (FESEM) (LEO1530, Japan), high-resolution transmission electron microscopy (HRTEM) (JEOL-2010, Japan), and energy dispersive x-ray spectroscopy (EDS). Photoluminescence (PL) measurements (HORIBA Jobin Yvon，labRAM HR) were performed at room temperature using a He-Cd laser line of 325 nm as the excitation source. The measurements of field emission characteristics of the products were carried out in a vacuum chamber maintained at a base pressure of ~10^{-5}Pa. A keithley 2410 sourcemeter was used for performing I-V measurements. DC voltages were employed between the flat anode and cathode in the examination of the emission process.

Results and Discussion

A typical SEM and XRD patterns of the as-grown ZnS nanostructures are shown in Figure 1. Figure 1(a) shows the SEM micrographs of the as-prepared nanostructures. The stem of the ZnS dentalation nanostructres is straight nanorod with smooth surface, and the diameter is about 50~200nm. The cone-shaped teeth of the nanostructure with the tip diameter of 10~30nm grow perpendicular to the stem. All main diffraction peaks in Figure 1(b) can be perfectly indexed to the hexagonal wurtzite structure of ZnS (JCPDS，No.75-1534) with lattice constants corresponding to a=b=3.242 Å and c=5.194 Å, and no other peaks were clearly detected.

TEM analysis was employed to further confirm the microstructure of nanostructures. Figure 2(a) shows the enlarged TEM micrographs of the as-prepared dentalation nanostructrues. The HRTEM image (Figure 2(b)) of the stem shows clear lattice fringes, which confirm the single-crystalline nature and the corresponding SAED patterns demonstrate that the stem could be indexed to a hexagonal structure growing along $[10\bar{1}0]$ direction. Figure 2(c) displays the HRTEM micrographs

and the corresponding SAED patterns of the teeth of the dentalation nanostructrues, indicating that the teeth is not fully crystallized but showing a polycrystalline morphology, and the surfaces of the teeth are covered by a layer of amorphous. This may be related to the reaction time. The EDS spectra (Figure 2(d)) imply that Zn and S are major elements, Cu comes from the Cu grid, no other elements were found in the microstructure.

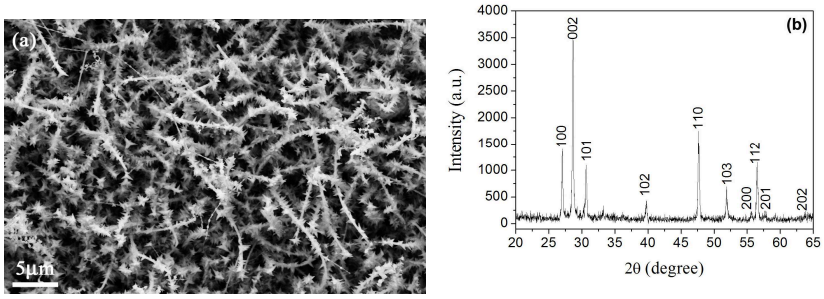

Fig. 1 Typical SEM (a) and XRD patterns (b) of the As-grown ZnS Nanostructures

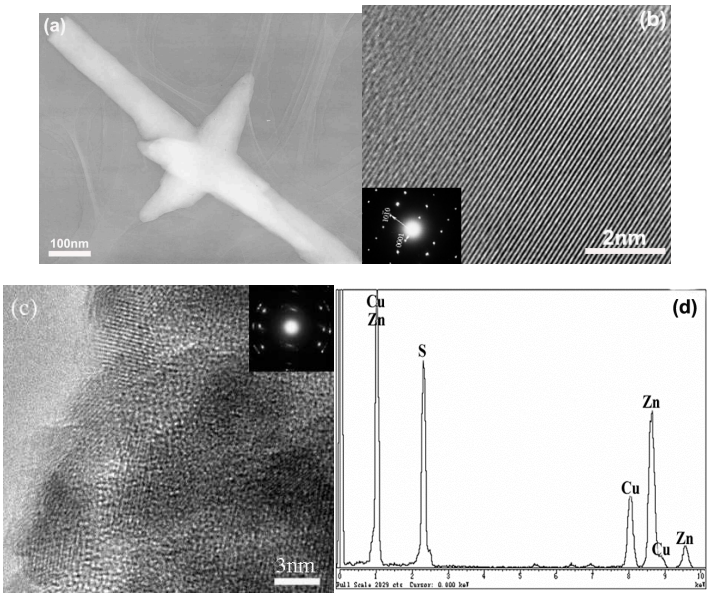

Fig. 2 (a) The Enlarged TEM Micrographs of the As-prepared Dentalation Nanostructrues. (b) HRTEM Image of the Stem and the Inset is the Corresponding SAED Patterns. (c) HRTEM Micrographs of the Teeth and the Inset is the Corresponding SAED Patterns. (d) EDS Spectra of the Dentalation Nanostructrues.

Room temperature photoluminescence (PL) spectra of the as-synthesized ZnS nanostructures were measured with excitation wavelengths of 325 nm as shown in Figure 3. The spectrum exhibit a strong emission centered at 520.89 nm corresponding to the characteristic green emission. The green emission observed here might be caused by the S vacancy due to the shortage of S source when heating the S powder.

The field emission current of the samples was measured at room temperature using a Keithley 2410 source-meter. The anode was a stainless steel plate with a diameter 5 mm, and the distance between the anode and cathode was 150μm. Figure 4 shows the field emission characteristics of the ZnS nanostructures. The current data was acquired by varying the applied voltage between the cathode and anode from 0 to 1100V with a step of 10V. The relatively smooth and consistent curves indicate the stability of emission from the dentalation emitters. From the relation curve of the emission current density vs. applied electric field, the turn-on field was extrapolated to be about 5.56V/μm, which is lower than that reported result from ZnS nanowires [22]. The possession of

decent turn-on field should be attributed to the specific sharp tips and high aspect ratios of the present needle-shaped structure.

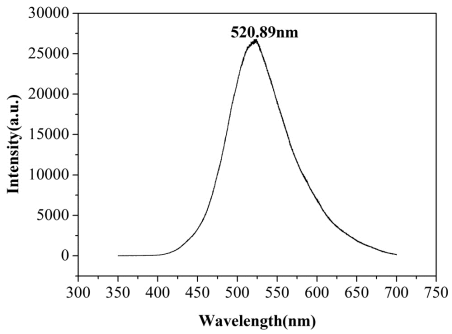

Fig. 3 Room Temperature Photoluminescence Spectra of the As-synthesized ZnS Nanostructures

The FE *I-V* characteristics can be analyzed by a simplified Fowler-Nordheim (F-N) equation:

$$J = \frac{A\beta^2 E^2}{\phi} \exp\left(-B\frac{\phi^{3/2}}{\beta E}\right) \tag{1}$$

Where J is the emission current density, E is the macroscopic field, ϕ is the work function of the emitter, A and B are the constants with values of $1.56\times10^{-10}AV^{-2}eV$ and $6.83\times10^{3}VeV^{-3/2}\mu m^{-1}$, respectively [23]. The β is the FE enhancement factor that represents the true value of the electric field at the tip compared to its average macroscopic value. The β can be calculated from the slope of the FN plot [$\ln(J/E^2)$vs1/E plot] if the work function is known. The inset in Figure 4 shows the F-N plot of the field emission result, and the emission process obeying the law well. Assuming the work function of ZnS to be 5.4eV [23], from the slope of curve shown in the inset of Fig. 4, the factor β can be calculated from the following equation:

$$\beta = -6.83\times10^{3}\frac{\phi^{3/2}}{S} \tag{2}$$

S is the slope of the straight line in Figure 4, the experimental value of β is estimated to be 554 for the ZnS dentalation structures. The factor β is strongly affected by the nanostructure density, the emitter geometry (such as aspect ratios), its crystal structure, and vacuum gaps. The relatively lower β value may be attributed to the low quality crystalline of the teeth. While since the dentalation structures shape gives them the advantage of having many sharp tips and edges, the electrons can be emitted easily form the ZnS thin layer even if a small voltage is applied on those sharp tips, exhibiting decent emission performance.

Summary

The synthesis of microstructures with sharp tips is always the center of field emission research and application. In this letter, compared with the traditional thermal evaporation techniques (above 1000℃), ZnS dentalation nanostructures have been synthesized in a large scale by simple thermal evaporation method at lower temperature with Au as catalyst. The turn-on field was extrapolated to be about 5.56V/μm. The possession of decent turn-on field should be attributed to the specific sharp tips and high aspect ratios of the present needle-shaped structure. The present nanostructures are expected to become valuable in fundamental field emission research and device applications

Abstract: Multi- walled carbon nanotube and nano TiO_2 composite,(MWCNT)-TiO_2,was synthesized via sol-gel deposition method. The product was characterized with FE-SEM and XRD analysis and the results were compared with nano-tube TiO_2 prepared by thermal treatment of the produced nano-composite. Photocatalytic degradation of acetaldehyde, under UV and visible light irradiation, was performed in a continuos flow reactor equiped with 80W Hg lamp and the results were compared with commercial TiO_2 powder (P25). Results showed considerable decrease in concentration of acetaldehyde fed into the reactor during a short time (70 min) for hybrid materials in comparison to nano-tube TiO_2. Furthemore, under visible light irradiation nanocomposite materials revealed good improvement in photocatalytic efficiency with respect to P25 powder.

Introduction

In recent years, attention to the environmental issues has become a driving force to develop new methods of removing pollutants. Photocatalytic degradation of environmentally inadaptable materials is a powerful method to gain this aim. Among photocatalysts, titanium dioxide, with a band gap of 3.25 eV (anatase), can absorb light with wavelengths of 385 nm and below to activate water molecules to create strongly oxidizing hydroxyl radicals and strongly reducing dioxygen ions (O_2^-) [1,2]. Absorption of a photon by TiO_2 crystals, promotes electrons to the conduction band and leaves a hole in the valence band [3]. High performance of titanium dioxide is also investigated in the so-called dye-sensitized solar cells[4]. To enhance the photocatalytic activity of TiO_2, firstly improving the surface and adsorption properties are necessary. Some methods have been investigated including reduction the particle size to nano scale and making porous nano TiO_2. Some others are the formation of composite materials that can enhance the adsorption properties, therefore better electron –hole transfer and higher rate of reaction than pure TiO_2 can be occurred. Coupling carbonaceous materials with TiO_2, is a new and effective route to improve the adsorption and photocatalytic activity owing to their exceptional optical, physical, chemical and thermal properties. As an example, the photocatalytic efficiency of TiO_2 was improved by combining it with activated carbon into nanocomposite [5,6].Due to the unique electronic properties of graphene, in the last years some investigations have been reported about titania-graphene composite to enhance photovoltaic behaviors of pure titania [7-9]. Among carbonaceous materials, carbon nanotube (CNT) have been found considerable attractions owing to its superior properties. CNTs can act as supports to concentrate organic pollutants on the composite surface and more importantly to extend electron-hole (e-h) recombination time as electron scavengers [10].

The present investigation, focuses on the improvement of TiO_2 photocatalytic properties by incorporation of carbon nanotube in its structure under the visible light irradiation.For comparison, nano-tube TiO_2 was prepared by thermal treatment on MWCNT-TiO_2 nanocomposite to remove carbonacious material and its ability to degrade gaseous phase acetaldehyde was examined.

Materials and Methods

Materials

MWCNTs with 20-40 nm in diameters and one micron in length (Nutrino, Iran), Ethanol (C_2H_5OH, Merck, 99% pure), Titanium tetraisopropoxide ($Ti(i\text{-}C_3H_7O_2)_4$, Panreac, 97% pure), Benzyl alcohol (C_7H_8O, Merck, 99% pure), Acetaldehyde (CH_3CHO, Merck, 99% pure) and commercial TiO_2 powder (Sigma Aldrich) were used as received.

Preparation of nanocomposites and nano-tube TiO_2

In a typical experiment MWCNTs were dispersed in ethanol and vigorously stirred. After stirring, deionized water and benzyl alcohol, were added to the suspension. Titanium tetraisopropoxide (TTIP) was dissolved in ethanol and slowly dropped to the CNT suspension. The final molar ratio of TTIP:ethanol:water:BA was 1:30:6:3. The entire mixture was stirred at for 1 hour. After that, the precipitate was filtered and dried in air at 100°C for 6 hours. The dried sample, was calcined in air at 400°C (with a ramp of 5°C per minute) to get the desired anatase crystalline phase. After formation MWCNT-TiO_2 nanocomposite further heat treatment was used in air at temperatures up to 550°C, to form nano-tube TiO_2 with decomposition and oxidation of the MWCNTs.

Photocatalytic experiments

To perform photocatalytic tests, 15 mlit/min acetaldehyde with initial concentration of 1000 ppm, was fed into the reactor and at a distance of about 3 cm from top of it, 80W Hg lamp was placed. 0.1 gr catalysts were distributed on a filter paper and were placed on a stainless steel support. The reactor was kept in dark for 1 hr to compelete adsorption of acetaldehyde by the catalysts. The acetaldehyde concentration variations as a function of time were monitored using VARIAN CP-3800 FID detector Gas Chromatograph. To eliminate UV irradiation in visible light experiments, a UV cutter (HOYA-HMC) was used.

Characterization techniques

The X-ray diffraction (XRD) patterns of the prepared samples were collected with a Phillips diffractometer using CuKα (λ=1.54056A) radiation in angular domain of $0 < 2\theta < 80$. The morphology of the samples was investigated by field emission scanning electron microscopy (FE-SEM) with a Hitachi-F4160. Powder surface area was determined from N_2 gas-adsorption data using Brunauer–Emmett–Teller technique (BET) with Belsorb II.

Results and Discussion

FE-SEM analysis

The morphological structure of the samples has been shown in Fig.1. According to FE-SEM images and comparison of the bare MWCNTs with produced samples, formation of desired structures is observed. However, the presence of aglomerated particles in the mixture is not controllable and the stoichiometric ratios of primary materials in the synthesis procedure, affects the amount of produced grains and aglomerates.

X-ray diffraction analysis

The XRD patterns of the prepared samples are shown in Fig.2. These patterns reveals that the entire crystallite phase is anatase; because there is no rutile peak. Comparison with P25 XRD pattern (Fig.3), verifies this claim.

The average crystallite size of the synthesized samples was calculated from the XRD data according to the Scherrer's equation [11]:

$$d = \frac{k\lambda}{\beta \cos\theta} \qquad [1]$$

where d is the crystallite size, k is a constant (0.9), λ is the wave-length of X-ray (CuKα), β is the half-peak width in radians and θ is the Bragg's diffraction angle in degree. Crystallite size and wieght percentage of crystalline phases are listed in Table.1. It can be seen from Table.1 that further thermal treatment to remove carbon nanotubes have enlarged crystallite size of nano-tube TiO_2. This phenomenon decreases the specific surface area.

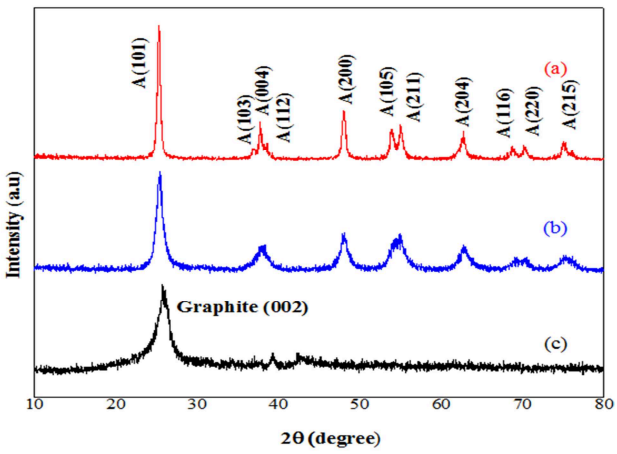

Fig. 2- XRD patterns (a) nano-tube TiO2 (b) MWCNT-TiO_2 nanocomposites (c) pure CNTs

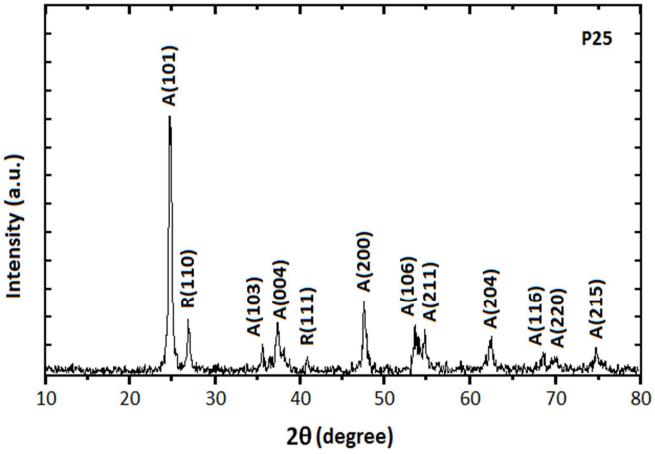

Fig. 3-XRD pattern of P25 (with the permission of ref [11])

TABLE 1- XRD RESULTS

Sample	Crystallite size (nm)	Anatase (%)	Rutile (%)
P25	25	80	20
MWCNT-TiO_2	59	100	-
Nano-tube TiO_2	165	100	-

Photocatalytic Activity

The photocatalytic activities of the nanocomposite and naotubes were determined comparatively by degradation of acetaldehyde in the air and were presented in Fig.4 and Fig.5. As can be seen

from the figures, under UV irradiation P25 shows the largest actitivity to decrease the concentration of acetaldehyde but in the case of visible light, nanocomposite sample is the most efficient material and gives the highest pollutant degradation efficiency. This can be explained by the synergystic effect of carbon nanotubes. Carbon nanotubes can act either electron sink or source. Two mechanisms are being discussed to explain the enhancement of the photocatalytic properties of CNT–TiO_2 composites. The first mechanism proposes that a high-energy photon excites an electron from the valence band to the conduction band of anatase TiO_2. Photo-generated electrons formed in the space-charge regions are transferred into the CNTs, and holes remain on the TiO_2 to take part in redox reactions. In the second mechanism, the photogenerated electron is injected into the conduction band of the TiO_2, allowing for the formation of superoxide radicals by adsorbed molecular oxygen. Once this occurs, the positively charged nanotubes remove an electron from the valence band of the TiO_2 leaving a hole. The now positively charged TiO_2 can then react with adsorbed water to form hydroxyl radicals.Also nano-tube TiO_2 has less activity. This is related to large crystallite size (acording to XRD results) and lack of enough active sites to promote degradation process.

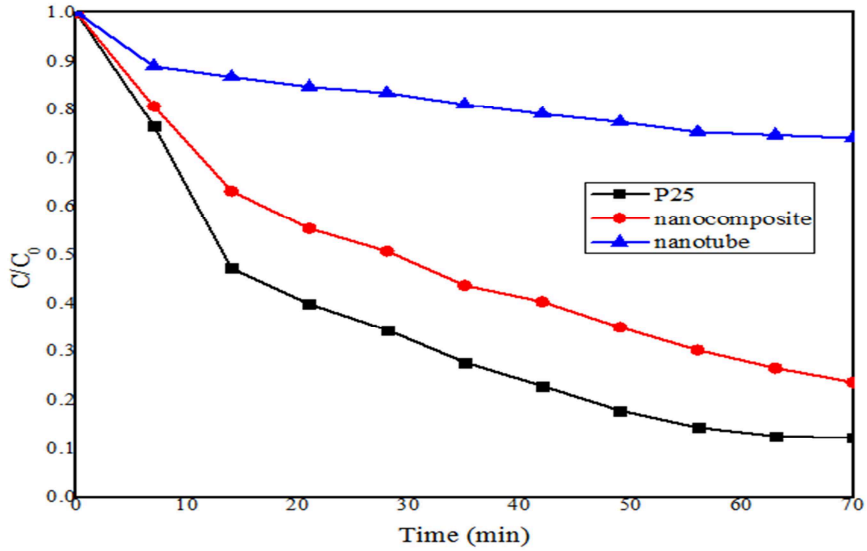

Figure 2- Photocatalytic activity under UV light

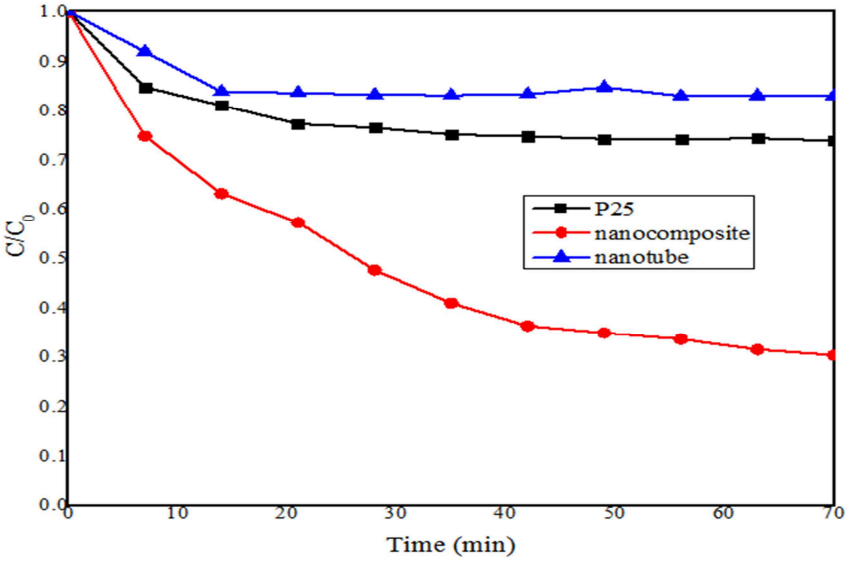

Figure 3- Photocatalytic activity under visible light

Conclusion

Nanocomposite MWCNTs - TiO_2 was synthesised by the sol-gel method. The prepared material was treated under thermal oxidation to prepare TiO2 nantube after removing the base carbon

material. The remained product after thermal treatment was a mixture of nanotube TiO2 and agglomerated TiO2 crystals in which the fraction of nanotube to the nanograin was influenced by the stoichiometry of primary materials used in the synthesis gel. Also, XRD patterns authorized pure anatase phase in the produced composite samples. In the visible light region, nanocomposite sample upgraded photocatalytic activity and showed good efficiency to remove organic pollutant in the contineous reactor. On the othre hand the nano-TiO_2 tubes could not show remarkable photoactivity towards visible light irradiation.

Keywords: Multiwalled carbon nanotubes; Epoxy resins; Nanocomposite

Abstract: In this paper, multiwalled carbon nanotubes (MWCNTs)/epoxy resins (EP) composite was prepared by situ polymerization. MWCNTs/EP composites were prepared with different content of MWCNTs. The study of morphology and properties showed certain content of MWCNTs can well homogeneous dispersed in EP. Since of interface interaction between MWCNTs and EP, the glass transition temperature (T_g), strength and toughness of MWCNTs/EP composites were improved. Compared to the neat EP, composites prepared with 10 wt% MWCNTs showed 20 ℃ rising in T_g and nine orders of magnitude reduce in volume resistivity. The percolation thresholds between 4 wt% and 6 wt% are observed. Compared to the neat EP, composites prepared with 6 wt% MWCNTs showed with 83 % increase in tensile strength, 83 % increase in elastic modulus and 89 % increase in impact strength.

Introduction

Since the considerable discovery of carbon nanotubes in 1991 by Iijima [1], they had inspired scientists to consider them for a range of potential application and have become one of the most promising fillers for reinforcement of muti-functional nanocomposites. Their remarkable mechanical [2-4] and geometrical properties (extremely high aspect ratio, nanometer-range diameter), made them ideal candidates for fibre reinforcement in composites materials.

Epoxy resins (EP) are one of the most important thermoset polymers and have been used extensively because of their performance. EP have been widely used in practical applications [5] such as adhesives, construction materials, composites, laminates and coatings owing to their excellent mechanical properties, ease of processing, low cost, and good chemical resistance. A number of recent research efforts have used CNTs for polymer composites' reinforcement [6-7]. Compared to those of the neat EP, the electrical and mechanical properties of the composites could increase.

In this paper, we described the influence of different contents of MWCNTs in the EP. The loss factor, volume resistivity, mechanical properties were tested and will be discussed.

Experimental

Mixture of MWCNTs/EP

Multiwalled carbon nanotubes with average length and diameter of 5-15 μm and 40-60 nm were obtained from Shenzhen nanoport PRC China. Epoxy resin (EP-51) was obtained from Wuxi resin factory of blue star new chemical materials CO, LTD. MWCNTs with different contents was added in the EP, and then MWCNTs were dispersed in the EP by emulsifying machine to obtained MWCNTs/EP mixture.

Preparation of MWCNTs/EP composite

The MWCNTs/EP mixture and 45wt% curing agent PA651 were put respectively in an oven at 60℃ for 2h. Then mixed and stirred at 100r/min to obtain a mixture. The mixture was put into the rectangular mold and then cured in an oven at 70℃/2h, 125℃/2.5h, and 150℃/1h.

Results and discussion

In the research, the addition of 2, 4, 6, 8 and 10wt%WMCNTs to EP was compared with neat EP. Fig.1 showed the loss factor tanδ as a function of MWCNTs contents. The results showed that compared with neat EP, the loss factor peak of MWCNTs/EP composites was shifted to higher temperature, namely T_g increased with the addition of MWCNTs. Because the MWCNTs had good thermal stability and MWCNTs can promote curing reaction of EP, so that the crosslinking density and curing degree increased, at the same time, free volume decreased and mobility of chains were reduced due to the addition of MWCNTs. At the other hand, acid-treated MWCNTs formed chemical bonds with the EP, so that the resistance of molecular chain movement increased. Therefore, dispersing the MWCNTs in EP could improve T_g.

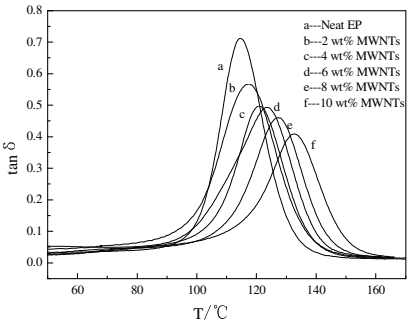

Fig. 1 Influence of MWCNTs content on the T_g of MWCNTs/EP composites

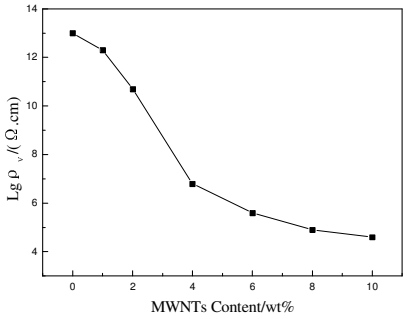

Fig. 2 Influence of MWCNTs content on the volume resistivity of MWCNTs/EP composites

Fig.2 showed volume resistivity as a function of weight fraction of MWCNTs in the EP. The volume resistivity of MWCNTs/EP composites is lower than neat EP, namely conductivity increased. Increasing additions of MWCNTs from 0 to 10wt% resulted in an almost 9 orders of magnitude reduction in resistivity. As the concentration of MWCNTs increased, the average distance between MWCNTs decreased until an effective interconnectivity of MWCNTs in the EP matrix is formed, and electron transport is then facilitated through tunneling throughout the polymer. So the electrical resistivity for this EP reduced and conductivity increased greatly. The percolation threshold was in 4-6wt%.

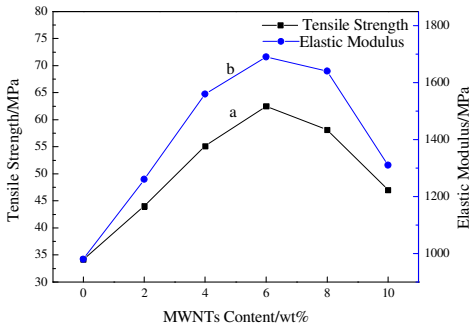

Fig. 3 Influence of MWCNTs content on the tensile strength and elastic modulus of MWCNTs/EP composites

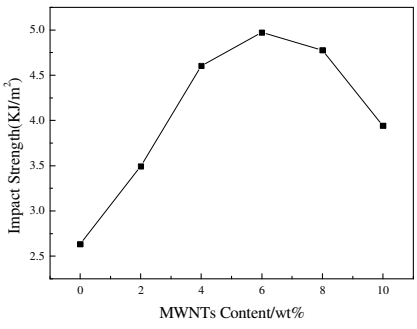

Fig. 4 Influence of MWCNTs content on the impact strength of MWCNTs/EP composites

Fig.3 (a) showed the tensile strength as a function of weight fraction of MWCNTs in the EP, and (b) showed the elastic modulus as a function of weight fraction of MWCNTs in the EP. Fig.4 showed the impact strength as a function of weight fraction of MWCNTs in the EP. All date sets reveal the increase and then decrease as a function of MWCNTs weight fraction. When the fraction of MWCNTs in the EP is 6% by weight, the tensile strength and the elastic modulus increased 83% and the impact strength increased 89% compared with neat EP. Owing to the excellent mechanical properties, high strength and good toughness of MWCNTs. Acid-treated MWCNTs were difficult aggregation in the EP, so it could form a good interface in the composites. The force on the composites effectively transferred to the MWCNTs through the interface and prevented the stress concentrations, thus the tensile strength and the impact strength increased. But when the MWCNTs is increased to a certain amount, they were easy aggregation again, and couldn't form a good interface, even formed defects in the matrix, so this made the stress concentrations, and tensile strength, elastic modulus and impact strength decreased.

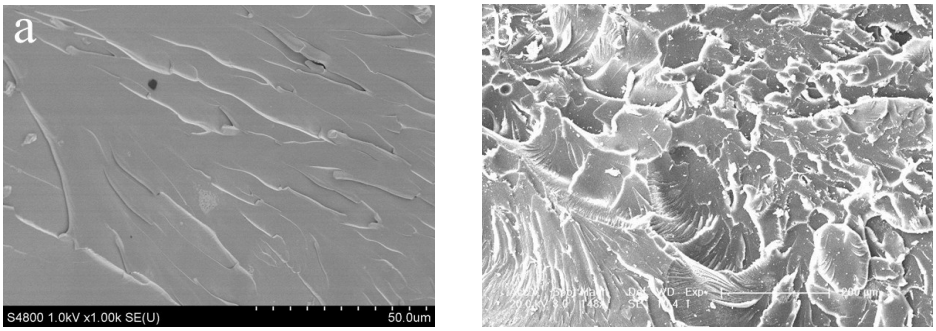

Fig. 5 SEM micrographs of fracture surfaces of neat EP and MWCNTs/EP composites

(a) cured neat EP , (b) 6wt% MWCNTs

The morphology and extent of dispersion of MWCNTs in the EP was investigated using scanning electron microscopy (SEM). The fracture surface of neat EP (Fig.5a) indicated brittle fracture of the materials. The MWCNTs/EP composites showed a somewhat rougher fracture surface which is a corroboration of the observed increase in fracture energy. After adding a certain amount of MWCNTs, the fracture surface of MWCNTs/EP composites became rougher than neat EP, and the fracture surface of the composites exhibited clear features of the toughness. So it indicated MWCNTs could increase the strength and toughness of EP, due to their mechanical properties, the fibre-shaped structure (high aspect ratio) and the huge interface provided. And in the Fig.5 (b) a good dispersion of the MWCNTs in the EP could be observed.

Key words: Natural Rubber; zinc oxide; nanocomposite; dispersion; anti-bacterial property.

Abstract: Natural rubber /Zinc Oxide (NR/ZnO) nanocomposites are fabricated by blending natural rubber latex with aqueous suspension of nano-ZnO particles. Its morphology and thermal/thermooxidative ageing resistance are investigated with scanning electron microscopy (SEM) and thermogravimetric analyzer (TGA). The results show that the mechanical properties of NR is greatly improved by the incorporation of nano–ZnO, nanoparticles, which are homogenously distributed throughout NR matrix as nano-clusters with an average size of 80 nm when the ZnO loading is less than 4 wt%. The thermal/thermooxidative aging resistance of NR/ZnO nanocomposites is compared to the pure NR. It is found that the introduction of nano-ZnO has no obvious impact to the thermal decomposing properties of NR matrix. ZnO/NR composites possess excellent antibacterial effect.

Introduction

Natural rubber latex, as one of the most important natural polymers, has been widely used in various areas. Many medical products such as medical glove, condom, blood transfusion tubing, catheter, injector closure and safe bag are made from natural rubber latex due to its excellent elasticity, flexibility, anti-virus permeation, human body compatibility and good formability.

Low tensile strength and poor tear resistance are the other major drawbacks of NRL products, however, especially for medical gloves and condoms. In the past attempts have been made to reinforce NRL products by using of carbon black, ultra-fine calcium carbonate , modified montmorillonite , silica and starch[1-4].

Nano-ZnO, as one of the multifunctional inorganic nanoparticles, has drawn increasing attention in recent years due to its many significant physical and chemical properties. The introduction of nano-ZnO into polymers could improve the mechanical and optical properties of the polymers due to a strong interfacial interaction between the organic polymer and the inorganic nanoparticles. Consequently, this nanoparticle could be widely applied in coatings, rubbers, plastics, sealants, fibers and other applications.

In this article, natural rubber latex/ZnO nanocomposites were prepared.The dispersion of nano-ZnO in the NR matrix was observed with SEM, and the effect of the addition of nano-ZnO on the thermal decomposition of NR was characterized by thermal analyses.

EXPERIMENTAL

Materials

Natural Rubber latex (NRL) with a total solid content of 60% was purchased from Shuguang Rubber Plantation (Maoming, China), and zinc oxide nanoparticles (average diameter: 40 nm, purity: 99.99%) from were purchased from the market.

Preparation of natural rubber latex/ ZnO nanocomposites

The natural rubber latex/ZnO nanocomposites were prepared by using of blending methods. Briefly, natural rubber latex and different contents of nano-ZnO slurry was blended under high shear stirring. The surface of nano-ZnO was treated through some methods before blending. Then the composites were vulcanized by the recipe for vulcanization: S,1； ZDC, 0.4； ZnO, 0.2.

Characterizations

Tensile and tear resistance testing were conducted on an Instron Series 3365 Automated Materials Testing System (Instron, USA) with a crosshead speed of 500 mm/min. The measurement was done under at room temperature.

Scannning electron microscopy (SEM) of the nanocomposites were taken with a Philips XL 30 FEG-SEW instrument (Philips, Eindhoven, Netherlands) at an acceleration voltage of 10 kV. The fracture surface was obtained by splitting the bulk sample quenched in liquid nitrogen. A sputter coater was used to pre-coat conductive gold onto the fracture surface before SEM observation.

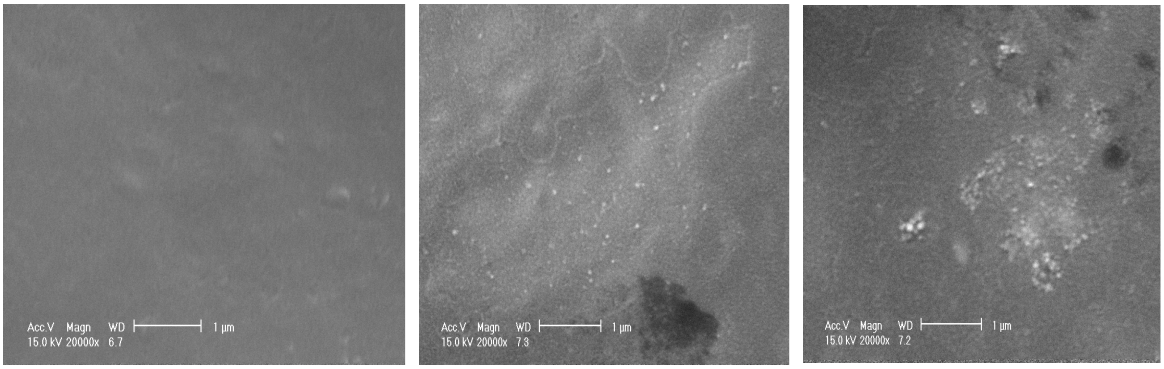
A STA449C thermogravimetric analyzer (TGA) (NETZSCH, DE) was used for thermal and thermooxidative decomposition measurement. In nitrogen or air, the measurement of the films (ca.10 mg) was carried out from 50℃ to 650 ℃ at a heating rate of 10℃/min. The flow rate of the carrying gas is 50 ml/min.

RESULTS AND DSCUSSION

Mechanical property

The incorporation of inorganic nanoparticales into elastomer matrix leads to a significant improvement in the mechanical properties of the host elastomer. Table 1 lists the mechanical properties of the pure NR and NR/ZnO nanocomposites with different ZnO loading.

As shown in table 1 the introducing ZnO into NR can significantly improve its tensile strength. The tensile strength increases with an increasing ZnO loading. At ZnO content of 2 wt%, the tensile strength has increased by 13 MPa compared to the pure NR. However, when the nano-ZnO content of the sample is more than 2 wt%, the tensile strength decreases.



Another noticeable improvement is observed in tear resistance. Poor tear resistance is one of the major problems for NRL product. Introducing nano-ZnO into NR can significantly improve its tear resistance. The tear strength increases with an increasing ZnO loading. At nano-ZnO content of 4 wt%, the tear strength (60.9 kN/m) is higher that of the pure NR (37.4 kN/m). However, the tear strength decrease significantly at the nano-ZnO content of 5 wt%.

However, the ZnO reduces the flexibility of NR due to the restriction of molecular chain slipping along the filler surface. The influence of ZnO on NR's elongation at break seems relatively unnoticeable at low ZnO (less than 3 wt%) , while it plays a critical role at higher loading of ZnO. Particularly, the elongation at break of the sample with the ZnO content of 5 wt% has a increase compared to that (880%) of the sample with ZnO content of 4 wt%.

TABLE 1 MECHANICAL PROPERTIES OF THE PURE NR AND NR/ZNO NANOCOMPOSITES

Nano-ZnO loading (wt%)	0	0.5	1.0	2.0	3.0	4.0	5.0
Tensile strength (MPa)	23.6	32.9	35.5	36.6	34.4	33.0	29.3
100% elongation (Mpa)	0.67	0.71	0.72	0.75	0.76	0.79	0.76
300% elongation (Mpa)	1.16	1.26	1.30	1.33	1.33	1.40	1.32
Elongation at break (%)	963	987	928	887	882	880	906
Tear strength (MPa)	37.4	40.8	43.0	45.2	47.5	60.9	51.9

Morphology of NRL/ZnO nanocomposite

(a) (b) (c)

Fig. 1 The morphology of NR/ZnO nanocomposites:(a)the pure NR, (b) NR with 2% nano-ZnO, (c)NR with 4% nano-ZnO.

Figure 1 shows the morphology fracfure obtained by splitting the bulk sample quenched nitrogen. There are a little amount of ZnO of larger sizes as the vulcanizing agent in the control sample (a);In the sample with a loading of 2% of nano-ZnO, it can be found that the ZnO dispersed evenly in the NR matrix, which had basicly reached dispersion state of nano-meter scale(about 80 nm),with a fuzzy interface between the ZnO and NR matrix, indicating that there is a strong interaction between ZnO and NR to comes the improvement in the physical properties of NR. However, when the content of ZnO was increased to over 4%, the physical properties decressed due to the large agglomeration the uneven dispersion of ZnO in the NR matrix.

Thermal and Thermooxidative Ageing Resistance

The thermal and thermooxidative ageing resistance of NR/ZnO nanocpmposite can be assessed, respectively, by the investigation of thermal and thermooxidative decomposition. Figure 2 shows TG and DTG curves of the pure NR and NR/ZnO nanocomposite in nitrogen. There is only one obvious thermal decomposition step of NR molecular chains, primarily initiated by thermal scission of C-C chain bonds accompanying by a transfer of hydrogen at the site scission.

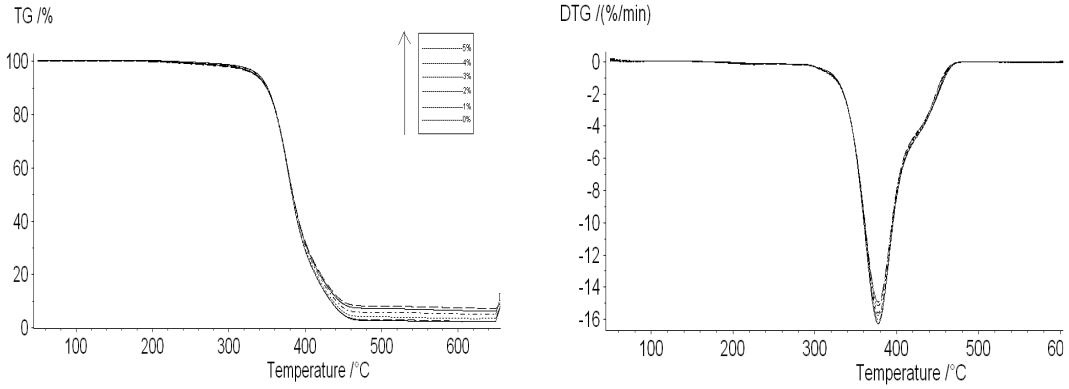


Fig. 2 TG and DTG curves for pure NR and NR/ZnO nanocomposites in nitrogen

The thermooxidative decomposition is obviously different from the thermal decomposition as shown in Figure 3, which are the TG and DTG curves of the pure NR and NR/ZnO nanocomposites in air, respectively. The first large decomposition peak is caused by oxidative dehydrogenation accompanying hydrogen abstraction, while the second weak peak is resulted from the oxidative reaction of residual carbon.

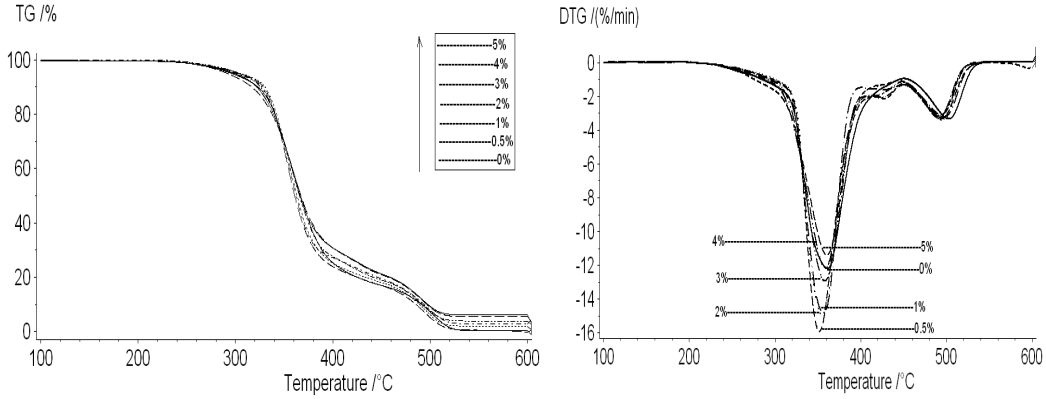

Fig. 3 TG and DTG curves for pure NR and NR/ZnO nanocomposites in air

The initial (T_0), maximal (T_p) and final (T_f) temperatures of decomposing are calculated from the TG and DTG curves. The temperature range of the thermal degradation, an important parameter to evaluate the degree of degradation, is expressed as $\Delta T = T_p - T_0$. These characteristic temperatures are summarized in Table 2.

TABLE 2 CHARACTERISTIC TEMPERATURES OF THERMAL AND THERMOOXIDATIVE DECOMPOSITION FOR PURE NR AND NR/ZNO NANOCOMPOSITES WITH DIFFERENT NANO-ZNO CONTENTS

Sample	Thermal decomposition				Thermooxidative decomposition			
	T_0(℃)	T_p(℃)	T_f(℃)	ΔT(℃)	T_0(℃)	T_p(℃)	T_f(℃)	ΔT(℃)
NR	353.2	377.9	412.0	24.7	332.6	361.4	388.0	28.8
0.5%	353.4	378.2	412.2	24.8	332.1	352.2	375.4	20.1
1%	352.8	377.9	412.2	25.1	331.3	355.3	378.1	24.0
2%	352.7	377.9	412.2	25.2	330.1	356.7	374.7	26.6
3%	353.0	378.2	411.9	25.2	328.9	358.4	381.3	29.5
4%	352.6	377.9	412.3	25.3	326.6	359.0	379.6	32.4
5%	352.4	377.9	412.3	25.5	324.8	360.7	382.1	35.9

When the ZnO/NR nanocomposite was degraded in air, the initial (T_0), maximal (T_p) and final (T_f) temperatures of decomposing were all lower that those of control sample, which is different from the simplely accelerating or delaying of degradation abilities demonstrated by the addition general kinds of nanoparticles such as SiO_2 into rubber. With the increment in nano-ZnO content, the initial decomposing temperature decreased, the maximal decomposing temperature, however, decreased then increased and finally approached that of pure NR. Previous studies [5-7] had shown that, the metal consists of variable valence would cause electron transferring and accelerate the production of free radicals to speed up the rupture of rubber hydrocarbons, resulting in the thermal degradation of rubber hydrocarbons and the production in ageing resistance. And the Zinc ion in the Nano-ZnO just possesses such a function. With the increment in nano-ZnO content, the physical shielding exhibited by ZnO caused the improvement in thermal degradation and ageing resistance; when the content of nano-ZnO was increased to a certain amount, however, the thermal decomposing and ageing resistance tended to approach thet of NR sample without the addition of nano-ZnO.

Anti-bacterial property

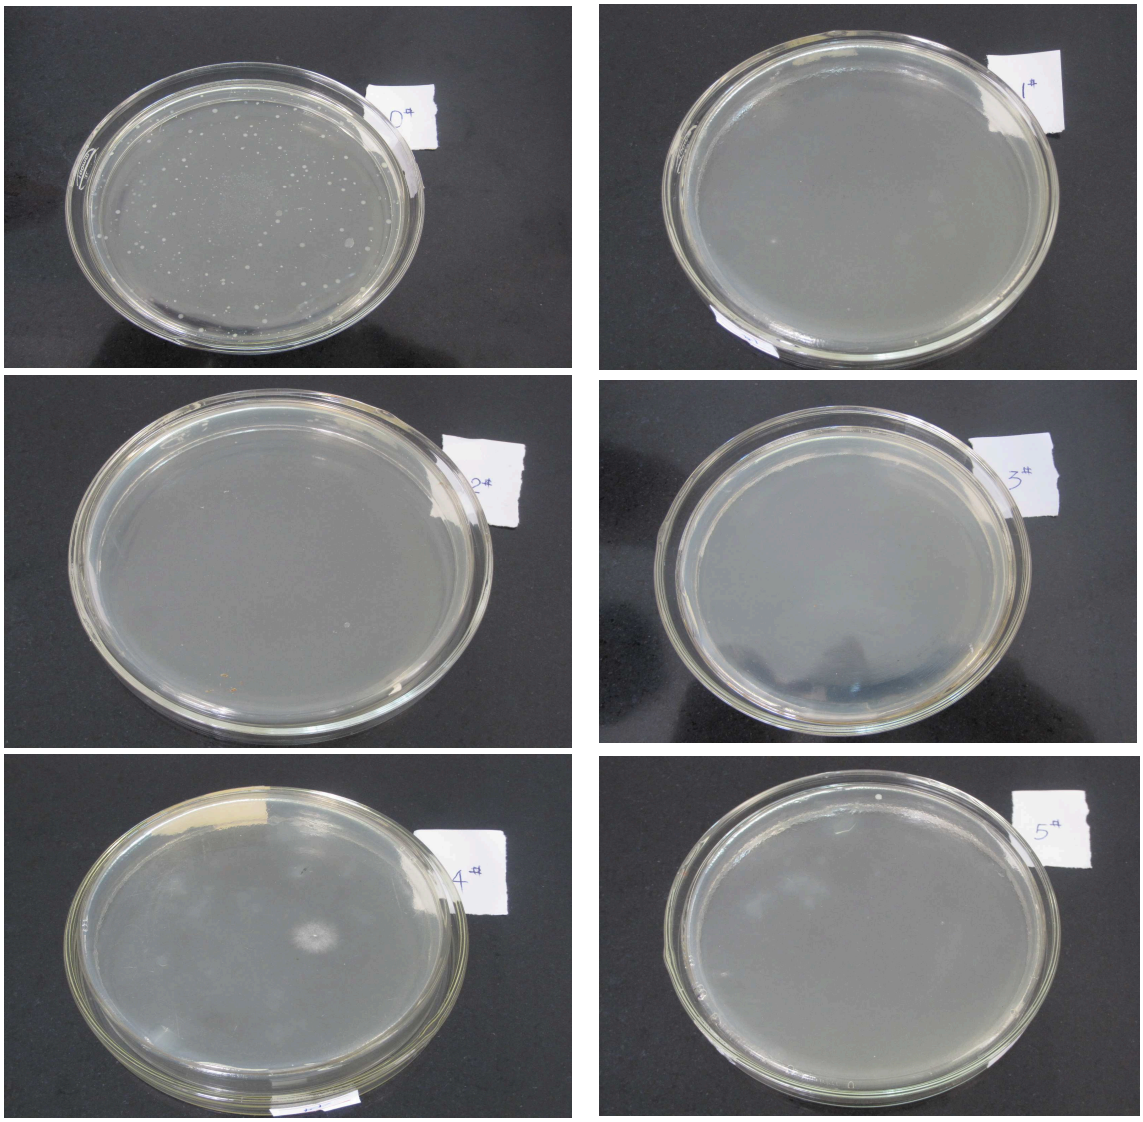

Fig.4 The colony's morphology of (0#) pure NR sample and (1#~5#) ZnO/NR nanocomposites

Fig.4 show the colony morphology of pure NR and ZnO/NR nanocomposites, and the number of Escherichia coli colony which had been cultivated at the antibacterial experiment for 24 hours.The number of Escherichia coli colony reached 70 cfu for each piece of the pure NR material. However, less than 10 cfu for each piece of ZnO/NR nanocomposites was observed. It is evident that the ZnO/NR nanocomposites possess excellent antibacterial property. Furthermore, the antibacterial rate didn't increase with the increasing loading of ZnO in nanocomposites.

Materials possess anti-bacterial function if its anti-bacterial rate is above 90%, according to antibacterial plastics standard (QB/T 2591-2003). In the current work we found that the antibacterial rate of ZnO/NR composite was all higher than 90%, which confirmed the fact that the ZnO/NR composites possess excellent antibacterial effect.

CONCLUSIONS

Natural rubber/ZnO nanocomposites was fabricated, and its physical properties, were investigated. The mechanical properties of NR are observed to improve by the incorporation of nano -ZnO. It can seen from the SEM micrograph that the nano-ZnO was dispersed evenly in the NR matrix in nano dimension..The thermooxidative decomposing temperature was reduced to some extent by the loading of nano-ZnO, however, with the increment in the ZnO content, the maximum decomposing temperature tended to approach that of pure NR sample. ZnO/NR composites possess excellent antibacterial effect.

Keywords: Bimodal nanocrystalline materials; Cohesive zone; Fracture toughness; Grain size

Abstract: To research the effect of grain size on the fracture toughness of bimodal nanocrystalline (BNC) materials which are composed of nanocrystalline (NC) matrix and coarse grains, we have developed a theoretical model to study the critical stress intensity factor K_{IC} (which characterizes toughness) of BNC materials by considering a typical case where crack lies at the interface of two neighboring NC grains and the crack tip intersect at the grain boundary of the coarse grain, the cohesive zone size is assumed to be equal to the grain size d of the NC matrix. Blunting and propagating processes of the crack is controlled by a combined effect of dislocation and cohesive zone. Edge dislocations emit from the cohesive crack tip and make a shielding effect on the crack. It was found that the critical stress intensity factor K_{IC} increases with the increasing of grain size d of the NC matrix as well as the coarse grain size D. Moreover, the fracture toughness is relatively more sensitive to the coarse grain size rather than that of NC matrix.

Introduction

Even though exhibiting remarkable improvement in strength, most of the experimental studies reveal that NC materials generally possess insufficient ductility compared with their coarse-grained conventional counterparts [1, 2]. However, the evidence of tensile superplasticity in NC materials has been reported, but these cases appear to be not numerous, and often occur only at high temperatures, or with micro tensile samples using specialized testing method [3-5].

As the deficiency of low ductility and the associated loss of toughness in some materials stop their applications in engineering. According to engineering practice and theoretical experience, people always build a composite structure to enhance the ductility of such materials [6-8]. Many approaches have been proposed to enhance the ductility of NC materials [9-12]. One of the several strategies that have been suggested for enhancing ductility in NC materials is to develop a bimodal grain size distribution, in which fine grains can provide high strength, whereas coarse grains can enable strain hardening to enhance ductility [13-15].

It can be seen from the above literatures that even though there are many experiment observations that the ductility of NC materials with a bimodal grain size distribution can be enhanced, there are few literatures doing quantitative study on the fracture toughness of BNC materials. For instance, Ovid'ko and Sheinerman [16] built a theoretical model that describes the generation of nanoscale cracks of BNC materials, in the frame work of their model, cracks were generated in the stress field of interfacial disclination dipoles formed at the interfaces between larger grains and NC matrix during plastic deformation. But, it did not consider the critical stress intensity factors. Fan et al. [17] studied the plastic deformation and fracture of ultrafine-grained Al–Mg alloys with a bimodal grain size distribution, the Ramberg–Osgood equation was used to fit the compressive stress–strain curves of the bimodal ultrafine-grained (ufg) alloys, it was found that the plastic deformation of the ufg Al–Mg alloys with a bimodal microstructure was highly localized. The fracture of the alloys was attributed to shear localization under the compressive tests and to a combination of shear localization, cavitation and necking under the tensile tests. However, the grain

size of their ufg matrix did not reach the nano-scale. Han et al. [18] investigated the strain rate sensitivity and the strain rate effect on the ductility of bimodal 5083 Al alloys, the mechanical responses of several bimodal 5083 Al alloys with different fractions of coarse grains were studied at different strain rates. It was found that the failure strain increases with decreasing strain rate for the plastic deformation when the strain rate is less than $10^{-1}\ s^{-1}$, but it was very difficult to conduct quantitative calculation using their model. Zhu et al. [19-20] built two statistical models to study the strength and ductility of BNC materials. The calculating results show that nano micro cracks don't lead to catastrophic failure, instead, they induce the back stress for strain hardening in BNC materials; However, their models did not consider the crack propagation and calculate the critical stress intensity factor. We [21] also built a constitutive model of BNC materials based on a strain-gradient plasticity theory, but we did not consider the fracture of such materials.

Besides, there are many other literatures to study BNC materials [22-24] and most of them mainly described the experimental phenomena rather than established a mathematical model to take quantitative analysis. During the last few decades, cohesive model of fracture has gradually evolved as an attractive tool to model crack initiation and propagation [25-28]. As can be seen from the above literatures, most of the cohesive zone models are used to study the fracture of coarse grained materials rather than NC/BNC materials. The present paper is aimed at studying the fracture toughness of BNC materials by using a combined dislocation—cohesive zone model.

Dislocations cohesive model

In this paper, we will focus on the dislocation shielding on a Dugdale [29] cohesive crack under mode I dominant conditions (Fig. 1). The crack lies at the interface of two adjacent NC grains with the crack tip intersecting at the grain boundary of the coarse grain. The rectangular cohesive law of Dugdale, as shown in Fig. 1 (b), is assumed to govern the traction within the cohesive zone OO' of length L. The origin of the (x, y) coordinate system (point O) is located at the tip of the cohesive zone. With increased external load, *N* edge dislocations will emit from the crack tip, and it is assumed that the emitted dislocation is retarded at the opposite grain boundary of the coarse grain, as shown in Fig. 1 (a).

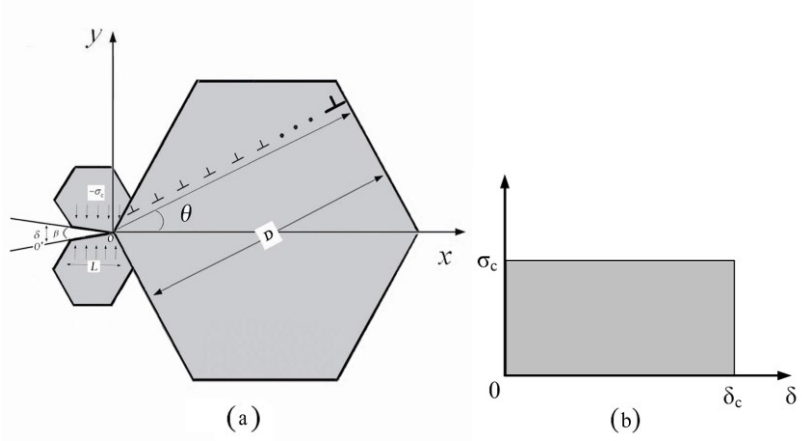

Fig.1 (a) A Dugdale cohesive crack, subjected to a remote mode-I loading, lies at the interface of two adjacent grains with the crack tip intersecting the grain boundary of the third grain. N edge dislocations with Burgers vectors b emit from the crack tip and slip to the opposite grain boundary, the crack tip cohesive zone size is L. The cohesive zone starts at O' where the crack-opening displacement is calculated. (b) Dugdale's (rectangular) cohesive law with cohesive strength σ_c and critical displacement δ_c.

The stress intensity factor K_{IC} at O is calculated as

$$K_{IC} = \sqrt{(K_{IC}^{c})^2 - (k_{II}^{dis})^2} - k_{I}^{dis} \quad (1)$$

where, K_{IC}^{c} is the intensity factor for the cohesive stress σ_c, while k_{I}^{dis} and k_{II}^{dis} are , respectively, the intensity factors for the normal (to the crack line) and shear stresses created by the generated dislocations. The mode I stress intensity factor for a semi-infinite crack subjected to a distribution of normal traction p(*x*) along the crack surfaces [30] is

$$K_{\mathrm{I}} = \sqrt{\frac{2}{\pi}} \int_{-\infty}^{0} \frac{p(t)}{\sqrt{-t}} dt \tag{2}$$

In the Dugdale model, the cohesive traction is $p_{\mathrm{c}}(t) = -\sigma_{\mathrm{c}}$ for $-L \le t \le 0$ and vanishes over the rest of the crack faces, as shown in Fig. 1 (b). The corresponding stress intensity facto at point O is [31]

$$K_{\mathrm{IC}}^{\mathrm{c}} = -\sigma_{\mathrm{c}} \sqrt{\frac{8L}{\pi}} \tag{3}$$

Note that in the Dugdale model, the cohesive stress σ_{c} is equal to the yield strength σ_y. However, all other cohesive zone models suggest that in the traction-separation process, the cohesive stress varies with the opening displacement, and there exists a maximum cohesive stress $\sigma_{\max}$ with value being a few times of the yield strength σ_y.[32] In the present paper, we will use equation (4) which provides a relation between the cohesive stress $\sigma_{\max}$ and the yield strength σ_y [33]

$$\sigma_{\max} = \frac{\sigma_y}{\sqrt{\alpha^2 - \alpha + 1}} \left[\frac{2E}{\sigma_y} \frac{\alpha + 1}{2 - \alpha} C e^{-1.5 H_0} + 1 \right]^n \tag{4}$$

where $\alpha = \sigma_{\mathrm{II}} / \sigma_{\mathrm{I}}$ is the bi-axiality ratio that defines the stress triaxiality, which is shown in Fig. 2. H_0 is set to a constant value of 0.5, an average value chosen to represent the equivalent plastic strain failure locus for lower triaxialities encountered in plane stress, C is a material dependent non-dimensional parameter. σ_y can be obtained by the well-known Hall-Petch relationship:

$$\sigma_y = \sigma_0 + \frac{k}{\sqrt{d}} \tag{5}$$

where σ_0 is the lattice friction stress, k is the H–P constant and d is the grain size. It should be noted that: 1) Many NC materials do not obey the Hall–Petch relation when the grain size decrease to a critical value (3-20 nm) [34-37]. Therefore, in this paper, we will not consider the NC materials with a grain size below 20 nm; 2) We assume that the crack tip curvature radius $\rho = 0$, it can be seen from Fig. 1 (a) that in the cohesive zone, the maximum opening displacement $\delta_{\mathrm{c}} = L\beta$, where β is the crack tip opening angle. In general, $1\mathrm{nm} \le \delta_{\mathrm{c}} \le 10\mathrm{nm}$ in the cohesive models [32], thus, in the present paper, we fix the cohesive zone $L \le 100\mathrm{nm}$, and the suggested model is questionable for the solids with grain sizes that exceed a hundred nanometers. By putting σ_0=25MPa and $k = 0.11 \times 10^6$ for NC copper into Eq. (4), we obtained the dependence of $\sigma_{\max}$ on grain size d for NC copper, as shown in Fig. 3.

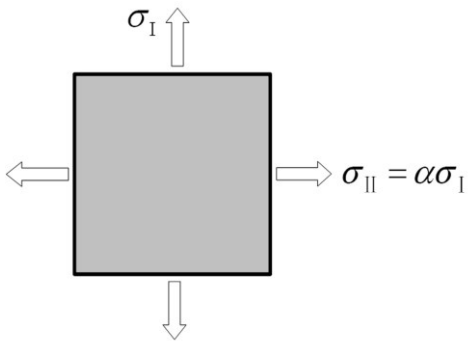

Fig.2 Schematic diagram of bi-axiality ratio, α, under conditions of plane stress.

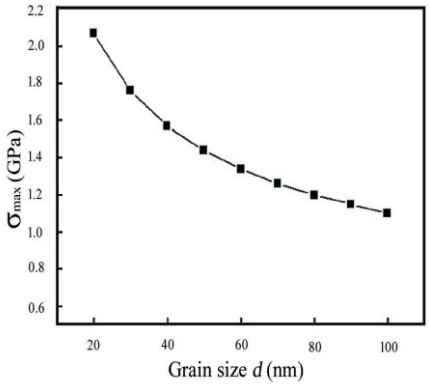

Fig. 3 Dependence of critical cohesive stress $\sigma_{\max}$ on grain size d.

Next, we will calculate the stress intensity factors $k_{\mathrm{I}}^{\mathrm{dis}}$ and $k_{\mathrm{II}}^{\mathrm{dis}}$. In doing so, as shown in Fig. 1 (a), θ is the angle made by the boundary plane (the dislocation Burgers vector) and the crack propagating direction. The stress intensity factors $k_{\mathrm{I}}^{\mathrm{dis}}$ and $k_{\mathrm{II}}^{\mathrm{dis}}$ for the dislocation-induced stresses can be calculated by [38]

$$k_{\mathrm{I}}^{\mathrm{dis}} = -\frac{3\pi D b_{\mathrm{T}} \sin\theta\cos(\theta/2)}{\sqrt{2\pi r_0}}\ ,\ k_{\mathrm{II}}^{\mathrm{dis}} = -\frac{\pi D b_{\mathrm{T}}[\cos(\theta/2)+3\cos(3\theta/2)]}{2\sqrt{2\pi r_0}} \tag{6}$$

where $D = G\ /[2(1-\nu)]$, D is the shear modulus, $b_{\mathrm{T}} = N\mathrm{b}$, is the sum of all the emitted dislocations, b =0.256 nm, denotes the Burgers vector magnitude of the edge dislocation, ν is the Poisson's ratio, r_0 is the distance between the edge dislocation and the crack tip.

Let us calculate *N*--the number of dislocations emitted from a crack tip and retarded at the opposite grain boundaries of the coarse grain. In the quasi-equilibrium state, the Burgers vector magnitude Nb corresponds to a minimum of the energy change ΔW within the dislocation generation process (Fig. 1). ΔW has three terms:

$$\Delta W = W_{\mathrm{s}} + W_{\mathrm{c}} - A \tag{7}$$

where W_{s} is the proper elastic energy of the dislocation, W_{c} is the dislocation core energy, A denotes the work spent to the generation of dislocations and the movement of dislocation from the crack tip to its final position.

Since the dislocation is located near the crack free surface, its stresses are screened. The proper energy of the dislocation can be calculated, with the aid of the formula taking into account the image forces that characterizes the screening effect, as [39]

$$W_{\mathrm{s}} \approx \frac{D b_{\mathrm{T}}^2}{2} \ln\frac{r}{r_{\mathrm{c}}} \tag{8}$$

where r_{c} is the dislocation core radius. The dislocation core energy W_c under the standard approximation is given as [16]

$$W_{\mathrm{c}} \approx D b_{\mathrm{T}}^2 / 2 \tag{9}$$

The work A spent on generation of the dislocation and the movement of the dislocation from the crack tip to its final position, is calculated in the standard way. The work A is represented in the following form:

$$A = b_{\mathrm{T}} \int_0^{\mathrm{r}} \sigma_{r\theta}^{K_I}(r,\theta)\, d\rho \tag{10}$$

Here $\sigma_{r\theta}^{K_I}(r,\theta)$, written in the polar coordinate system (r,θ) with the origin at the crack tip can be given by

$$\sigma_{r\theta}^{K_{\mathrm{I}}}(r,\theta) = \frac{K_{\mathrm{I}}^{\mathrm{c}} \sin\theta\cos(\theta/2)}{2\sqrt{2\pi r}} \tag{11}$$

According to formula (10-11), one will obtain

$$A = b_T r\left(\frac{K_I^c \sin\theta\cos(\theta/2)}{\sqrt{2\pi r}}\right) \quad (12)$$

Then, with formulas (8-12), we obtain the following formula for the characteristic energy change ΔW

$$\Delta W = \frac{Db_T^2}{2}\left(\ln\frac{r}{r_c}+1\right) - \frac{b_T r K_I^c \sin\theta\cos(\theta/2)}{\sqrt{2\pi r}} \quad (13)$$

With the condition $\partial(\Delta W)/\partial b_T = 0$ of the minimum of the energy change ΔW, one finds the following expression for the number of emitted dislocations:

$$N = \frac{(1-v)K_I^c \sin\theta\cos(\theta/2)\sqrt{2\pi r}}{b\mathrm{G}[\ln(r/r_c)+1]} . \quad (14)$$

In the present work, it is assumed that all the emitted dislocations will reach the opposite grain boundary, that is, each dislocation will slip the same distance which equals to the coarse grain size *D*.

In our previous paper [40], we have calculated the critical crack intensity factor K_{IC} as a function of θ for NC Ni, as shown in Fig. 4. It can be seen from Fig. 4 that the critical intensity factor K_{IC} reaches the maximum value when the boundary plane makes the angle θ of around 70° with the direction of crack growth. By putting $\theta = 70^\circ$, we obtained the relationship between *N* and *D* the coarse grain size for NC copper which is shown in Fig. 5. It shows that *N* increases with increasing the coarse grain size *D*. It should be noted that the value of *N* is relatively small and the increase rate tends to be reduced. This means that for small grain sizes, dislocation emission along one slip plane cannot lead to a significant crack blunting and the crack can easily grow. It is because that the driving force being exerted on the dislocations will be getting smaller as the dislocations move far away from the crack tip, and the dislocations are arrested at grain boundaries which make the sliding of later emitted dislocations become more and more difficult.

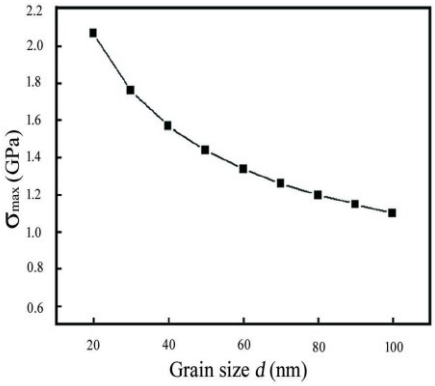

Fig.4 Dependence of critical crack intensity factor K_{IC} on the angle θ made by the boundary plane and the crack growth direction for NC nickel.

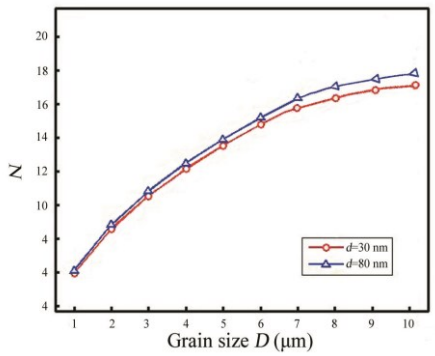

Fig.5 The maximum number *N* of edge dislocations that can be emitted from the crack tip along one slip plane as a function of coarse grain size *D* in NC copper.

Results and discussion

To understand the fracture toughness of BNC materials，numerical simulation based on the aforementioned model were carried out for the cases of BNC copper. Detailed information about the parameters of BNC copper is listed in Table 1.

TABLE 1 MATERIAL PARAMETERS IN CALCULATIONS FOR CU.

Description	Notation	Value
Magnitude of the burgers vector	G	0.256×10^{-9}m
Shear modulus of copper	b	42GPa
Poisson ratio	ν	0.3
Friction stress	σ_0	25MPa
H–P constant	k	0.11×10^{6}
Distance between the edge dislocation and the crack tip	r_0	1μm
Angle made by the boundary plane (the dislocation burgers vector) and the crack propagating direction	θ	70°
Dislocation core radius	r_c	0.256×10^{-9}m

When the grain size d of NC matrix is constant, with Eq. (6) and Eq. (3) substituted to Eq. (1), one will obtain the relationship between the fracture toughness and the coarse grain size D. Fig. 6 shows our calculating result which demonstrates that when the grain size d of NC matrix is constant, the critical stress intensity factor K_{IC} .increases with the increased coarse grain size D, and the change is obvious. For example, when the grain size of the NC matrix d=30 nm, the fracture toughness increases by 31.6% as the coarse grain size D increases from 1 to 10 μm. It is because that the number of emitted dislocations N increases with increasing the coarse grain size D which can prove more shielding effect on crack.

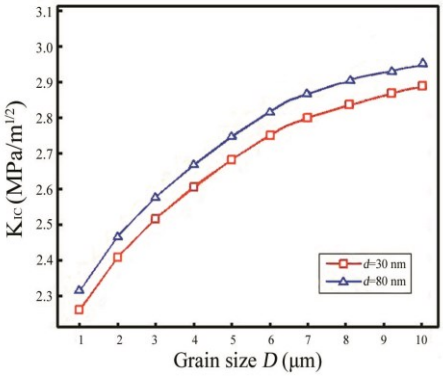

Fig. 6 Critical stress intensity factor KIC vs. coarse grain size D in NC copper.

With the same calculation procedure, when the coarse grain size D is fixed can obtain the relationship between the fracture toughness and the grain size d of the NC matrix. Fig. 7 shows our calculating result which suggests that when the coarse grain size D is constant, the critical stress intensity factor increases with the increased grain size d, and the increase is relatively small. For example, as D is set to be 5 μm, K_{IC} increases by 4.2% when the grain size d increases from 20 to 100 nm. It demonstrates that the fracture toughness of BNC materials is not highly sensitively to the grain size d of the NC matrix. In addition, our calculated fracture toughness values are between 2 and 3 MPa/m1/2, which are smaller than the experimental data. This can be explained by two reasons: 1) In the present model, we did not consider the dislocations already existing in real materials but the dislocations emitting from crack tip, 2) we did not consider the alternative

deformations such as grain boundary sliding, diffusional creep, rotational deformation and nanoscale twin which are capable of causing good toughness of BNC materials under certain conditions.

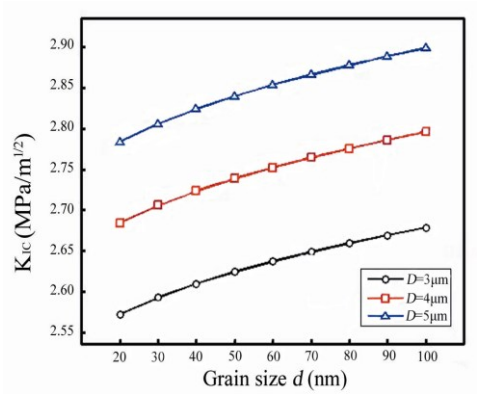

Fig.7 Critical stress intensity factor K_{IC} vs. grain size d in NC copper.

Conclusions and prospects

In the present work, we have developed a theoretical model to study the critical stress intensity factor K_{IC} of BNC materials: the cohesive stress near crack tip in the NC matrix initiates edge dislocations which move from the grain boundary of the coarse grain to the opposite one. The emitted dislocations provide a shielding effect on the crack. The dependence of both the maximum number of dislocations, emitted from a crack, and the critical stress intensity factor on grain size d of the NC matrix (ranging from 20 to 100 nm) as well as to the coarse grain size D (ranging from 1 to 10 μm) for Cu were calculated. The calculating results show that: i) BNC materials have higher fracture toughness than NC materials, ii) when the grain size d of NC matrix is constant, the critical stress intensity factor increases with increased coarse grain size D , and the change is obvious, iii) as the coarse grain D is fixed, the critical stress intensity factor increases with the increased grain size d of NC matrix, and the increase is relatively small. In this model, we only consider the K_{IC} of the BNC materials in a certain case: the crack lies at two neighboring NC grains and the crack tip intersect at the grain boundary of the coarse grain. It is known that the crack blunting and growth processes are strongly influenced or even controlled by alternate deformation modes (e.g., diffusional creep, rotational, grain boundary sliding and twin deformation), these deformation modes may cause high toughness of NC materials under certain conditions, and the influence of alternative deformation modes on the toughness of NC materials is largely unknown and needs further study.

Abstract. In this study, the effect of solid-liquid volumetric ratio in laminar flow of nano-fluid has been investigated numerically. The conservation equations are utilized in three dimensional elliptical forms for laminar and steady flow, and the effects of adding aluminum oxide nano-particles to water based-fluid are studied. First, the influence of solid-liquid volumetric ratio on the secondary flow vortices, non-dimensional temperature is investigated for a flow with a fixed low Reynolds number and different Grashof numbers in a horizontal pipe. Then, the effect of variation in solid-liquid volumetric ratio on Nusselt number and convective heat transfer coefficient along the pipe is studied. The results of this study are in good agreement with the current literatures.

Introduction

With the progress of sciences and developing the fields related to heat, lots of efforts have been made to enhance heat transfer. Among these researches, using additive materials to improve the fluid properties, relating to heat transfer, has been the subject of most researches in this field [1,2]. Nano-fluid concept refers to a new type of heat transfer fluids in which metallic or non-metallic nano-particles are added to the fluid, and since these particles are too small, in order of the based fluid molecules, they are suspended in the fluid and the fluid remains homogenous and particle deposition does not occur. Moreover, nano-particles do not cause blocked ducts, pipe erosion and also pressure drop in pipes. Nano-particles strongly enhance heat conductivity of the based fluid [3-6]. Pec and Chou [7] studied experimentally mixture friction and heat transfer behaviors of two types of nano-fluids. They used aluminum oxide (Al_2O_3) and titanium oxide (TiO_2) nano-particles into water as the based fluid. The results have shown the Nusselt number for both nano-fluids increases with solid volumetric ratio and Reynolds number. Wang et al. [8] proposed a model based on experiments to predict the effective heat conduction of nano-fluids. They used non-metallic copper oxide nano-particles with the volumetric ratios of less than 0.5%.

Governing Equations

In this study, the conservation equations are utilized in three-dimensional elliptical form for laminar and steady flow. Physical properties are considered to be constant except the density variations which are obtained by Boussinesq approximation. Therefore, with ignoring viscose dissipation, the conservation equations are given as follows:

Continuity equation:

$$\frac{\partial u_j}{\partial x_j} = 0 \qquad (1)$$

Momentum equation:

$$\frac{\partial}{\partial x_j}(\rho_{nf} u_i u_j) = \frac{\partial}{\partial x_j}\left[\mu_{eff}(\frac{\partial u_i}{\partial x_j})\right] - \frac{\partial p}{\partial x_i} - \rho_{nf,0} g_i \beta_{nf}(T - T_0) \quad (2)$$

Energy equation:

$$\frac{\partial}{\partial x_i}\left[(\rho c_p)_{nf} u_i T\right] = \frac{\partial}{\partial x_i}\left(k_{eff}\frac{\partial T}{\partial x_i}\right) \quad (3)$$

And the boundary conditions are:

$$V = Const., \quad T = Const., \quad at \quad z = 0$$
$$\frac{\partial T}{\partial r} = q'', \quad u_j = 0, \quad at \quad r = a \quad (4)$$

Non-dimensional numbers Prandtl, Reynolds, Grashof and local Nusselt numbers are as follows:

$$Pr_{nf} = \frac{\upsilon_{nf}}{\alpha_{nf}} \quad (5)$$

$$Re_{nf} = \frac{u_m d}{\upsilon_{nf}} \quad (6)$$

$$Gr = \frac{g_i \beta_f q'' d^4}{k_{ef} \upsilon_f^2} \quad (7)$$

$$Nu_\theta = \frac{q'' d}{k_{eff}(T_w - T_b)} \quad (8)$$

Numerical Solution

Governing equations are solved for laminar flow heat transfer. Figure 1 shows that structured grid was used for the solution domain (pipe). In order to discretize the governing equations, finite volume method was applied. Second order upwind difference scheme was used to discretize convective term in governing equations. SIMPLEC algorithm was utilized for the coupling between velocity and pressure since it is suitable for incompressible pipe flow. In addition, energy equation was discretized via second order upwind difference scheme.

To assure the validity of the results, first, the grid independency of the results was investigated. In this regard, different computational grids were studied and finally, it was observed that the results of the grid with the size of 36*160*36 are independent of grid size in perimeter, axial and radial directions, respectively.

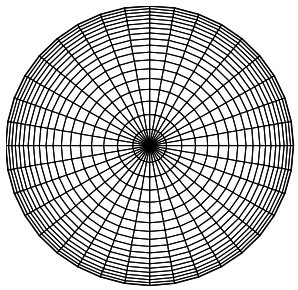

Fig 1. Computational Grid in Two-dimensional Outlet Plane with the Meshes with Similar Distances

Investigation of Variation in Nusslet Number and Convective Heat Transfer in Regard to Increasing Solid-Liquid Volumetric Ratio

Figure 2 shows the variations of Nusselt number which represent the ratio of convective heat transfer to conductive (molecular) heat transfer in terms of non-dimensional length of the pipe.

It is observed that Nusselt number decreases with increasing metallic solid nano-particles volumetric ratio i.e. molecular heat transfer increase relative to conductive heat transfer with increment of metallic solid nano-particles volumetric ratio. However, this phenomenon does not imply decreasing the heat transfer because the outlet temperature of the nano-fluid is more than that of based fluid and even the outlet temperature of the nano-fluid increases with increasing the volumetric ratio of nano-particles. Therefore, it can be concluded that molecular heat transfer (conduction) of the nano-fluid is more than that of based fluid. This fact was predictable since heat conductivity of nano-fluid is more than that of base fluid.

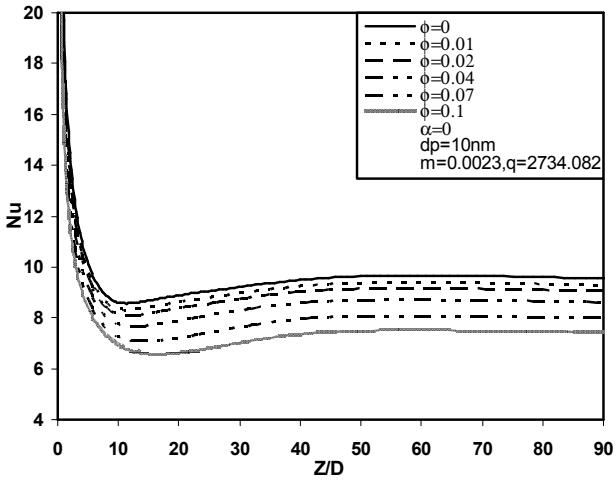

Fig 2- Nusselt Number Variations

Investigation was also done on coefficient of convective heat transfer (h) of the nano-fluid. Figure 3 shows the variations of convective heat transfer coefficient of nano-fluid in terms of a function of non-dimensional length.

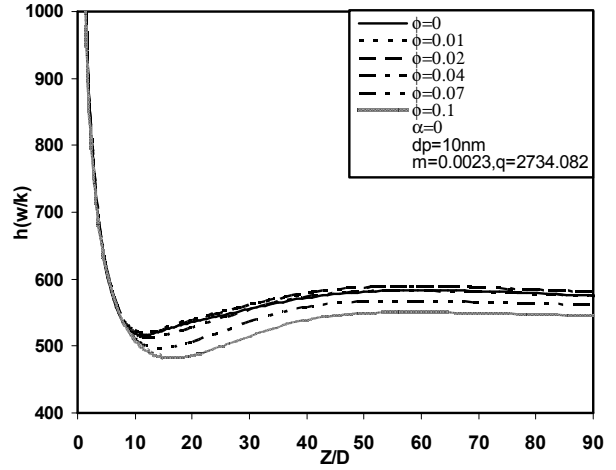

Fig 3- Variation of Heat Convection Coefficient in Terms of a Function of Non-dimensional Length

As it is obvious, first, the heat convection coefficient decreases with the increment of volumetric ratio of nano-particles and then increases. So it can be predicted nano-fluid temperature increases with volumetric concentration of solid particles and also the mean temperature of nano-fluid becomes closer to wall temperature. In this case, the thickness of thermal boundary layer is less hence, heat convection coefficient of nano-fluid increased with volumetric concentration of solid particles. But, when volumetric concentration of solid particles increases in a constant heat flux, buoyancy forces

reduce, yielding decrement of secondary velocities and consequently heat convection coefficient. Hence, for the cases with low volumetric ratios, which secondary velocities do not decrease so much, the coefficient of convective heat transfer of nano-fluid is more than that of the based fluid. But for high volumetric ratios, although the nano-fluid mean temperature approaches the wall temperature, secondary velocities decrease to some extent, leading the heat convection coefficient of nano-fluid lessens the heat convection coefficient of the based fluid (water).

Investigation on the Effects of Solid-Liquid Volumetric Ratio on Secondary Velocities and Non-Dimensional Temperature Contours

From figures showing secondary velocity vectors, decrement of buoyancy forces reduces the secondary velocity vectors and consequently, heat convection coefficient of nano-fluid decreases with increment of nano-particle concentration. This phenomenon can be justified in regard to the constant heat flux, changing the physical properties of nano-fluid and reduction of Grashof number.

Figures 4 to 7 illustrate secondary velocity vectors for a middle cross section. Obviously, increasing volumetric ratio of nano-particles and with constant heat flux and constant mass flow rate, leads to decrement of these vectors. Non-dimensional temperature contours are also shown in figure 4 to 7, in which the maximum temperature is above the pipe axis and close to upper wall, and the minimum temperature is below pipe axis and close to lower part of the wall. This is due to displacement of cool and warm fluid (secondary flows).

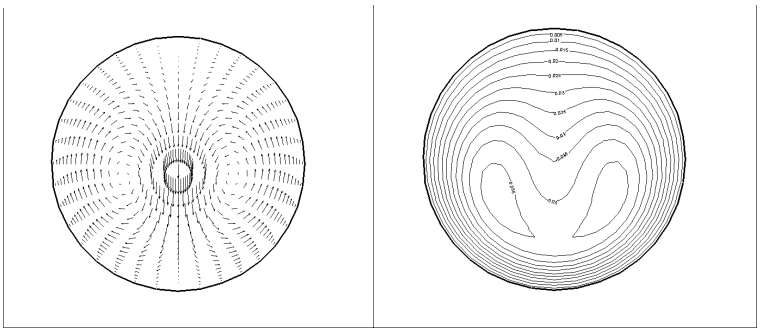

Fig- Secondary Velocity Vectors and Non-dimensional Temperature Contour for Volumetric Ratio of $\varphi = 0.02$

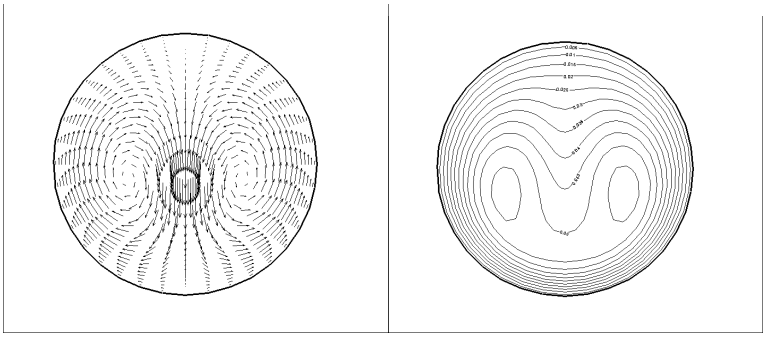

Fig- Secondary Velocity Vectors and Non-dimensional Temperature Contour for Volumetric Ratio of $\varphi = 0.04$

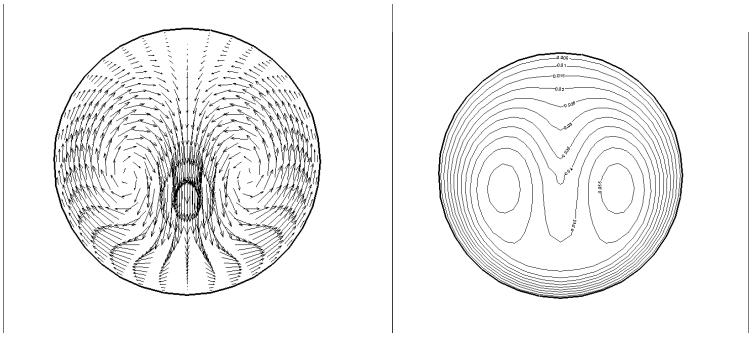

Figure 6- Secondary Velocity Vectors and Non-dimensional Temperature Contour for Volumetric Ratio of $\varphi = 0.08$

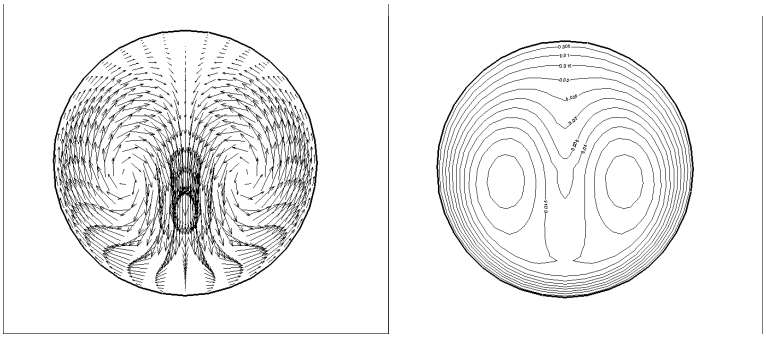

Figure 7- Secondary Velocity Vectors and Non-dimensional Temperature Contour for Volumetric Ratio of $\varphi = 0.1$

Conclusion

In this article, solid-liquid volumetric ratio of a nano-fluid in a laminar pipe flow has been investigated numerically. The nano-fluid included water as based fluid and Al_2O_3 nano-particles. The nano-fluid flow in a horizontal pipe was studied numerically considering synthetic heat transfer. The results have shown increasing volumetric ratio of nano-particles leads to increment of secondary velocity vectors and consequently, the temperature of nano-fluid in the transverse section of the pipe becomes homogenous. It is also observed adding solid nano-particles increases convective heat transfer coefficient for constant values Grashof and Reynolds number. For low volumetric ratios, the convective heat transfer coefficient of nano-fluid is more than that of based fluid due to the fact that in this case, there is no significant reduction in secondary velocities. But for high volumetric ratios, although the mean temperature of nano-fluid becomes closer to the wall temperature, secondary velocities decrease and hence, the convective heat transfer coefficient of nano-fluid becomes less than that of based fluid (water). Furthermore, the maximum temperature is above the pipe axis and near the upper part of the wall and the minimum temperature is below the pipe axis and near the lower part of the wall which is due to displacement of cool and warm fluids (secondary flows).

Particle Swarm Optimization Technique for DNA Sensor Model Based Nanostructured Graphene

Vladimir Popov[1,a]

[1]Ural Federal University, 620083, Ekaterinburg, Russia

[a]popovvvv@gmail.com

Keywords: DNA biosensors, Nanomaterials, Particle swarm optimization, Genetic algorithm, Runge Kutta neural network.

Abstract: DNA biosensors has received significant attention. In particular, we can mention the model of a graphene-based DNA sensor which is used for electrical detection of DNA molecules. In this paper, we consider a method of selection of PSO parameters for optimization of the analytical model of a graphene-based DNA sensor. In particular, we consider genetic algorithms, multilayer perceptron networks with gradient learning algorithm, recurrent neural networks with gradient learning algorithm, and 4-order Runge Kutta neural networks with different learning algorithms. Also, we present experimental results for different intelligent algorithms.

Introduction

Biological DNA sensors has during the past years received significant attention (see e.g. [1]). In particular, DNA sensors have been commonly considered for diagnostic prediction in genetic research such as cancer or hereditary disease (see e.g. [2,3]). It should be noted that different interfaces between nanomaterials and biosystems are widely studied (see e.g. [4]). In particular, the limit of planar semiconductor devices is well known. In order to overcome the limit, various nanomaterials are widely proposed in sensor platform (see e.g. [5,6]). In particular, we can mention graphene with a two-dimensional thick monoatomic block of a carbon allotrope. It offers a large detection area for DNA sensing [7-10]. In paper [11], a particle swarm optimization method (PSO) was proposed to optimize the analytical model of a graphene-based DNA sensor which is used for electrical detection of DNA molecules.

PSO is a well-known computational method [12]. The method allows us to optimize a problem by iteratively trying to improve a candidate solution with regard to a given measure of quality.

It should be noted that PSO is one of the most efficient methods. The method is extensively used to solve many problems.

However, different PSO parameters significantly affect the quality of solutions [12]. There are a number of different strategies for setting PSO parameters [12]. In this paper, we consider a method of selection of PSO parameters for optimization of the analytical model of a graphene-based DNA sensor.

Implementation of PSO in DNA Sensor

In this section, we consider the implementation of PSO in DNA sensor that presented in the paper [11]. It should be noted that in our experiments we use basic definition and the general scheme of the implementation of PSO in DNA sensor. Following [11], we consider the DNA concentration model (see [13]):

$$I_d = \frac{3q^2(3\pi a^3 t^3 k_{BT})^{1/2}}{hL}\left(J_{-1/2}(\eta) + J_{-1/2}(-\eta)\right)\left(\frac{AF^2 + BF + C}{F}V_{gs(withoutDNA)} - V_t\right).$$

The parameters to be optimized in the DNA sensor model are A, B, and C coefficients in polynomial function

$$AF^2 + BF + C$$

that models iteration method of the DNA molecules adsorbed on graphene surface (see [11,13]). Vector

$$V[i] = (A[i,k+1] - A[i,k], B[i,k+1] - B[i,k], C[i,k+1] - C[i,k])$$

is the movement velocity vector of the particle i. Following [11], we assume that the number of particles is equal to 200, the number of dimensions is equal to 3, the maximum number of iteration is equal to 300, c1=2, c2=2.

The fitness function is the sum of squares of differences of the modeled current waveform for particle and the experimental current of the DNA sensor [11]. Mean absolute percentage error (MAPE) index is used as an error evaluation parameter to evaluate the quality of the obtained waveforms with respect to the experimental results [11].

Inertia Weight

In paper [11], inertia weight W was given by relations 0.4 < W < 1.2. However, any clear evidence of such choice was not given.

It is natural to consider some intelligent algorithm for the prediction of the value of W. In our computational experiments, we consider genetic algorithms (GA), multilayer perceptron networks (MPN) with gradient learning algorithm, recurrent neural networks (RN) with gradient learning algorithm.

Let f(x) be the best fitness value for x iterations and fixed value of W. Let fT(x) be the best fitness value for x iterations and values of W that predicted by intelligent algorithm T. It is clear that we can consider f[T,x] = fT(x) / f(x) as a measure of the quality of the convergence of the optimization process using PSO with intelligent algorithm T for prediction of W. Selected experimental results for different intelligent algorithms are given in Table 1 and Table 2.

Table 1. The convergence of the optimization process using pso with different intelligent algorithms for w.

x	10	20	40	60	100	200	300

F = 100	96.48 %	96.11 %	96.54 %	96.81 %
F = 500	96.06 %	96.43 %	96.38 %	96.52 %

In Table 2, we use results for W = const from [11]. It is easy to see that we obtain only small difference for the convergence of the optimization process using PSO with different intelligent algorithms for W. However, it is clear that RN gives us some better results for the convergence of the optimization process using PSO.

It should be noted that W = const gives some better accuracy based on MAPE value for some values of concentration F then GA and MPN. However, we obtain slightly better results for accuracy based on MAPE value for PSO with RN.

Fitness Function

In this section, we continue the investigation of the prediction of the value of W by recurrent neural networks. In particular, we consider the optimization process using PSO with RN and the fitness function that predicted by 4-order Runge Kutta neural networks (see [14]). We consider 4-order Runge Kutta neural networks with the zero-order nonlinear recursive least square learning algorithm (RK[0]) and the first-order nonlinear recursive least square learning algorithm (RK[1]). We assume that the fitness function is a polynomial function that depends from differences of the modeled current waveform for particle and the experimental current of the DNA sensor.

Let fRK[j](x) be the best fitness value for x iterations where values of W were predicted by RN and the fitness function was predicted by 4-order Runge Kutta neural network RK[j]. Let f[RK[j],x] = fRK[j](x) / f(x). Selected experimental results for PSO with RN for W and 4-order Runge Kutta neural network for the fitness function are given in Table 3 and Table 4.

Table 3. The convergence of the optimization process using PSO with RN for W and 4-order Runge Kutta neural network for the fitness function.

x	10	20	40	60	100	200	300
F[RK[0],x]	0.821	0.863	0.911	0.933	0.933	0.933	0.933
F[RK[1],x]	0.544	0.673	0.789	0.791	0.791	0.791	0.791

Table 4. Accuracy based on MAPE value for PSO with RN for W and 4-order Runge Kutta neural network for the fitness function.

Concentration *F* (nM)	W = *const*	RK[0]	RK[1]
F = 0.01	95.42 %	96.49 %	98.13 %
F = 0.1	96.48 %	96.74 %	98.32 %
F = 1	96.67 %	96.83 %	98.47 %
F = 10	96.61 %	97.05 %	98.55 %
F = 100	96.48 %	96.92 %	98.12 %
F = 500	96.06 %	96.73 %	97.91 %

It is easy to see that we obtain significantly better convergence of the optimization process using PSO with 4-order Runge Kutta neural network for the fitness function. It is clear that RK[0] not gives us significant advantage for the accuracy based on MAPE value. However, we obtain considerably better results for accuracy based on MAPE value for PSO with RK[1].

Summary

In this paper, we have considered a method of selection of different PSO parameters for optimization of the analytical model of a graphene-based DNA sensor. In particular, we have considered inertia weight W and the fitness function. We have used genetic algorithms, multilayer perceptron networks with gradient learning algorithm, recurrent neural networks with gradient

learning algorithm, and 4-order Runge Kutta neural networks with different learning algorithms. We have presented experimental results for different intelligent algorithms. The best results we have obtained for simultaneous use of 4-order Runge Kutta neural networks with the first-order nonlinear recursive least square learning algorithm and recurrent neural networks with gradient learning algorithm.

Keywords: gas sensor, PECH, ethanol, MWCNTs, two-layer film, composite film

Abstract. In this paper, Polyepichlorohyron(PECH)/multi-wall carbon nanotubes(MWCNTs) composite films and PECH/multi-wall carbon nanotubes two-layer film were deposited on interdigitated electrodes by airbrush technology to detect ethanol vapor of various concentrations at room temperature. Thickness and structure of the film were taken into account, so films of different thicknesses and with different structures were prepared respectively. The responses of the sensors to ethanol showed that composite film had a higher response than two-layer film, and the thick composite film performed better than its counterpart when they were exposed to ethanol vapor.

Introduction

Ethanol is liquid at atmospheric pressure and room temperature, but it is very easy to volatilize and belongs to volatile organic compounds (VOCs). It is combustible in air, so the detection of ethanol is very necessary, and much research has been done on the detection of ethanol. Wang, T.H. et al. fabricated the ZnO nanowires ethanol gas sensor [1,2]. Tomoki Maekawa et al developed ethanol gas sensor based on SnO2, which had showed high performance [3,4,5]. However, gas sensors based on semiconductor metal oxide have high power consumption because most of them work at high temperature operation [6,7]. As a result, the research of gas sensor working at room temperature is of great value. Gas sensors based on organic materials like polymers are thought to be a good choice [8,9].Polymer sensing materials have been used in various devices such as quartz crystal microbalance [10], surface acoustic wave (SAW) [11] device, opto-chemical device and chemical resistance. In this paper, gas sensors were prepared by using PECH combined with multi-wall carbon nanotubes to detect ethanol. In order to consider different factors affecting the response of the sensors, three different devices were prepared, one was made by depositing two-layer film with PECH upside and MWCNTs downside, the other two were made of PECH/MWCNTs composite film with different thicknesses. The testing result showed that composite film showed better response and linearity than two-layer film, and the sensor with a thicker film performed better in term of response and linearity than its counterpart.

Experimental

Materials

PECH was purchased from Alfa Aesar. Tetrahydrofuran, toluene and MWNTs (Outer diameter >50 nm, length 10-20um, 3.6 wt% in isopropanol) were purchased from Chengdu Organic Chemicals Co. Ltd, Chinese Academy of Sciences. All of these chemicals were utilized without further purification.

Preparation of Sensitive Films

In this experiment, the interdigitated electrode pairs (IDTs) with gold electrodes (width and gap of interdigitated electrodes were 50 um) on a silicon substrate with a sensing area of 5×8 mm2 were used. The structure of ethanol gas sensor was shown in the Fig.1. The sensitive films were fabricated as follows:

(1)Preparation of PECH and MWCNTs two-layer films: MWCNTs (3.6wt% in isopropanol) was diluted 20 times in isopropanol and then ultra-sonicated for ten minutes. Then 0.2 ml MWCNTs solution (0.18wt% in isopropanol) was airbrushed on the interdigitated electrodes, and 0.2 ml PECH (dissolved in THF, 10 mg/ml) airbrushed on the MWCNTs. All devices were dried at 60℃ in vacuum oven for 24 hours.

(2)Preparation of PECH and MWCNTs composite films: MWCNTs (3.6 wt% in isopropanol) was diluted 20 times in isopropanol followed and ultra-sonicated for ten minutes, then mixed with the PECH (dissolved in THF, 10 mg/ml) with the weight ratio of 1:1. And 0.2 ml of the mixture was airbrushed on the interdigitated electrodes after it was sonicated for ten minutes. In contract, another device was prepared with 0.4 ml of the mixture airbrushed. All devices were dried in a vacuum oven at 60℃ for 24 hours.

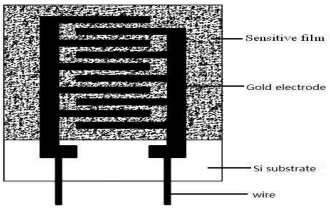

Fig.1 Structure of Toluene Gas Sensor

Experimental Procedures

The concentrations of ethanol vapor were controlled by MF-3C liquid organic solvent dynamic gas distribution device. N2 was used as a carrier gas. The changes of electric resistance caused by adsorption and desorption of alcohols were monitored by Keithley 2700, and the data was received by a computer system via a GPIB interface board. All experiments were carried out at room temperature.

Results and Discussions

The Sensitive Properties of the Films with Different Structures

In this paragraph, the dynamic response of the sensors with composite film exposed to different concentrations of ethanol was showed in Fig.2. The resistance of the sensors increased when they were exposed to the ethanol vapors at room temperature, which can be explained by "swelling effect". The distance of the conductive particles continuously increased and decreased through swelling/shrinking due to the adsorption/desorption of ethanol vapor, resulting in the increase and decrease of the whole resistance. Fig.3 showed the sensitivity curves of the sensors with different structures, one was made by depositing the polymer upside and MWCNTs downside. The other was made as the composite film, the response(S) was defined as (Rg-Ra)/Ra×100%， where Ra was the initial resistance of the sensor and Rg was the resistance of the sensor exposed to ethanol vapor. It could be clearly observed that the PECH/MWCNTs composite film showed a much better response to the ethanol vapors than the PECH/MWCNTs two-layer film. The response of the composite film to 2000ppm was 5.8%, while the response of the two-layer film to 2000 ppm was only 2.6%. Moreover, the sensitivity of the composite film is 2.75E-5/ ppm compared to 1.355E-5/ ppm of the two-layer film, which meant that the composite film had a larger sensitivity than the two-layer film.

In addition, the response time and the recovery time were defined as 90 percent and 10 percent of the time for sensors to arrive at its stable state after exposure to ethanol vapor or nitrogen, respectively. It was found that both the response time and recovery time of the sensor with two-layer film were 250s; while the response time and recovery time of the composite film were 200s. So the composite film was better than that of layer film.

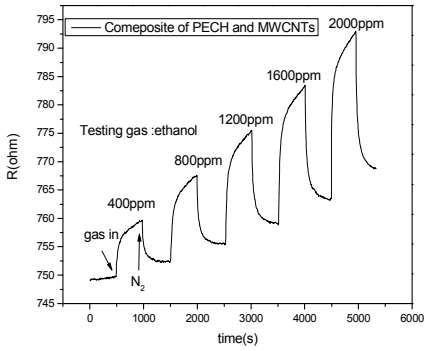

Fig.2 Real Resistance-time Curve of the Composite Film to the Ethanol Vapor Ranged from 400 ppm to 2000 ppm at Room Temperature

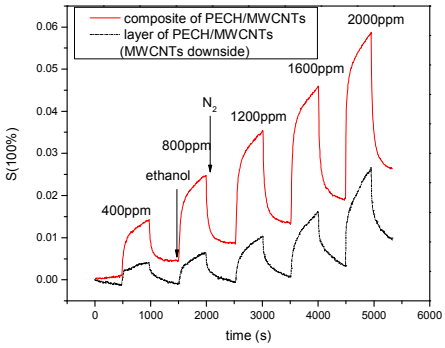

Fig.3 Dynamic Response Curves of the Composite and Two-layer Films to the Ethanol Vapor Ranged from 400ppm to 2000ppm at Room Temperature

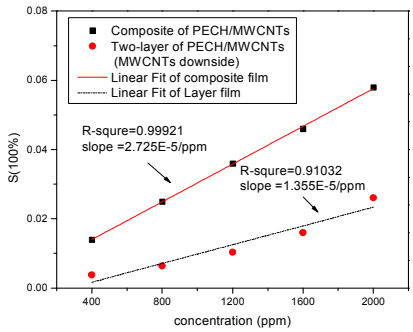

Fig.4 Sensitive Properties of the Composite and Two-layer Films with Ethanol Concentration Change Ranging from 400ppm to 2000ppm

The Sensitive Properties of Composite Films with Different Thicknesses

In order to study the effect of different thicknesses on the response of sensors, two sensors of composite films with different thicknesses were fabricated, one was airbrushed with 0.4 ml of the PECH/MWCNTs solution, and the other was airbrushed half quantity of that. The dynamic response curves of the two sensors were showed in Fig.5 (the sensors airbrushed with 0.4 ml and 0.2 ml of the solution were marked as sensor 1 and sensor 2, respectively). The initial resistance of sensor 1 was about 330Ω, while the initial resistance of sensor 2 was about 5720Ω, it could be seen that the sensor 1 had a better performance than sensor 2, i.e, the response of sensor 1 was about 5.69% when exposed to 2000 ppm of ethanol vapors, while the response of sensor 2 could only reach to about 3.0% at the same concentration. In addition, it could be seen from Fig.5 that the dynamic response curve of sensor 1 was much smoother than that of sensor 2, which meant that the signal noise ratio of sensor 1 was larger than that of senor 2. It could be seen from Fig.6 that the sensitivity of sensor 1 was 2.625E-5/ ppm, which was higher than 1.595E-5/ppm of sensor 2, which meant that sensor 1 had a better sensitivity to ethanol than sensor 2. Moreover, the R2 of the two sensors were 0.99674 and 0.9275 respectively, i.e, sensor 1 had a better linearity than sensor 2.

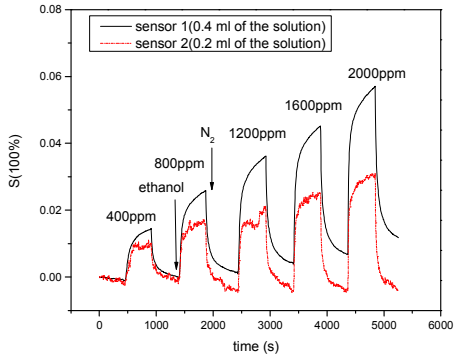

Fig.5 Dynamic Response Curves of the Two Different Composite Films to the Ethanol Vapor Ranged from 400ppm to 2000ppm

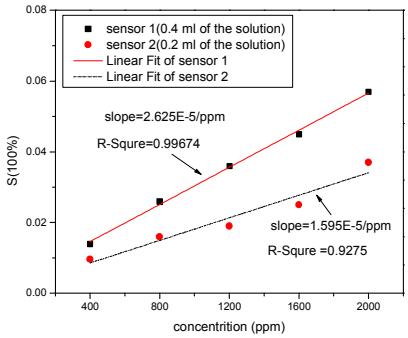

Fig.6 Sensitive Properties of the two Different Composite Films with Ethanol Concentration Change Ranging from 400ppm to 2000ppm.

The Selectivity of PECH Toward Ethanol

Selectivity is one of the most important elements of an excellent gas sensor. However, the VOC gas sensors perform a bad selectivity to testing gas because most of the VOC gases can cause the change of the resistance of the sensor. In order to test the selectivity of the sensors, the composite film sensor was exposed to vapors (the concentration is 2000ppm) of methanol, ethanol, acetone and isopropanol. Fig.7 showed that the responses of the sensor toward ethanol, methanol, acetone, isopropanol were 0.06, 0.02, 0.035 and 0.045, respectively, which showed that the response of the sensor to ethanol were the largest, so the sensor has an excellent selectivity toward ethanol.

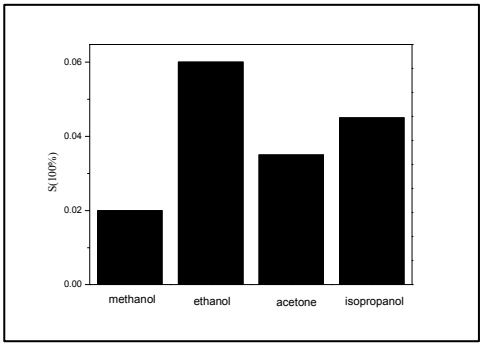

Fig.7 Selectivity of the Sensor with Composite film

In order to find out the reason why the sensor with composite film and the sensor with a thicker film had a better response, the morphologies of the surface of the sensitive films were observed by scanning electron microscope, and the SEM images were showed in Fig.8, Fig.9 and Fig.10, respectively. It can be observed from the Fig.8 and Fig.9 that the surface of the composite film had a much rougher surface than the two layer film, and the much rougher surface can preferably absorb the target gas because it had a lager contact area to the target gas. Similarly, the surface of sensor 1 had a rougher surface than sensor 2 although they were both composite films. So sensor 1 had a better response than sensor 2. Moreover, the amount of the PECH polymer may also be one of the reasons.

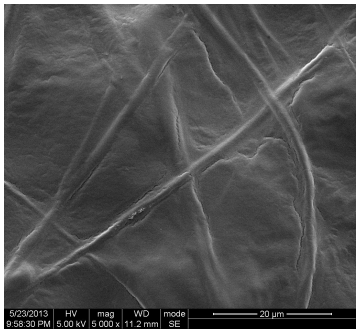

Fig.9 SEM Images of the Surface of PECH/MWCNTs two Layer Film

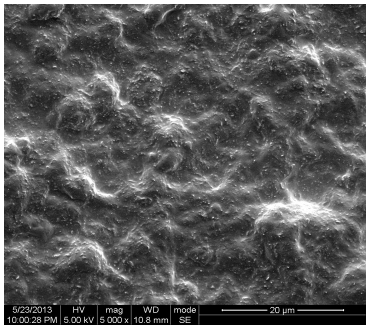

Fig.10 SEM Images of the Surface of PECH/MWCNTs Composite Film of Sensor 2

Conclusions

In this paper, three gas sensors were fabricated with different structures and different thicknesses by using PECH and MWCNTs. It was found that sensor with composite film had a better response and lineality than the two layer one, and the sensor with a thicker film performed better than its counterpart when exposed to ethanol gas.

Keywords: polyacetylene, expanded graphite, composites

Abstract. Expanded graphite (EG) is a promising conducting filler to enhance the conductivity of the polyacetylene (PA)/EG composites and also an ideal support to catalyst PA to polymerize on the surface of EG. The expanded interlayers of EG prepared by chemical oxidation is between 100 and 1500 nm. Diameters of the $Fe(naph)_3$ nanoparticles deposited on the external surface and internal surface (i.e. surface of the expanded graphitic layers) of EG range from 7 to15 nm. PA/EG composites were prepared by heterogeneous polymerization. PA catalyzed by $Fe(naph)_3$ nanoparticles supported on the external surface and at the edge of the expanded layers was inclined to form bigger aggregation, while PA grown between the interlayers exhibit smaller size. The bulk conductivity of the prepared composites is 5.78×10^3 $S\cdot m^{-1}$.

Introduction

Composites of conducting polymers with carbon materials have attracted a great of interests due to their unique electrical and mechanical properties and their potential applications in light emitting devices, batteries and electromagnetic shielding coating [1-4]. Carbon nanotubes (CNTs) as conducting fillers have been used to enhance the conductivity of the conducting polymers. Polyaniline/multiwalled carbon nanotube (MWNT) composites have been fabricated by in situ polymerization with bulk conductivity of 5180 $S\cdot m^{-1}$ [5]. Polypyrrole/carbon nanotube composites have been prepared by electropolymerization with a DC conductivity of 3965 $S\cdot m^{-1}$ [6]. In the previus work, polyacetylene (PA)/MWNT nanocomposites with core-shell structure were prepared and the bulk conductivity of the nanocomposites is about 240 $S\cdot m^{-1}$ [7].

Graphites are also an promising conducting filler, which are abundant in mineral reserves, highly conductive and lower cost than CNTs. Expanded graphites (EG) synthized from graphite by intercalation of oxidants and expansion at high temperature [8, 9] maintain the excellent electrical property and thereafter become an ideal catalyst support [10]. The conductivity of poly (phenylene sulfide)/EG composites reach 10^{-1} $S\cdot m^{-1}$ after the introduction of EG to the composites [11]. Although the polymethyl methacrylate (PMMA) is an insulator with conductivity of 10^{-14} $S\cdot m^{-1}$, the conductivity of PMMA/EG could be increased to 10^{-2} $S\cdot m^{-1}$ [12]. In addition, the special sandwich structure and long distance between the graphitic layers of EG make it easy to intercalate atoms and molecules into the expanded interlayers.

In this paper, natural flake graphite was used to synthize EG by chemical oxidation. Prior to polymerization, $Fe(naph)_3$ nanoparticles was supported on the surface of EG by a process of impregnation. EG performed not only as the conducting filler to improve the electrical properties of the PA/EG composites, but also as the catalyst support during polymerization in which PA grown on

the sueface of the EG. The bulk conductivity of the PA/EG composites is 5.78×10^3 $S\cdot m^{-1}$ which is measured by a four-probe approach.

Experimental

Synthesis of EG.

EG was prepared from natural flake graphite by chemical oxidation [8, 10]. 3.0 g of natural flake graphite was first treated with 30 mL mixed acid consisting of perchloric acid and phosphoric acid with a volume ratio of 5:1. Subsequently, 0.3 g of potassium permanganate was added into the mixed acid solution bit by bit to form graphite intercalated compound (GIC). The mixture was magnetically stirred for 1 h. 100 mL of deionized water was used to dilute the viscous mixture. 30 mL of hydogen peroxide was then added into the mixture to reduce the residual potassium permanganate and the reduzate of manganese dioxide into bivalent manganese ion. Graphite oxide was separated by centrifugalization for 15 min at 3000 $r\cdot min^{-1}$, followed by washing with distilled water to reach neutral. GIC was dried in an oven at 60 °C for 12 h. GIC (1.0-2.0 g) was explosively expanded at 900 °C for 10-20 s in an electric furnance to form EG.

Preparation of PA/EG composites.

0.5 g of EG was first impregnated with 1.0g of $Fe(naph)_3$ in 10 mL toluene under magnetically stirring for 48 h at room temperature. The suspension was separated by filtration and the $Fe(naph)_3$/EG was obtained after drying in an oven at 90 °C for 3 h. PA/EG composites was prepared by a method of heterogeneous polymerization based on a previous work [7]. 0.5 g of $Fe(naph)_3$/EG and 40 mL of anhydrous toluene were mixed in a 250 mL three-necked flask which was primarily purged with dry nitrogen for 20 min to remove oxygen. Subsequently, 0.02 mol of $Al(i\text{-}Bu)_3$ was added into the flask in nitrogen atmosphere. Upon the introduction of acetylene gas, polymerization started to run under stirring and lasted for 40 min at room temperature. The mixture after reaction presented purple. Toluene and ethanol solvents containing hydrochloric acid (volume ratio of 2 to 1) were used to wash the products until the filtrate became colourless. The product was dried under vacuum at room temperature overnight. For comparison with the composites, PA was prepared following the same protocols except substituting $Fe(naph)_3$/EG with $Fe(naph)_3$.

Characterization.

The morphologies and structures of the samples were analyzed using a JEM-2100UHR high resolution transmission electron microscope (HRTEM) with an accelerating voltage of 200 kV. A Hitachi S4800 scanning electron (SEM) was used to analyze the samples with an accelerating voltage of 5 kV. Fourier-transform infrared spectroscopy (FTIR) analyses were performed on a NEXUS FTIR spectrometer using KBr tablets. The bulk conductivity of the samples were measured by a four-probe approach at room temperature.

Results and dissussion

Morphology of the EG is revealed by SEM image. As shown in Fig. 1a, the prepared EG has a legume-like structure which can be attributed to the opening of plannar graphite networks caused by the rapid gasification of the itercalation compounds and surface oxygen groups. As a result of expansion, the EG exhibits a loose and porous structure with interlayer spacing between 100 and 1500 nm. This structure endows the EG with high surface area and large pore size. Thus, the EG is able to effectively support the $Fe(naph)_3$ catalyst which disperse on the surface and into the expanded graphite interlayers which is indicated by the SEM images. During impregnation process, the $Fe(naph)_3$ catalyst is easy to disperse into the expanded interlayer. And the expanded interlayer

has enough space to accommodate the $Fe(naph)_3$ nanoparticles which formed after being heated at at 90 °C for 3 h.

Representative TEM image of $Fe(naph)_3$/EG is shown in Fig. 1b. $Fe(naph)_3$ nanoparticles are well dispersed on the external and internal surface of EG with diameters of 7-15 nm. The TEM image also comfirms the loose structure of the EG.

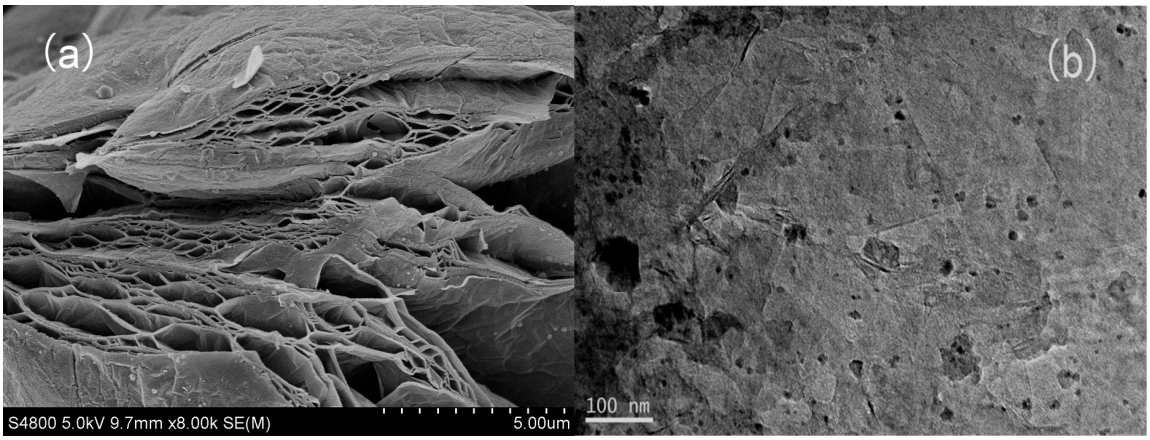

Fig 1 SEM image of EG (a) and TEM image of $Fe(naph)_3$/EG

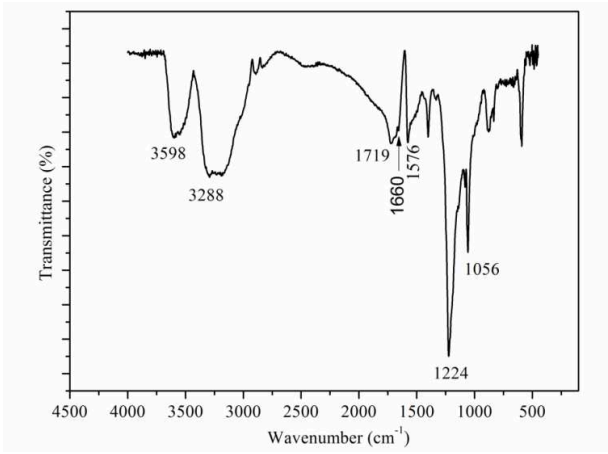

Fig. 2 FT-IR spectrum of PA/EG composites

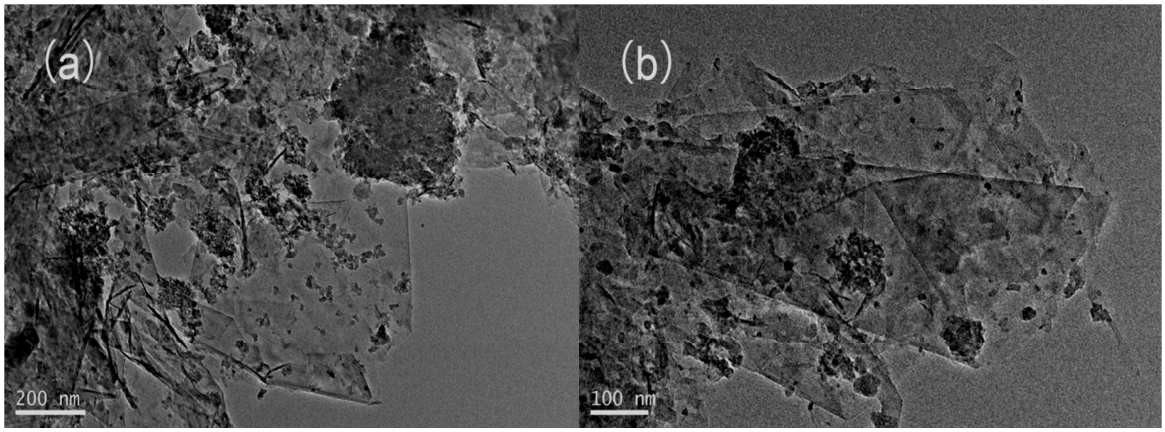

Fig. 3 TEM images of PA/EG composites

FTIR spectrum of PA/EG composites is shown in Fig. 2. The adsorption band at 3288 cm^{-1} corresponds to the hydroxy group which derives from oxidation of PA. And the peaks at 1660 and 1719 cm^{-1} can be asigned to α, β-unsaturated ketone and isolated ketone chromophores which is from the oxidation of C=C of PA [13]. Thus, PA formed on the surface of the EG and PA/EG were successfully prepared.

TEM images of the prepared PA/EG composites are shown in Fig. 3a and b. PA contained in the PA/EG composites are inclined to aggregate with different sizes. Because the acetylene monomers polymerized on the external and internal surface of the EG were through a process of heterogeneous polymerization [14] which was catalyzed by $Fe(naph)_3$ nanoparticles. The $Fe(naph)_3$ nanoparticles dispersed on the external surface and at the edge surface of the expanded layers are easy to contact with the acetylene monomer. As a result, the PA formed in bigger aggregation on the external surface. However, the $Fe(naph)_3$ nanoparticles deposited on the internal surface contact with less acetylene monomers which led to PA with smaller size. In addtion, PA formed at the edge surface of the expanded layers prevent the $Fe(naph)_3$ nanoparticles deposited on the internal surface of the expanded layers from contacting with acetylene monomer. Therefore, many $Fe(naph)_3$ nanoparticles are still contianed in the PA/EG composites after acid washing.

The bulk conductivity of the PA/EG composites is 5.78×10^{3} $S\cdot m^{-1}$ lower than that of EG (3.43×10^{4} $S\cdot m^{-1}$). Compared with PA (4.55×10^{-10} $S\cdot m^{-1}$) preapred by the same method, the bulk conductivity of PA/EG composites increases by 13 orders of magnitude. This reason can be attributed to the synergistic effects between PA and EG [15]. Electron of the graphite layer only flow horizontally to form a two dimentional conductive netmork. But, after filled with PA between the interlayers, the conjugated electron of PA and EG may have chance to exchange, which form a three dimentional conductive network. Thus, the bulk conductivity of the PA/EG composites could be increased to 5.78×10^{3} $S\cdot m^{-1}$ after the introduction of EG.

Summary

EG as a conducting filler was supported with $Fe(naph)_3$ nanoparticles to prepare PA/EG composites by a process of heterogeneous polymerization. The $Fe(naph)_3$ nanoparticles dispersed well on the external and internal surface of the EG. But the PA grown on the surface of EG is un-uniform. EG plays a more important role to improve the bulk conductivity of the PA/EG composites.

Keywords: epoxy resin；SiO_2；the compressive mechanics properties

ABSTRACT: The EP/SiO_2 nanocomposites were prepared by using epoxy resin as matrix, nano-SiO_2 as the modifier, polyamide as curing agent. The surface morphology of nano-SiO_2 was observed, the average particle diameter of nano-SiO_2 is 20nm. Their mechanics properties were studied and the experiment results were analyzed. The results indicated that the compressive stress-strain curves of the nanocomposites had obvious three phases characters, i.e., linear elastic phase, plastic yield flat phase and compact phase. Along with the nanograins content of the nanocomposites increasing, the compressive elastic modulus and compressive strength of the nanocomposites augmented. When the nanograins content is 5% and the transfiguration speed is 10mm/min, the compressive elastic modulus and compressive strength of the nanocomposites respectively improved 22.7% and 35.2% comparing with their of the pure epoxy resin. At the same nanograins content, with the transfiguration speed increasing, their compressive strength added.

Introduction

Epoxy resin (EP) as a typical representative of the thermosetting resin, with adhesive properties, mechanical properties, excellent insulating properties and shrinkage of small, low cost and other advantages, has been widely used in mang areas such as adhesives, paint, construction materials and composite matrix etc.. But cured EP which is brittle, fatigue resistance, heat resistance, impact resistance, poor, largely limits its application in some fields [1]. Therefore, in the premise of ensuring the EP of excellent performance, the toughening modification has become a hot research topic concerned in recent years.

The modified method of epoxy resin has use elastomer, thermoplastic resin, liquid crystal polymer blends [2-3], also has the nanocomposite modification techniques, such as nano-Al_2O_3 [4], nano carbon black [5], nano-Si_3N_4 [6], nano-SiO_2 [7-10], nano-TiO_2 [11], nano-ZnO [12], etc.. The nanocomposite modification techniques can improve greatly the toughness, strength, wear resistance and heat resistance of epoxy resin.

In this paper, the EP/SiO_2 nanocomposites were prepared by using epoxy resin as matrix, nano-SiO_2 as the modifier, polyamide as curing agent. The surface morphology of nano silica was observed, and the compression mechanical properties of the composite were experimentally studied.

Experiment

Preparation of the Nanocomposite Materials

Preparation of Nano-SiO_2

The right amount of anhydrous ethanol, distilled water and concentrated ammonia have been put in a clean beaker successively and be mixed uniformly. In the case of stirring, a certain amount

mixed solution of TEOS and ethanol have been dropped in the beaker slowly. After dripping finished, the solution were continued to stir about 2 hours. A white powder was obtained by vacuum filtration the solution, washing it by distilled water, drying, calcining in the muffle furnace; nano-SiO_2 powder was obtained.

Preparation of the EP/SiO_2 Nanocomposites

We measure out 20ml acetone and put into the beaker, then adding a certain amount of nano-SiO_2 powder. At first the solution were stirring for 15 minutes with a magnetic stirrer, then placed the beaker in ultrasonic cleaning instrument and ultrasound for 1 hour.

8g epoxy resin (E-44) preheated to 80℃ was added into the beaker and stirred for 10 minutes, then ultrasound for 30 minutes. Next, the beaker were put into the electric air blowing drying box and keep warm at 90℃ for 24 hours.

7.5g polyamide curing agent preheated to 80℃ was added into the beaker and stirred for 10 minutes, then the viscous liquid in the beaker was pouringed to self-made mold. Putting the mold into the electric air blowing drying box and keeping warm at 90℃ for 6 hours, the EP/SiO_2 nanocomposites were obtained.

Preparation and Analysis of the Samples

Referring to the test method for properties of resin casting body (GB2567-2008), the specimen was got by self-made mold and was cylinder specimen. Samples of five different nano-SiO_2 contents were prepared. The nano-SiO_2 contents (relative to the quality of epoxy resin matrix) are respectively 0%, 0.5%, 1%, 3% and 5%. The size of compressed sample was about diameter 19mm and height 40mm.

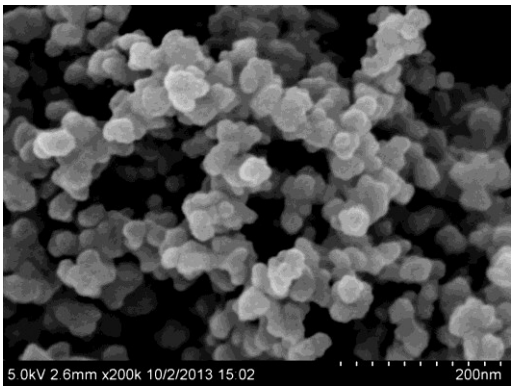
The surface morphology of nano-SiO_2 was observed by scanning electron microscope.

The uniaxial compression experiment was carried out under the conditions of 20℃and relative humidity 50%. The stress-strain curves of specimens were obtained by electronic universal testing machine at the deformation rate of 1mm/min, 5mm/min and 10mm/min respectively.

Results and discussion

Surface Morphology of Nano-SiO_2

Fig.1 was the SEM picture of nano-SiO_2. From the picture, we could see that the particle size of nano-SiO_2 was uniform and was about 20nm.



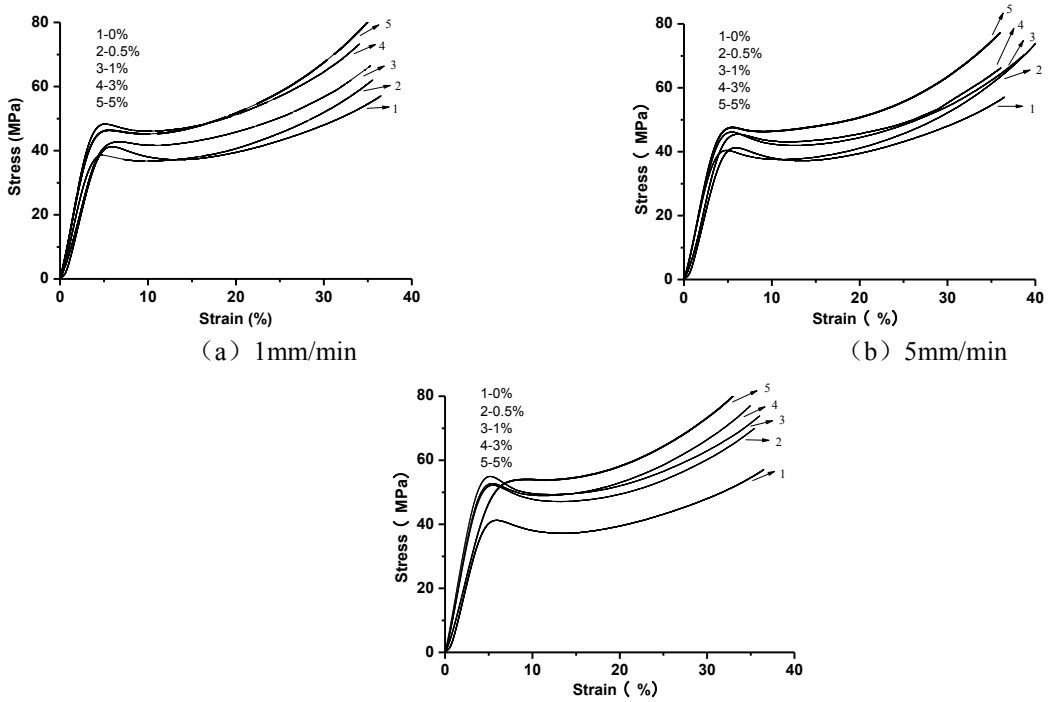


Fig.1 SEM Picture of Nano-SiO_2

Effect of Nano-SiO_2 Content on the Compression Properties of EP/SiO_2 Nanocomposites

Fig.2 was the compression stress-strain curves of the composites with different nano-SiO_2 contents at different deformation rates. As could be seen from Fig.2, the experimental curves had three stages, namely the linear elastic, plastic yield plateau region and densification section. With the increasing of the nano-SiO_2 content, the compressive strength of the composites increased.

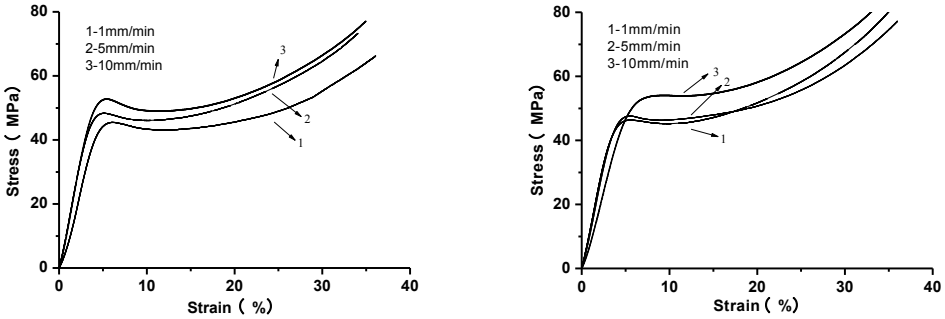

Fig.2 Effects of the Nano-Sio_2 Contents on the Stress-Strain Curves of the Composites At Different Deformation Rates

Effect of the Deformation Rate on the Compression Properties of EP/SiO_2 Nanocomposites

Fig.3 was the compression stress-strain curves of the composites at different deformation rates. From fig.3, we could seen that at elastic segment, with the increasing strain rate, the corresponding stress value of the sample which had the same nano-SiO_2 content was not obviously increased when it achieved to the same strain. That suggested the EP/SiO_2 nanocomposites did not have obvious strain rate effect under quasi-static compression process.

Fig.2 Effects of the Nano-SiO_2 Contents on the Stress-strain Curves of the Composites at Different Deformation Rates

The Compression Properties of EP/SiO_2 Nanocomposites

According to the experimental curve, we obtained the compression mechanical properties of the EP/SiO_2 nanocomposite (when the deformation was 5%, the corresponding stress and strain were used to calculate the modulus of elasticity in compression of the EP/SiO_2 nanocomposites), the results in table 1.

From table 1, we could seen that with the increasing of nano-SiO_2 content in the composite, the compression elastic modulus and compressive strength of that increased; while the nano-SiO_2 content was same, with the increasing of strain rate, compressive strength of the composite increased.

TABLE 1 COMPRESSIVE MECHANICAL PROPERTIES OF EP/SIO_2 NANOCOMPOSITES WITH DIFFERENT NANO-SIO_2 CONTENTS

SiO_2 [%]	Strain rate [mm/min]	Elastic modulus [MPa]	Average elastic modulus [MPa]	Compressive strength [MPa]
0	1	802.50	803.76	59.64
	5	803.88		62.43
	10	804.91		63.79
0.5%	1	800.33	875.84	63.97
	5	808.62		65.71
	10	1018.56		70.01
1%	1	819.42	929.08	66.62
	5	919.13		72.11
	10	1048.69		74.21
3%	1	966.71	959.51	72.21
	5	889.76		75.06
	10	1022.07		78.56
5%	1	943.18	985.88	77.09
	5	1028.21		81.42
	10	986.24		86.24

Conclusion

(1) The EP/SiO_2 nanocomposite materials were prepared by using epoxy resin as matrix, silica nanoparticles as modifier, polyamide as curing agent. This method is simple and easy to operate.

(2) The compressive stress-strain curve of EP/SiO_2 nanocomposite had three stages, namely the linear elastic, plastic yield plateau and tight stage. That does not have obvious strain rate effect in the quasi-static compression process. With the increasing of nano-SiO_2 content in the composite, the

compression elastic modulus and the compressive strength of it increased. When the nano-SiO_2 content was 5%, at 10mm/min deformation rate, the compression elastic modulus and compressive strength of the nanocomposites improved by 22.7% and 35.2% than those of pure epoxy resin were. For the composite of the same content, with the increasing of deformation rate, compressive strength of the nanocomposites increased.

Keywords: Geopolymer, metakaolin, nano-SiO_2, SiO_2/Na_2O molar ratio, microstructure

Abstract. This study explores the effects of the SiO_2/Na_2O molar ratio (1.0-2.0) on the properties of 1% nano-SiO_2 metakaolin-based geopolymers. The porosity, flexural strength, DTA/ TGA, and NMR are investigated to study the mechanical and microstructure properties of the geopolymers. The results show that the flexural strength increased, and that the products of geopolymerization filled pores with curing time, causing the microstructure to become denser. Moreover, a nano-SiO_2 metakaolin-based geopolymer sample with a SiO_2/Na_2O ratio of 1.5 exhibited more strength and less porosity. Applying the 1% nano-SiO_2 to a geopolymer enhances compactness, improves uniformity, and increases strength.

Introduction

Geopolymers are amorphous three dimensional aluminosilicate materials with ceramic-like properties that are produced and hardened at ambient temperature. Geopolymeric materials are attractive because they exhibit desirable properties, such as rapid compressive strength development, low permeability, resistance to acid, resistance to freeze-thaw cycles, and a tendency to drastically decrease the mobility of most heavy metal ions within the geopolymeric structure [1-3].These characteristics make geopolymers promising building, toxic waste immobilizing, sealing, and temperature-resistant materials [4]. Their porosity can be less than that of cements or mortars and thus superior mechanical properties are obtained [5]. Geopolymer production generates almost no NOx, SOx, CO, and only emits small amounts of CO_2 [6].

Nanoparticles are particles between 1 and 100 nm that create volume and surface effects. Nanoparticle preparation and application and their size and surface effects offer various benefits; they can be used to develop high-performance polymers [7]. Nanosynthesis technology has been widely applied to develop novel materials with better properties and to improve conventional material properties. Studies have been conducted on nanocoatings, high-strength structural materials, macromolecular-based nanocomposites, magnetic materials, optical materials, and bionic materials [8]. To understand the effects of different SiO_2-to-Na_2O molar ratios (1.00-2.00) on the 1% nano-SiO_2-metakaolin-based geopolymers. The mechanical properties were determined by porosity and flexural. Moreover, the microstructure of all samples were determined by DTA/ TGA, and NMR.

Materials and Methods

Materials

Metakaolin was calcined using kaolin at 650 °C for 3 h. The Na_2SiO_3 solution was produced in Taiwan. It was composed of 29.5% SiO_2, 9.1% Na_2O, 61.4% H_2O, and the Ms (SiO_2/Na_2O) was 3.4. Analytical-grade 99% pure NaOH was used. The nano-SiO_2 used was a white powder. The SiO_2

content was 99.9%, the average particle size was approximately 10 nm, and the specific surface area was 670 m^2/g.

Sample Preparation

NaOH and distilled water were mixed with a Na_2SiO_3 solution and allowed to cool to room temperature. With constant stirring, nano-SiO_2 was added to the alkali activator. The SiO_2/Na_2O ratio were 1.00, 1.25, 1.50, 1.75 and 2.00; the solid-to-liquid ratios was 1.03; and the nano-SiO_2 additions were 1%. The alkali activator solution was prepared 24 h before use to ensure that the activator component was mixed uniformly. Table 1 shows the mixture proportions. A mechanical mixer was used to mix the activator solution and 1000 g metakaolin for a few minutes. The fresh paste was then rapidly poured into plastic molds (5 × 5 × 5 cm). Samples were placed into an oven at 80 °C for 24 h. Mechanical properties and the microstructure performance of specimens were tested after 1, 7, 14, 28 and 60 days.

TABLE 1 THE MIXTURE PROPORTIONS OF SAMPLES

SiO_2/Na_2O	Nano-SiO_2 addition(%)	Mixture proportion by weight (g)				
		Metakaolin	Nano-SiO_2	Na_2SiO_3	NaOH	H_2O
1.00	1	1000	10	575.1	158.3	350.8
1.25	1	1000	10	718.9	141.4	289.7
1.50	1	1000	10	862.7	124.5	228.5
1.75	1	1000	10	1006.5	107.6	167.3
2.00	1	1000	10	1150.3	90.7	106.2

Results and Discussion

Material characteristics

The metakaolin used in this study was obtained from kaolin calcined at 650 °C for 3 h. It was slightly pink. Before and after calcination, the proportions of kaolin and metakaolin were 3.35 (compared to kerosene). However, the pH values of kaolin and metakaolin were 6.52 and 5.74, respectively. This is because dehydroxylation during calcination makes metakaolin weakly acidic. The chemical composition of raw materials was determined using X-ray fluorescence. The results show that kaolin is mainly composed of SiO_2 (53.7%) and Al_2O_3 (37.88%). Metakaolin is composed of 59.6% SiO_2 and 38% Al_2O_3. Table 2 shows the chemical composition of the raw materials.

TABLE 2 CHEMICAL COMPOSITION OF THE RAW MATERIALS

Composition	Kaolinite	Metakaolin
SiO_2 (%)	53.70	59.60
Al_2O_3 (%)	37.88	38.00
Fe_2O_3 (%)	0.88	1.30
CaO (%)	0.20	0.24
K_2O (%)	0.34	0.32

Flexural strength

Figure 1 showed the flexural strength of 1% nano-SiO_2-metakaolin-based geopolymers with various SiO_2-to-Na_2O ratios. It can be concluded that flexural strength of geopolymers with different SiO_2-to-Na_2O ratio at 60 days were 14.5 MPa, 14.7MPa, 15.4 MPa,13.9 MPa and 12.9 MPa, respectively. It indicated that the flexural strength of metakaolin-based geopolymer whose SiO_2-to-Na_2O ratio of 1.5 was the largest. The increase of the SiO_2/Na_2O ratio in the geopolymeric system caused the dissolution of considerable aluminosilicates and the subsequent gradual shift of the

chemical system from the monosilicate chains and cyclic trimers to species with larger rings and complex structures and polymers, resulting in the 3D polymeric framework and increasing the mechanical properties of the resulting geopolymeric materials. When the SiO_2/Na_2O ratio continued to increase from 1.75 to 2.00, the metakaolin-based geopolymer strength decreased. When the SiO_2/Na_2O ratio increased, the high content of the sodium-silicate solution caused the geopolymer paste to become sticky because of the viscous nature of the sodium-silicate solution. The high amount of the sodium-silicate solution may inhibit the geopolymerization process.

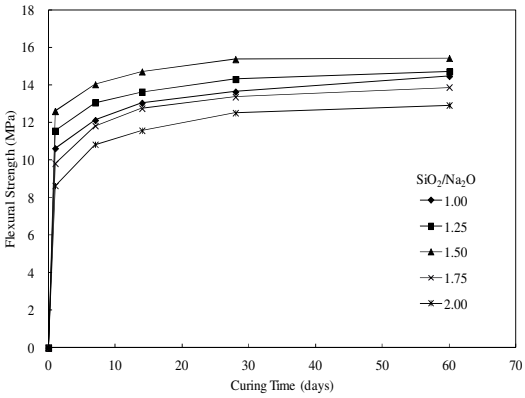

Figure 1 Flexural strength of geopolymers.

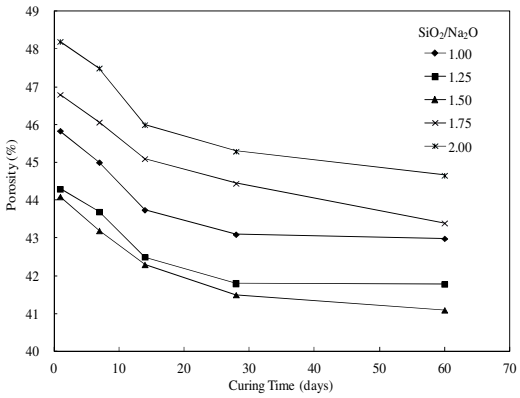

Figure 2 Porosity of geopolymers.

Porosity

Figure 2 presents the porosity is a main factor of affecting the sample's mechanical characteristics. The structure tends to be denser and the strength will be enhanced if the porosity gets lower. Figure 2 shows the porosity of nano-SiO_2-metakaolin-based geopolymers with various solid-to-liquid ratios after 1, 7, 14, 28 and 60 days of curing. The porosity range is between 41.1% and 48.2%. The results displayed that the porosity would decrease slightly with the growth of the curing time. When the SiO_2/Na_2O ratio was 1.50, the geopolymer porosity was the smallest, which is consistent with the following higher mechanical strength and smaller cumulative pores.

TG/DTA analysis

Figure 3 shows the thermogravimetric analysis of 1% nano-SiO_2-metakaolin-based geopolymers with various SiO_2-to-Na_2O ratios. Three distinct endothermic peaks appear in the DTA spectra: 130 °C, 450 °C, and 650 °C. Therefore, the whole area was divided into three sections: 50–350 °C, 350–550 °C, and 550–690 °C. Although the first endothermic peak was not completely symmetrical, it can be assumed that two or more endothermic peaks overlapped part of this temperature range. The weight loss occurring at the temperature range of 50–340 °C was primarily caused by the dissipation of free water in the pores. A further increase in temperature produces shrinkage, and finally damages the geopolymer structure. The continuous weight loss at 350–550 °C was due to the evaporation of structural water. Because water is a vital aspect of the final geopolymer structure ($Mn((SiO_2)z–AlO_2)n\cdot wH_2O$), an adequate water content should be present in the initial geopolymer paste to proceed reactions.

Table 3 shows the weight loss of nano-SiO_2-metakaolin-based geopolymers. The weight losses occurring at 350–550 °C during the polymerization reaction were related to gels. When SiO_2/Na_2O ratio was 1.5, the weight loss of the nano-SiO_2-metakaolin-based geopolymers was slightly higher due to forming more gels than other ratios. At SiO_2/Na_2O ratio was 1.5, the weight losses of the geopolymer at 350–550 °C and 550–690 °C were relatively high. When the curing time increased, the weight loss at a temperature range of 350–550 °C gradually increased. As the curing time increased, the polymerization reaction became more thorough, and the structure of the specimen became gradually denser. Therefore, the weight loss in the two highest temperature ranges was greater. These results are consistent with the previous mechanical characteristics.

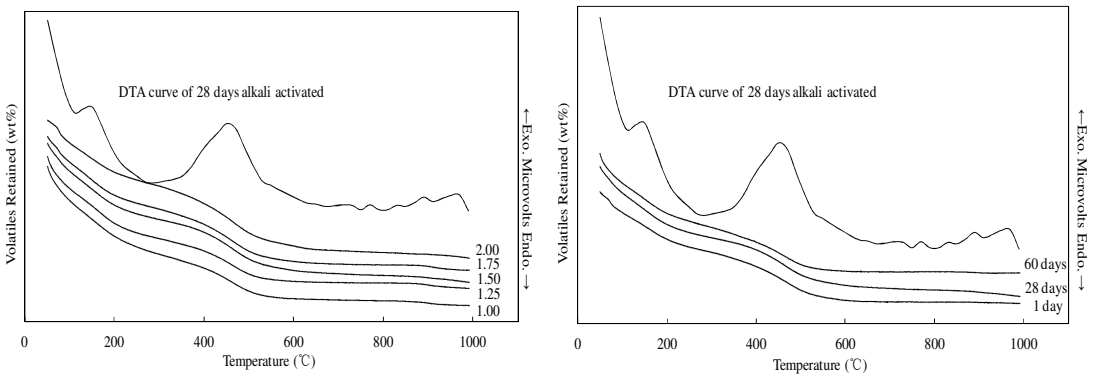

Figure 3 TG/DTA of 1% nano-SiO_2-metakaolin-based geopolymers with various SiO_2/Na_2O ratios.

TABLE 3 WEIGHT LOSS OF NANO-SIO_2-METAKAOLIN-BASED GEOPOLYMERS

SiO_2/Na_2O	Nano-SiO_2 addition (%)	Curing Time (days)	Temperature (℃)		
			50-350	350-550	550-690
1.00	1	28	19.60	8.63	1.21
1.25	1	28	18.37	8.77	1.43
1.50	1	28	16.90	9.87	1.84
1.75	1	28	16.73	7.45	0.63
2.00	1	28	15.19	7.35	0.64
1.50	1	1	18.16	8.54	1.07
1.50	1	28	16.90	9.87	1.84
1.50	1	60	14.87	9.91	1.93

NMR Analysis. The main characteristics of the geopolymer structure, such as the elements location of Si and Al, coordination, cross-linking degree of the tetrahedral, can be analyzed by MAS-NMR to obtain a better understanding of the structural properties and the geopolymerization process. Figures 4 and 5 show the ^{29}Si MAS NMR spectra of nano-SiO_2-metakaolin-based geopolymers. The ^{29}Si MAS NMR spectra of samples are broad, diffuse, and have no sharp peaks. ^{29}Si chemical shifts are sensitive to changes in the coordination of the Si atom. The Q^0 species, which denote silicate ions with no bridging oxygen atoms, typically exhibit ^{29}Si chemical shifts of approximately -65 ppm. For each of the additional bridging oxygen atoms, a shift of approximately 10 ppm to the shielded region; that is, the ^{29}Si chemical shift of the fully polymerized silicon species (Q^4) is approximately -110 ppm.

Figures 4 and 5 show that the resonance of nano-SiO_2-metakaolin-based geopolymers of the two major components are -90 and -97 ppm, which can be assigned to Q^4 (3Al) and Q^4 (2Al), respectively. Compared with MK, the signal center shifted to a lower magnetic field, and was still positioned in the range of geopolymer resonance. This indicates a change in the environment of the Si atoms. Furthermore, the changes of peak location, intensity, and full width at half maximum in ^{29}Si NMR spectra are caused by different Si/Al molar ratios, the type of cation used, and the adsorbed molecules of the sample structure.

Summary

This study presents the effects of different SiO_2-to-Na_2O molar ratios (1.00-2.00) on the 1% nano-SiO_2-metakaolin-based geopolymers.The geopolymer with the optimal SiO_2-to-Na_2O molar ratio and nano-SiO_2 addition level contained more structural water and gels that are beneficial to structure development. In summary, the application of nano-SiO_2 to a geopolymer enhanced its

compactness and increased its strength. Moreover, a nano-SiO_2 metakaolin-based geopolymer sample with a SiO_2/Na_2O ratio of 1.5 exhibited more strength and less porosity. Applying the 1% nano-SiO_2 to a geopolymer enhances compactness, improves uniformity, and increases strength.

Key words: ZnO nanofibers; electrospinning; AZO glass;

Abstract: ZnO electrospun nanofibers were considered to be potential novel materials in applications of photovoltaic devices and sensors. AZO glass was usually used in those devices as transparent electrodes. ZnO nanofibers on AZO glass were synthesized by electrospinning and calcination process. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), Raman spectroscopy and photoluminescence (PL) spectrum was employed to investigate the morphology, structure and optical performance of ZnO nanofibers. Network structure composed of sheet ZnO was observed. Raman spectra and PL spectrum indicated the existence of defect states in the ZnO nanofibers.

Introduction

Electrospinning technology, created by Formhals in 1934 [1], is a process that allows the continuous production of fibers ranging from several nm to over 1μm. And it was thought to be a simple, versatile and convenient method and potential for textile processing firstly due to its characteristics of easy control and low cost. In recent year, electrospun nanofibers were found to have wide application prospect on the photovoltaic devices, and bioscoffolds result from its high surface-to-volume ratio and large specific surface area [2, 3]. Zinc Oxide (ZnO) electrospun nanofibers with the advantages of ZnO one-dimensional nanostructure and electrospun nanofibers have attached much attention in the past ten years [4-7]. Great improvement of ZnO electrospun nanofibers had been achieved in the application of solar cell, sensor, photo catalytic activity, detector *etc.* in past five years, which demonstrated ZnO electrospun nanofibers as a novel 1D semiconductive materials have a huge application potential [8-11].

In particular, most of the applications in devices need electrodes to connect with an external circuit. AZO film was an appreciated material usually used as electrodes in optoelectronic devices, especially in devices with ZnO structure. Therefore, we will report the ZnO electrospun nanofibers synthesis on a glass with AZO film coated on surface in this paper. The ZnO nanofibers were successfully synthesized by electrospun technology and calcinations on AZO glass. The morphology, microstructure and optical properties are studied subsequently.

Experimental procedure

Polyvinyl alcohol (PVA) and $Zn(CH_3COO)_2 \cdot 2H_2O$ was used as the precursor for ZnO nanofibers synthesis by electrospun technology. A PVA aqueous solution was prepared firstly by solving 10 g PVA in distilled water with a weight ratio of 10%. Then 0.6 g $Zn(CH_3COO)_2 \cdot 2H_2O$ was added into the PVA solution with constant stirring until the transparent solution was obtained. The obtained

solution was placed in a plastic syringe and fed through a metal capillary with flat tip and a diameter d=0.4 mm. The syringe with solution was then fixed on the electrospun system (shown in figure 1) with a distance of 15 cm between the tip of capillary and the collector. AZO glass was placed on the metal roller as collectors. Electrospun was carried out at a voltage of 18 kV and a rotation speed of 4000 r/min at room temperature. After dried at 100 °C for 1 hour, the composite nanofibers were calcined at 400 °C and 600 °C temperatures in air to get ZnO nanofibers. X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), Raman spectroscopy and PL spectra were employed for analysis of microstructure, morphology and photoluminescence emission properties.

Results and analysis

Fig.1 shows the SEM images of aligned ZnO nanofibers on AZO glass. The morphology shown in fig.1 (a) indicated the volatilization of solvent was incomplete. After calcination, a network structure with flat ZnO nanofibers was formed, which indicated the morphology of ZnO nanofibers was not the typical ones. The shape of a single fiber was not columniform. TEM was employed to examine the microstructure of ZnO nanofibers in greater detail. Fig.2 shows the TEM images of different magnifications of ZnO nanofibers calcined at 400 °C and 600 °C for 2 hours. The low-magnification TEM micrograph (fig.2 (a, c)) shows the sheet structure of a single fiber. The network structure was shown by HRTEM shown in fig.2 (c) clearly. The polycrystalline structure of ZnO nanofibers was clearly observed at higher magnification, as shown in fig.2 (b, d). Figure 2 (b) shows the nanofibers calcined at 400 °C were composed of small grains with a diameter of no more than 10 nm. Grain coarsening was occurred at high calcination temperature, which was shown in fig.2 (d). The ZnO grain with diameter of tens of nanometers was obtained in the nanofibers calcined at 600 °C.

The Raman scattering was performed to investigate the vibrational properties of ZnO nanofibers on AZO glass at room temperature. Fig.3 (a) shows one normal mode at 436 cm^{-1} was observed in the Raman spectra of ZnO nanofibers calcined at 400 °C, which was corresponding to E_{2H} phonon scattering mode. The appearance of E_{2H} confirmed the wurtzite crystal structure of ZnO nanofibers since E_{2H} mode is related to the band characteristic of wurtzite phase [12]. However, the peak of E_{2H} was very weak, which indicated the low crystalline structure of ZnO nanofibers. The peaks of ZnO at 328, 436 and 584 cm^{-1} were observed clearly in the Raman spectra of ZnO nanofibers calcined at 600°C, which were assigned to E_{2H-2L}, E_{2H} and E_{1L}, respectively [13]. The strong E_{2H} peak demonstrated higher crystalline structure of ZnO, while the appearance of E_{1L} peak was attributed to the formation of oxygen deficiency, interstitial Zn and free carrier [14]. The peak at 328 cm^{-1} was ascribed to the multiple phonon scattering [15]. More peaks were observed in the Raman spectra of ZnO nanofibers treated at 600 °C. The strong and sharp peak of E_{2H} indicated the perfect wurtzite structure and high crystalline of ZnO nanofibers. The peak at 384 cm^{-1} corresponds to A1 symmetry with TO mode. Meanwhile, the peak of E_{1L} was considered to be related to the defect states.

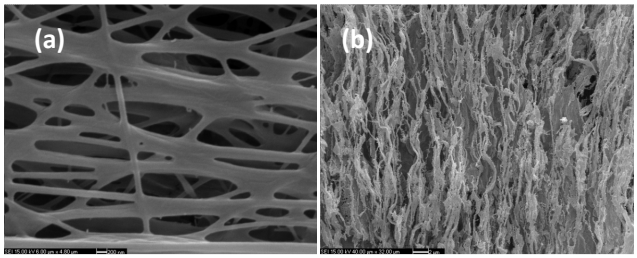

Fig. 1 SEM images of PVA/ Zn $(CH_3COO)_2 \cdot 2H_2O$ composite electrospun nanofibers and ZnO nanofibers calcined at 600 °C.

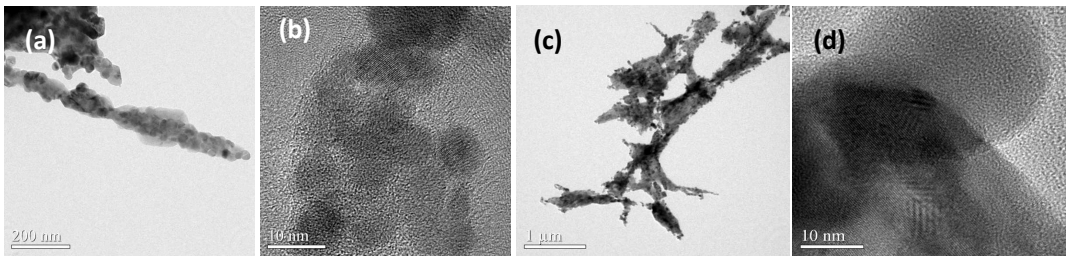

Fig. 2 (a) TEM images of ZnO nanofibers calcined at 400 °C for 2 hours on AZO glass. (b) HRTEM images of ZnO naonofibers shown in (a). (c) TEM images of ZnO nanofibers calcined at 600 °C for 2 hours on AZO glass. (d) HRTEM micrograph of ZnO nanofibers shown in (c).

The photoluminescence (PL) spectrum of ZnO nanofibers on AZO glass calcined at 400 °C and 600 °C measured at room temperature with excitation wavelength of 325 nm was shown in fig. 4. Emission peaks at 396, 450, 467nm were observed in ZnO nanofibers calcined at 400 °C. Ultraviolet (UV) emission around 396 nm was attributed to the exciton recombination related to the near band edge emission of ZnO [16]. The blue emission of 450 and 467 nm could be considered originating from the intrinsic defects in the ZnO nanofibers, such as Zn interstitial and oxygen vacancies. Emission peaks at 395, 450, 468 and 516 nm were observed in ZnO nanofibers calcined at 600 °C. The weak and broad green peak around 516 nm was owing to the transitions in defect states [17]. The existence of defect states in ZnO nanofibers demonstrated by PL results was in well agreement with the results of Raman analysis.

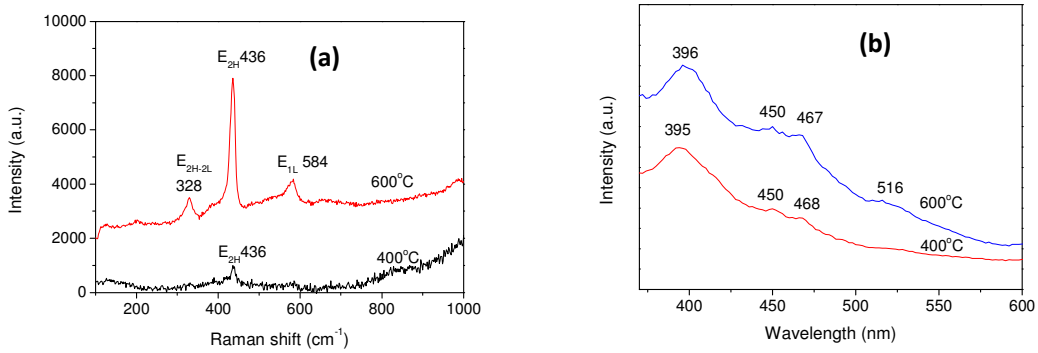

Fig. 3 (a) Raman spectra of ZnO nanofibers on AZO glass calcined at 400 °C and 600 °C. (b) Room temperature photoluminescence spectrum of ZnO nanofibers on AZO glass calcined at 400 °C and 600 °C.

Conclusion

ZnO electrospun nanofibers on AZO glass were obtained after calcinations at 400 and 600°C. Network structure composed of sheet ZnO was formed after electrospinning and calcination. Small grains with diameter of no more than 10 nm and big gains with diameter of tens nanometers were observed in the ZnO nanofibers calcined at 400 and 600°C respectively. The existence of defect states in the ZnO nanofibers was determined by the appearance of E_{1L} peak in Raman spectra and peak of 516 nm in PL spectrum.

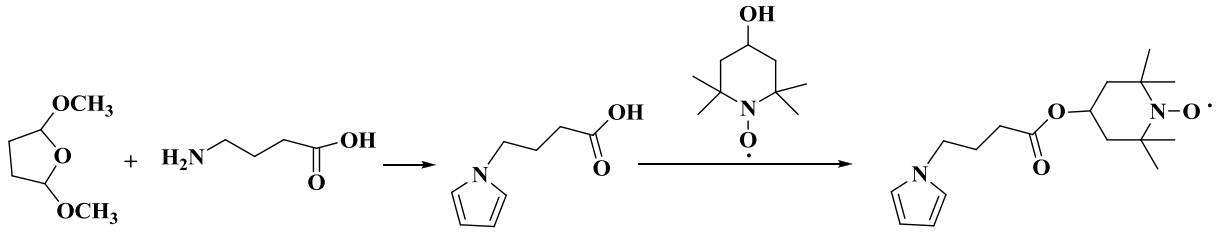
Keywords: PolyPyrrole; 2,2,6,6-tetramethylpiperidin(TEMPO); Cathode; Li-ion Battery

Abstract: 4-(3-(Pyrrol-1-yl) butyric acid base)-2,2,6,6-tetramethylpiperidin(Py-B-TEMPO) was synthesized by etherification reaction of 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy. And the polymer of its monomer was prepared by chemical oxidative polymerization and the chemical structure and battery performance of the prepared materials were characterized comparably by Mass spectrometry, ^{1}H NMR, FT-IR spectra and galvanostatic charge-discharge testing using simulant lithium ion half-cell method, respectively. The results shows that the introduction of the TEMPO group to the pyrrole could prevent the polymer from agglomeration and optimize the particle morphology of the resulting polymers, all of which made it demonstrate a significantly improved specific capacity of 86.5 $mAh \cdot g^{-1}$ (99% of the theoretical capacity) compared with PPy (21.7 $mAh \cdot g^{-1}$). Moreover, it gives an obvious voltage plateau of nearly 3.5 V which is comparable to the redox potential of TEMPO.

Introduction

Recently, the need for human beings to manufacture a more lightweight, safety and high energy-density power source becomes increasingly important. Li-ion battery as its widely applied in portable electronic devices has been considered to be the most promising technology for future.[1-3] The application of electroactive conducting polymers (e.g., polyacetylene, polyaniline, polypyrrole, polythiophene) in Li-ion battery have been widely studied.[4, 5] Among the conducting polymers, polypyrrole (PPy) is one of the most popular for use as a cathode for its high specific energy (ranging from 80 to 390 $W \cdot h \cdot kg^{-1}$)[4]. However, the specific capacity of undoped PPy is always low (only about 20 $mA \cdot h \cdot g^{-1}$). This has limited the commercial application of PPy as a cathode material. However, the usage of electroactive conducting polymers in rechargeable batteries has been hampered, because they exhibit low doping levels, this drawback lower their capacities which limit charge/discharge rates of the batteries.[6] As an alternative, using molecular design to improve the doping levels and accelerate the electrode kinetics may be useful. Recently the radical polymers bearing organic redox radicals as pendant groups on their structural unit have been researched, because of their high electrical storage capacity and high charge-discharge rate capability since PTMA was reported by Nakahara's group in 2002.[7]

In this work, we synthesized a compound of a polypyrrole derivative bearing TEMPO, and then the polymer of the prepared monomer is synthesized by chemical oxidation polymerization. The structure and morphological analysis of the polymers is characterized. Coin cells are assembled to evaluate the electrochemical performance of the polymers as a cathode material.



Experimental

Materials.

4-Hydroxy-2,2,6,6-tetramethylpiperidine 1-Oxyl Free Radial (99%), 4-Amino butyric acid (98%), 2,5-dimethoxytetrahydrofuran (98%), pyrrole were purchased from Aladdin. All other reagents were received as analytical grade and used without further purification.

Synthesis of Py-B-TEMPO.

The synthesis of Py-B-TEMPO is shown in Scheme 1.

Scheme 1. The synthesis route to Py-B-TEMPO.

Synthesis of pyrrole butyric acid[8].

2,5-dimethoxytetrahydrofuran (6.61g, 0.05mol) and 4-Amino butyric acid (4.12g, 0.04mol) were dissolved in a mixture of 30ml deionized water and 20ml glacial acetic acid and heated reflux(60 °C) for 1h until the solution turned jacinth. The reaction mixture was then cooled and extracted with CH_2Cl_2, and the organic fraction was washed with saturated brine for three times. The organic phase was separated, dried, and evaporated to dryness. Flash chromatography of the residue (silica gel, petrol ether/EtzO 20:1) afforded the title compound (4.34 g, 71.1% yield) as a white liquid. 1H NMR ($CDCl_3$, 400 MHz) d/ppm: 2.19 (t, 2H), 2.43 (t, 2H), 4.05 (t, 2H), 6.29 (t, 2H), 6.77 (t, 2H), 11.56(s, 1H).

Synthesis of Py-B-TEMPO.

4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy (2.1g) and Pyrrole butyric acid (2.4g) was dissolved in 40ml dichloromethane in the pre-dried three-necked flask, then 2.76g 1-(3-Dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride as dehydrating agent and 0.73g 4-dimethylaminopyridine was added as acylating catalyst, and stirring for 24h at room temperature. The reaction mixture was then separated by vacuum filtration. The filtrate was washed with saturated brine for three times. Organic phase was dried over sodium sulfate. The ester was purified by column chromatography using silica gel and petroleum ether/ethyl acetate afforded the title compound as golden flakes like crystals. Mass spectrometry (MS) $[M]^+$. Found: 307.4.

Chemical Polymerization of Py-B-TEMPO.

A solution of Py-B-TEMPO (0.3 g) was dissolved in CCl_4 (20ml), and then was added into a 250 ml boiling flask-3-neck. To this solution, 10ml of CH_3NO_2 containing 0.63 g of $FeCl_3$ was added drop wise for about 0.5 h, with magnetic stirring at near 0 °C. With increasing of density of $FeCl_3$•$6H_2O$ in the reactor, the mixture turned black. After the addition was completed, the stirring was continued overnight at room temperature. After completion of the reaction, 100ml deionized water was added to deposit the copolymer, which was then filtered and washed with methanol and water alternately for several times, until the filtrate became colorless. Finally, the black powder was dried in vacuum at 60 °C for 24 h, and 0.3 g black powder was obtained. Yieds: 75%.

Characterization.

FT-IR spectra of PPy-B-TEMPO and PPy were recorded with KBr pellet method on Nicolet 6700 spectrometer (Thermo Fisher Nicolet, USA) in the frequency range of 4000-400 cm^{-1}. Morphological analysis was examined using a Hitachi S-4800 scanning electron microscopy (Hitachi, Japan).

Electrochemical Measurement.

The PPy-B-TEMPO and PPy electrode was prepared by coating a mixture containing 50% prepared materials, 40% acetylene black, 10 % PVDF binder on circular Al current collector foils, followed by drying at 60 °C for 24 h. After that, the cells were assembled with lithium foil as the

anode, the prepared electrodes as cathode and 1 M LiPF6 dissolved in ethylenecarbonate (EC) and dimethylcarbonate (DMC) (EC/DMC = 1:1 wt) as the electrolyte. The charge-discharge measurements were carried out on a LAND CT2001A in the voltage range of 2.5-4.2 V versus Li/Li^+, using a constant current density of $20mA \cdot g^{-1}$ at room temperature.

Results and Discussion.

Materials Characterization.

As shown in Fig. 1, the two samples exhibited the characteristic bands of PPy,[9] involving the pyrrole ring fundamental vibration at 1545 cm^{-1} and 1459cm^{-1}, the C-H in-plane vibration at 1286 cm^{-1} and 1045 cm^{-1} and the C-N stretching vibration at 1172 cm^{-1}. We can observe that PPy-B-TEMPO has similar peaks which are assigned to the polypyrrole ring stretching. As expected, the spectrum of PPy-B-TEMPO also shows the characteristic absorption peaks at 1733, 1167 and 1365 cm^{-1}, corresponding to the C=O, C-O and nitroxyl radical groups, respectively.[10] This indicates the 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy group has been successfully introduced into the pyrrole butyric acid and the nitroxyl radical has not been destroyed during the polymerization progress.

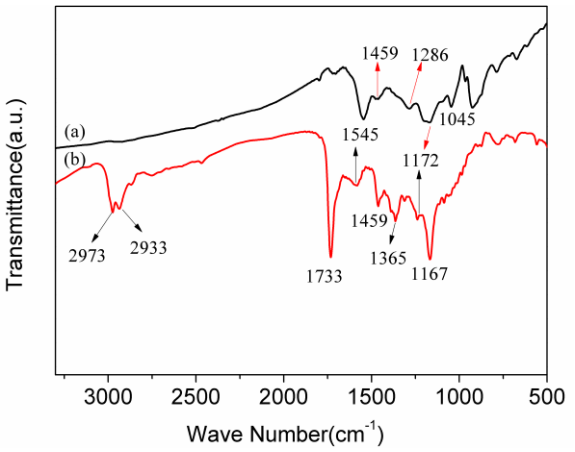


Fig. 1 FT-IR spectra of a) PPy and b) PPy-B-TEMPO

Fig. 2 shows the morphological analysis of the PPy-B-TEMPO and PPy polymer. As shown in Fig. 2 (a), the PPy polymer has a dense packing structure as plate-like and the aggregation of PPy particles can be noticed obviously. While, as shown in Fig.2 (b), the polymer of PPy-B-TEMPO shows a loose stacking structure. This open structure of PPy-B-TEMPO with the porous morphologies is in favor of the contact of electrode-active material and electrolyte; as a result, much more electrode-active material is effectively utilized and the electrochemical properties of PPy-B-TEMPO is obviously improved. All of those are very important to prepare a good cathode material for Li-ion batteries.

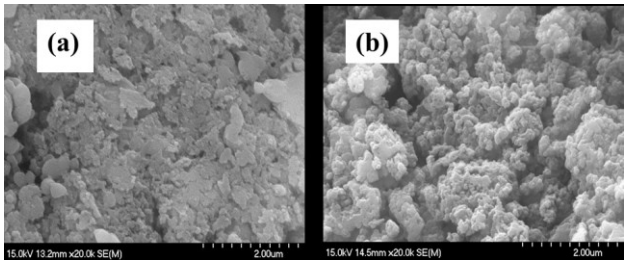

Fig. 2 SEM images of (a) PPy and (b) PPy-B-TEMPO.

Charge/Discharge Performance.

Fig. 3 a) shows the charge/discharge curves (initial cycle) of PPy and PPy-B-TEMPO cathodes in $LiPF_6$ EC/DMC (v/v, 1:1) electrolyte at a constant current of 20 $mA \cdot g^{-1}$ between 2.5 and 4.2 V. At low current density of 20 $mA \cdot g^{-1}$, an initial discharge capacity of PPy-B-TEMPO up to 86.5 $mAh \cdot g^{-1}$ can be obtained, which is higher than that of PPy electrode of 21.7 $mAh \cdot g^{-1}$. It can be ascribed to the contribution of redox-active nitroxyl radical, as well as the prominent structure features of PPy-B-TEMPO, which can allow the electrolyte to better infiltrate into the polymer and provide ionic channels for polymeric electrode redox reactions. Also, we notice that it gives an obvious voltage plateau of nearly 3.5 V which is comparable to the redox potential of TEMPO.

Discharge profiles of the polymer material at 20 $mA \cdot g^{-1}$ are shown in Fig. 3 b), compared with the PPy, the cycling stability of PPy-B-TEMPO exhibits a serious capacity degeneration, which is possibly caused by the seriously re-aggregation of PPy-B-TEMPO during the repeated charge and discharge process, due to the pristine looser stacking micro-structure of PPy-B-TEMPO than that of PPy. However, it is noteworthy that a flat voltage plateaus is still obviously observed in the charge-discharge curves of the PPy-B-TEMPO even at 50^{th} cycles, implying that PPy-B-TEMPO electrodes has a lower polarization during the charge-discharge process.

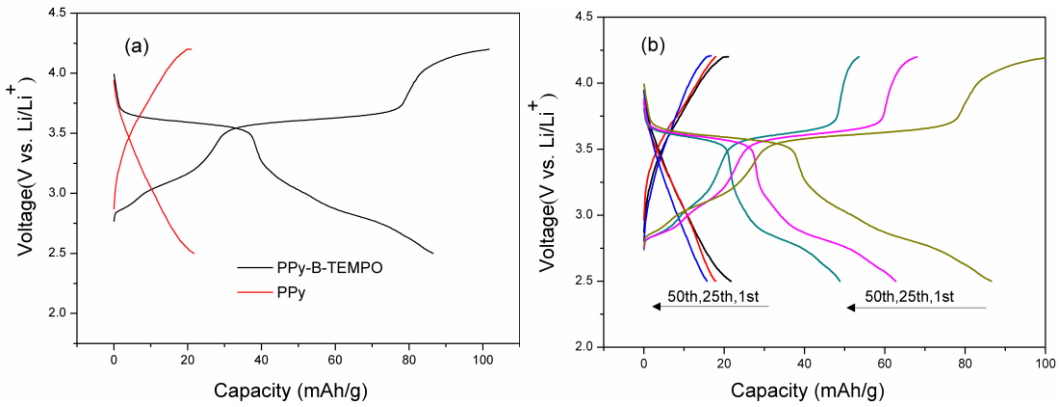

Fig. 3 Charge/discharge curves of PPy and PPy-B-TEMPO in LiPF6 EC/DMC (v/v, 1:1) electrolyte at a constant current of 20 mA g−1. b) Discharge profiles of PPy and PPy-B-TEMP

Conclusions

The monomer of Py-B-TEMPO was prepared by the reported method. And the polymer of PPy-B-TEMPO was synthesized by chemical oxidation polymerization. The charge/discharge measurements show that the PPy-B-TEMPO had high capacity of 86.5 $mAh \cdot g^{-1}$, which was significant higher than PPy of 22.6 $mAh \cdot g^{-1}$. The PPy-B-TEMPO electrode also shows an obvious voltage plateau of nearly 3.5 V, compared to the pristine PPy-based electrode and was promising as advanced cathode material.

Nanostructured Morphology of Spinel $LiMn_2O_4$ Oxide under Microwave Heating

Di Huo

Key Laboratory of Anisotropy and Texture of Materials (Ministry of Education), Northeastern University, Shenyang 110819, Liaoning, P R China

Email: dhuo@mail.neu.edu.cn

Key words: $LiMn_2O_4$; surface morphology; microwave heating; nanorod; nanowhisker.

Abstract: The surface morphology and structure of the cubic stoichiometric spinel $LiMn_2O_4$ powder prepared by microwave heating were examined using X-ray diffraction, scanning electron microscopy and transmittance electron microcopy. It is shown that the surface morphology of $LiMn_2O_4$ particle changed with increasing preparing temperature, while the crystal structure kept unchanged. Novel nanostructured morphologies including nanorods and nanowhiskers were formed under appropriate synthesis conditions. The growth mechanism of the nanostructured morphology of spinel $LiMn_2O_4$ was discussed in accordance with period bonding chains (PBCs) theory.

Introduction

Stoichiometric spinel $LiMn_2O_4$ has attracted considerable attention as an active cathode material in Lithium ion batteries. It is commonly regarded as a potential candidate material to replace $LiCoO_2$ and $LiNiO_2$ due to the advantages of low cost, environmental benignity and operational safety of the manganese element [1, 2]. However, the poor performances such as considerable capacity fading on cycling at an elevated temperature and low capacity of the micrometer-sized grade $LiMn_2O_4$ powder restricted its wide practical applications [3]. Therefore, various efforts had been made to enhance the electrochemical properties of spinel $LiMn_2O_4$ cathode.

The stoichiometry, crystal structure and morphology of the cathode materials in Lithium ion batteries are crucial for its electrochemical properties [4]. In recent years, substantial researches have confirmed that crystalline $LiMn_2O_4$ powders with specific nanostructured morphological features possessed improved electrochemically performances. For instances, the nanosized $LiMn_2O_4$ particles exhibit excellent rate performance and capacity retention on cycling at 30-50℃, and structural stability [5,6]. In particular, one-dimensional ultrathin $LiMn_2O_4$ nanowire showed very good electrochemical performances at high current rate in a large compositional range [7, 8]. These improved properties are mainly attributed to the merits of morphological and structural features of the nanostructured spinel $LiMn_2O_4$.

The particle size and morphology of $LiMn_2O_4$ are directly related to synthesis method and conditions. Until now, sol-gel [9] and hydrothermal plus ion exchange [10] or hydrothermal [11] methods were used to make the one-dimensional crystalline $LiMn_2O_4$. It was also mentioned that spinel $LiMn_2O_4$ powder with needle-like morphology was obtained under microwave heating by using γ-MnOOH and $LiOH \cdot H_2O$ as starting precursors [12]. In this paper the cubic spinel $LiMn_2O_4$ powders with nanostructured surface morphologies were found under conditions of high temperature and oxygen flow protection using microwave heating, and the growth mechanism of the nanostructrured surface morphologies was also discussed.

Experimental

Commercial analytical grade MnO_2 and Li_2CO_3 were used as starting materials without further treatment. The reactants were weighed on mole ratio of $LiMn_2O_4$ stoichiometrically, and then mixed and ball milled in ethanol for 8 hours. After drying at 100℃, the mixture was put into a SiC crucible with a diameter of 20 mm and a height of 40 mm which was also used as an inductor to microwave energy. The crucible was then placed in a quartz tube which inserted vertically in TE_{101} microwave heating cylinder cavity. The employed microwave frequency is 2.45GHz and the power input is in range of 300-500W. The heating temperature was controlled in the range of 850-1200℃, the duration time was 20-30min and the samples were ground intermittently 2-3 times during this process. Oxygen was used as protection gas, and the flow rate was 1.2mL/min. An infrared thermo detector （WGG2-201, Shanghai, China）was used to monitor surface temperature of the powder in crucible.

Phase composition of the as-synthesized $LiMn_2O_4$ powder was examined by X-ray diffractometer （XRD, Model D/max-rA, Rigaku, Japan）employing graphite-monochromated CuK_α radiation. After being dispersed in ultrasonic bath and surface coated with gold, the morphology and surface composition of the $LiMn_2O_4$ powders were characterized by field emission scanning microscopy （FESEM, JEOL，JSM-6301F）equipped with EDS(Oxford). Transmission electron micrographs and selected area diffraction pattern were obtained using an analytical Transmission Electron Microscopy (TEM, Philip, EM420, Holland).

Results and Discussion

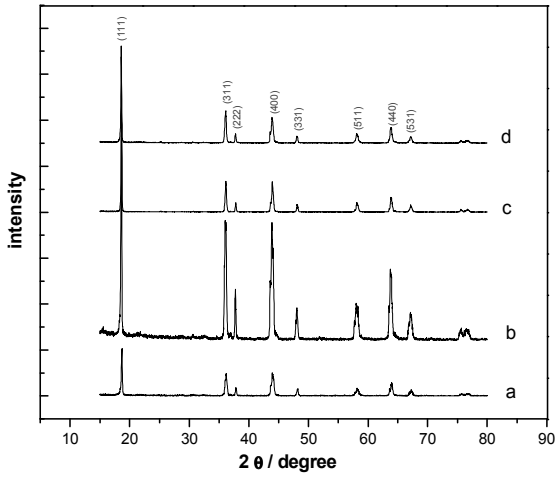

Fig.1. XRD spectra of the as-calcined $LiMn_2O_4$ powder under microwave heating at: 850℃ (a); 1000℃ (b); 1100℃ (c); 1200℃ (d)

Fig. 1 shows XRD spectra of the $LiMn_2O_4$ powders calcined at different temperatures by microwave. It is shown that in the temperature range of 850-1200℃ and under flow oxygen protection, the crystalline phase of the stoichiometric $LiMn_2O_4$ powder had predominately been single spinel phase which can be indexed with standard cubic spinel structure (JCPDS No.35-0782, space symmetry group Fd3m). In fact, the X–ray diffraction peaks splits of several crystallographic planes of the lower temperature synthesized $LiMn_2O_4$ samples almost completely disappeared as the temperature increased to 1100℃. It had been mentioned that there was a wide range of solid solution within the Li-Mn-O family of spinel compounds, and a number of discrete phases with

different crystallographic structures were formed as the temperature was raised from 800℃ to 1200℃ in conventional solid state synthesis [13]. Different from the above phenomenon, in this experiment the highest symmetry of spinel cubic crystal structure was achieved as the sample was heated in range of 1000℃ to 1100℃, and the phase composition remain unchanged till 1200℃ under flow oxygen. The cubic crystalline $LiMn_2O_4$ spinel demonstrated higher crystal structure stability under microwave heating than that under the conventional heating in the same temperature range. This probably is due to the microwave heating features of faster heating and cooling, shorter duration time and also higher partial oxygen pressure utilized.

On the contrary to the high stability of cubic spinel crystal structure of $LiMn_2O_4$ powders, their surface morphologies were varied obviously in the temperature range of 850-1200℃. Fig. 2 (a) shows SEM micrograph of the $LiMn_2O_4$ powder heated by microwave at 850℃. It can be found the crystalline particles exhibit very flat and well developed crystallographic facets. Theoretically, the $LiMn_2O_4$ crystalline particle exhibits regular polyhedral shape which is bounded by the planes of {111}, {110} and the truncated {100}, therein some {111} facets presents almost perfect triangle shape. Here, the marked feature of microwave irradiated $LiMn_2O_4$ powders at 850℃ is that the faceting planes of {111} show very flat and sharp terrace-edges between the crystallographic planes on the crystalline particle surfaces.

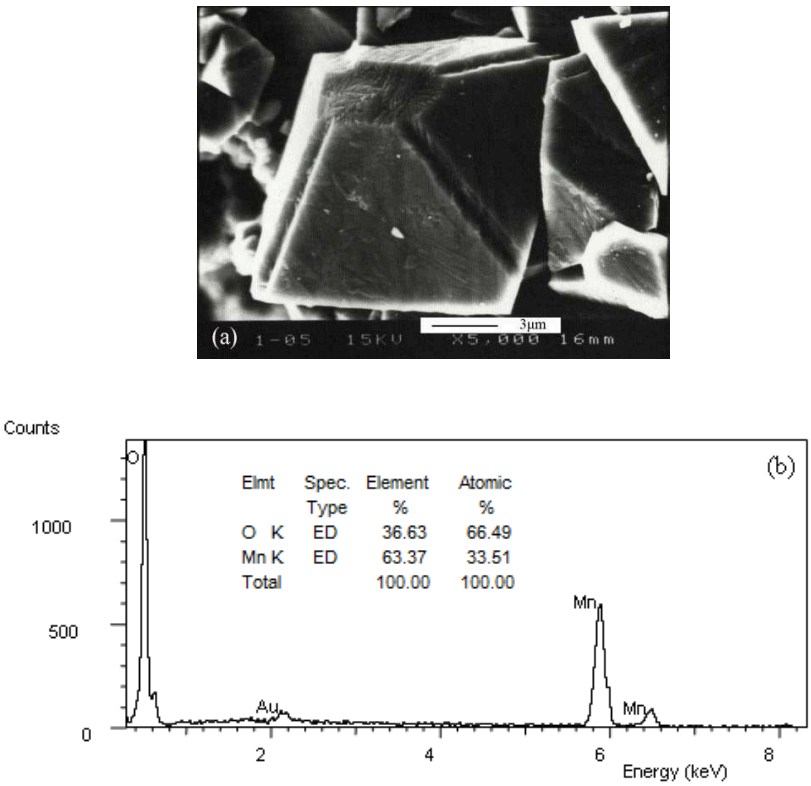

Fig. 2. SEM micrograph of the spinel $LiMn_2O_4$ particles heated at 850℃(a); EDS analysis of surface composition of the spinel particles (b)

The morphology of crystal depends kinetically on the growth rate of crystallographic planes, and the crystal planes with higher growth rate usually disappear from crystal forms, so the equilibrium shape of crystal is generally bounded by crystal planes having the lowest growth rate [14]. Periodic Bond Chains (PBCs) theory is useful for building up the relation between crystal structure and crystal growth morphology [15]. The {111} planes of spinel $LiMn_2O_4$ crystal can be assigned to F plane of the PBCs theory, and it can be predicted that the equilibrium morphology of spinel crystals

should be an octahedral shape composed of six {111} triangular planes for their lowest surface energy [16,17]. However, the $LiMn_2O_4$ particles prepared by microwave heating showed predominately an polyhedral form exhibiting faceting of {111}, {100} and {110}, and this equilibrium growth particle shape is similar to the one found in conventional solid state synthesized $LiMn_2O_4$ powders [18], except that there is no round transition facets between the crystallographic faces. Generally, due to the dangling or unsaturated bonds among the ions in crystal surface layers, the coordination relations of the ions near the crystal surface can affect their geometric profile. The EDS results of in this work showed that the ratio of Mn/O on particles surface is closer to its theoretical value, as shown in Fig. 2(b). It means that no or less of chemical composition on particles surface layer is lost, for which an ideal coordination relation among the ions and configuration near to theoretical value are achieved, so the majority {111} planes on polyhedral shape particles show more flat and smooth layered characters.

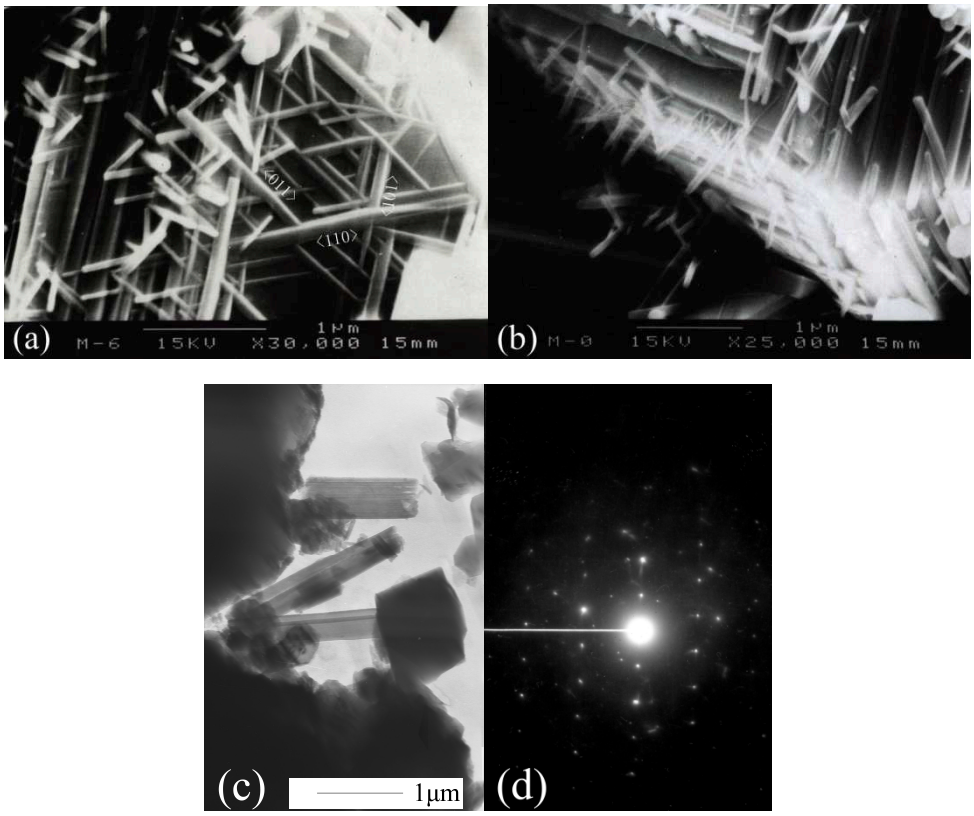

Fig. 3. SEM Micrographs of the nanorods formed on {111} surfaces (a) and on corner (b) of spinel $LiMn_2O_4$ particles at 1000℃, and TEM image(c) and SAED pattern (d) of the spinel nanorod

The surface morphology of spinel crystalline particles changed tremendously with increasing microwave heating temperature. When the reactant mixture was microwave heated at 1000℃, it was found that on the surface of some particles a lots of one-dimensional crystals nucleated along the [110]directions on spinel triangular {111} planes, as shown in Fig. 3a. Some of them grew habitually into nanorod and out of particles surface with about 100nm in diameter and several micrometers in length. All of these one-dimensional nanorods predominately nucleated on the layered slice planes of {111}, and strictly keeping crystallographic directions of [110] on {111} faces, i e., {111}[110] of spinel $LiMn_2O_4$ crystal, as shown in Fig. 3b. The TEM image of the nanorods and its selected area electron diffraction pattern (SAED) are shown in Fig. 3c and 3d, which also indicate the cubic spinel crystal structure of the nanorod $LiMn_2O_4$.

When the temperature was increased to 1100℃, some peculiar morphologies were generated on {111}, {110} and truncated {100} faces of the original equilibrium particles. It is admitted that there was uneven temperature distribution in the SiC crucible. In relatively lower temperature zones, the truncated {100} face and the vicinal {110} face between the {111} faces were still covered with a thin layer before the powder decomposed as shown in Fig. 4a. With the temperature increased, the thin layer on {110} step facets and {100} rough facets eroded away, so the kinked surface of {100} (K face of PBCs) and stepped surface of {110} （S face of PBCs）of the crystal began to emerge. It can also be noted that the decomposed original {110} step faces are virtually consisted of even fine sub-steps of several nanometer high.

However, in relatively higher temperature zones, the growth of nanowhiskers at the expense of dissociation of {110} and {100} surface planes of the spinel crystal become pronounced and then new crystal morphologies were formed. Different from the nanorod crystals observed above, a quantity of nanosized whisker crystals with about 1 micrometer in length and 10 nanometers in diameter nucleated and grew on the layered growth {111} faces, and all these newly formed crystals tend to align along the [110] direction of the crystal and some of the nanowhiskers have also grown out of the crystal surface, as shown in Fig. 4b. The same as the growth of nanowhisker on layered eroded {110} crystal faces, a large number of nanowhiskers can be seen on the truncated {100} crystal faces and they also kept with [110] directions. The crystallographic configuration of these nanowhiskers is totally in the same way as that of the nanorods in Fig. 3a.

It is reasonable to postulate that the growth of crystalline spinel $LiMn_2O_4$ powders prepared by microwave solid state synthesis is by way of both diffusion and vapor-condensation mechanisms. As using microwave to heat the mixture of MnO_2 and Li_2CO_3 reactants, MnO_2 has higher ability of coupling with and absorbing microwave energy [18]. With heating temperature increased the phase transformation process can be in the thermodynamically sequence of MnO_2-Mn_2O_3-Mn_3O_4, therein the last ferrite phase Mn_3O_4 has the highest dielectric couple loss to microwave energy, which means microwave energy can be effectively used to heat the reactants. This may also be the reason that the heating rate of the reactant mixtures became accelerated in later period of microwave synthesis in this experiment. The ability of coupling with or absorbing microwave energy of Li_2CO_3 is relatively low, it can thus be thought that Li_2CO_3 was heated by conduction heat from the microwave inductor SiC crucible and the high temperature of heated MnO_2, and then the heated Li_2CO_3 decomposed and reacted with MnO_2 and gradually intercalated into MnO_2 to form $LiMn_2O_4$ spinel composite oxide. If the temperature was increased to even higher temperature, not only solid diffusion mechanism, but vapor-condensation mechanism for mass transport will play an important role in the nucleation and growth of $LiMn_2O_4$ crystal, so the surface morphology of $LiMn_2O_4$ becomes various kinds due to this change.

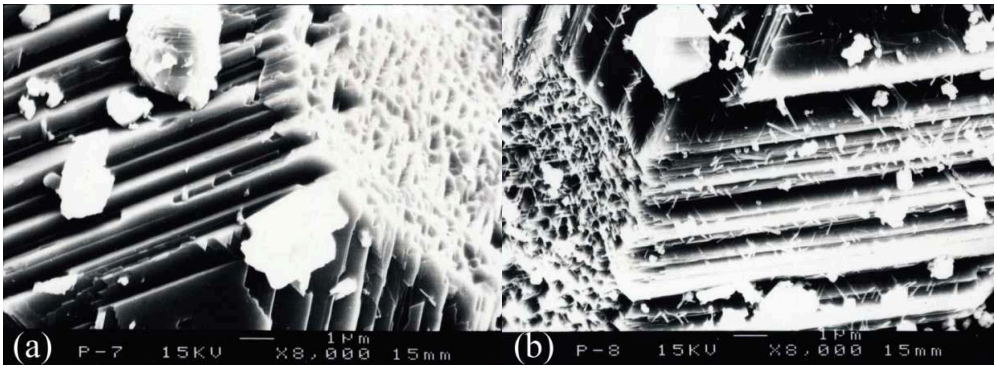

Fig.4. SEM surface morphologies of the spinel formed at the temperature of 1100℃ (a) and 1150 ℃ (b)

External conditions, such as the supersaturation and temperature at the surface, can definitely influence crystal shape. The existence of various kinds of morphological crystals may indicate that the mechanisms of nucleation and growth changed when the powder mixture was heated at higher temperatures. In view that cubic structure of $LiMn_2O_4$ standard spinel belongs to Fd3m space group, oxygen ions occupied the 32e crystallographic position and arranged according to the a-b-c-a-b-c----- sequence to form face centered cubic close packing [19]. The closest packed {111} planes consisted of oxygen anions are the first atomic vicinal plane, and crystal directions of {111}[110] are the most dense package direction of Mn ion at 16d octahedral position, which also means {111}[110] that the crystallographic direction is stronger periodic bond chain sectors. Due to higher bond energy in the periodic bond chains sector direction, the growing units can readily adhere to and integrate into the crystals [14]. Therefore under appropriate conditions, the reactant ions detached and/or diffused away from {110} and {100} crystal faces, and then incorporated into and grew quickly along with the {111}[110] crystallographic directions, finally leading to one-dimensional nanorod or nanowhisker crystals. The theoretical calculation [20] and experimental result [16] confirmed that the most stable crystallographic plane with the lowest solid–to–vapor surface energy of spinel $LiMn_2O_4$ is {111} planes, which abide with increasing sequence of $\gamma_{SV\{111\}}<\gamma_{SV\{100\}}<\gamma_{SV\{110\}}$. So, under the even higher temperatures, the decomposed crystal planes of {110} and {100} will lead to more supersaturated concentration of reactant ions around the crystal, which results in different crystal morphologies other than nanorods on the $LiMn_2O_4$ powder surface. As shown in this work, when the microwave heating temperature was increased to 1200℃ a lots of sub-micron sized round island crystals emerged on the {111} planes besides the one-dimensional nanostructured crystals.

Conclusion

The intrinsic characters of microwave heating such as fast kinetic, short duration time and selectively internal heating are beneficial for increasing mass transport rate which may involve evaporation-condensation mechanism. With microwave heating combined with oxygen flow protection, a number of novel nanostructured surface morphologies of spinel $LiMn_2O_4$ oxide were formed in the temperature range of 850-1100℃, while the crystal structure kept unchanged. It may be indicated that under a certain condition one-dimensional $LiMn_2O_4$ nanorods or nanowires can be prepared in a facile and fast way by microwave heating.

Abstract: Performances of Ag-SnO_2 electrical contact materials can be strongly affected by the microstructure. In this work, Ag-SnO_2 composite powders were synthesized by chemical reductive precipitation method. During the precipitation process, Ag particle was deposited onto the surface of SnO_2 particle with the assistance of citric acid. The microstructure and properties were analyzed for the prepared Ag-SnO_2 electrical contact materials. Our research reveals that the particle size of SnO_2 has significant influence on the morphology of the Ag-SnO_2 composite powders, and therefore on the microstructure and physical properties of the electrical contact materials. With the decrease of particle size of SnO_2, hardness of the Ag-SnO_2 electrical contact materials increases, while electrical conductivity decreases.

Introduction

Silver-tin oxide composite materials have been widely applied to low voltage switch in the past two decades [1]. In practice, the advantages of eco-friendly, low temperature rising and anti-welding behaviors makes them the most attractive replacement for Ag-CdO electrical contact materials. For Ag-MeO electrical contact materials, microstructural control has been considered to be the decisive factor for high performances [2]. Various preparation [3-7] and processing [8, 9] methods have been used for microstructural optimization of the Ag-MeO electrical contact materials. Previous research [7, 10] has revealed that homogeneous distribution of SnO_2 in Ag matrix is beneficial to good electrical and mechanical properties. An chemical reductive precipitation method was once developed by Wolmer et al. [5] to prevent SnO_2 from aggregation. Paul et al. [6] investigated the effects of coating process, and the results indicate that chemical plating can also enhance the wettability between SnO_2 particles and Ag matrix, and improve the thermal and electrical conductivity of the Ag-SnO_2 electrical contact materials. Whereas, a fundamental research describing the influence of the particle size on the basic properties of Ag-SnO_2 electrical contact materials was scarce but urgently need.

In this work, the chemical reductive precipitation method was successfully used to prepare the Ag-SnO_2 composite powders with different particle sizes of SnO_2. The influence of SnO_2 particle size on microstructure and properties of the electrical contact materials was systematically investigated.

Experiment Details

Reagents

Silver nitrate ($AgNO_3$, analytical reagent) was provided by the Sino-platinum Metals. Tin (IV) chloride ($SnCl_4 \cdot 5H_2O$, analytical reagent), tin (II) chloride ($SnCl_2 \cdot 4H_2O$, analytical reagent), citric acid anhydride ($C_6H_8O_7 \cdot H_2O$, analytical reagent), urea ($CO(NH_2)_2$, analytical reagent) and Ascorbic acid ($C_6H_8O_6$, analytical reagent) were purchased from Sinopharm Chemical Reagent Co.. These chemicals were used as received without further purification. Four kinds of SnO_2 particles, S1, S2, S3 and S4, were used for the preparation of the electrical contact materials, as shown in Table 1. The precursor of S1 was synthesized via direct hydrolyzing of Tin (IV) chloride. The precursor of S2 was synthesized via the homogenous precipitation of tin (II) chloride. The obtained precursors were transformed into SnO_2 by calcining at 600 ^oC in air. S3 and S4 were purchased from Luoyang Found New Materials Technology Co., Ltd..

Synthesis Of The Ag-Sno_2 Composite Powders And Contact Materials

The mass radio of Ag to SnO_2 is 88:12 in the final electrical contact materials. In a typical synthesis, SnO_2 and $AgNO_3$ was added to a strongly stirred 2M citric acid solution, and then followed by a ultrasonic dispersion. Afterwards, the silver was slowly reduced by dropwise addition of ascorbic acid solution. The obtained precipitates were aged for 30 min at room temperature, and then dried at 80 ^oC after rinsing with deionized water and ethanol. The dried cakes were lightly crushed with an agate pestle and mortar, and then calcinated in air at 600 ^oC to obtain the Ag-SnO_2 composite powders. The as-prepared composite powders were then hot-pressed to fabricate the electrical contact materials (Φ12×5 mm) in a graphite die at 700 ^oC with a pressure of 60 MPa under the protection of argon.

Characterization Techniques

Density of the Ag-SnO_2 contact materials was measured by the Archimedes method. Hardness was determined using a Vickers hardness tester. An FQR 7051 vortex conductivity apparatus was used to investigate the electric conductivity of the Ag-SnO_2 contact materials. XRD analysis was conducted under 40 kV/40 mA using nickel-filtered Cu Kα radiation (Model PW 3040/60; PANALYTICAL B.V, Almelo, the Netherlands). Particle size distributions were analyzed by the Laser particle size analyzer (LA-920; HORIBA, Kyoto, Japan). Particle morphologies were observed via field emission scanning electron microscope (FE-SEM) with an acceleration voltage of 10 kV (Model JSM-7001F; JEOL, Tokyo, Japan). Microstructures of the Ag-SnO_2 electrical contact materials were examined by scanning electron microscope (SEM, JSM-6510A; JEOL, Tokyo, Japan).

Results and Disccusion

Morphology of the SnO_2 particles

The mean sizes of the used SnO_2 particles are shown in Table 1. The morphologies of the SnO_2 are presented in Figure 1. All the four kinds of particles show narrow size distribution and loose aggregation, which is also verified by the analysis of particle size distribution (Figure 2). The grain size of S1 is about 15 nm calculated by the Scherer formula, which is out of the range of Laser particle size analyzer.

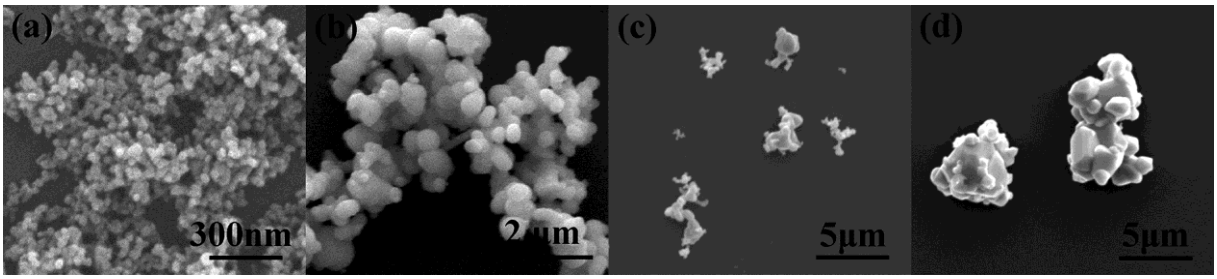

Fig. 1 FE-SEM micrographs show the morphologies of the original SnO2 core: (a) S1; (b) S2; (c) S3; and (d) S4.

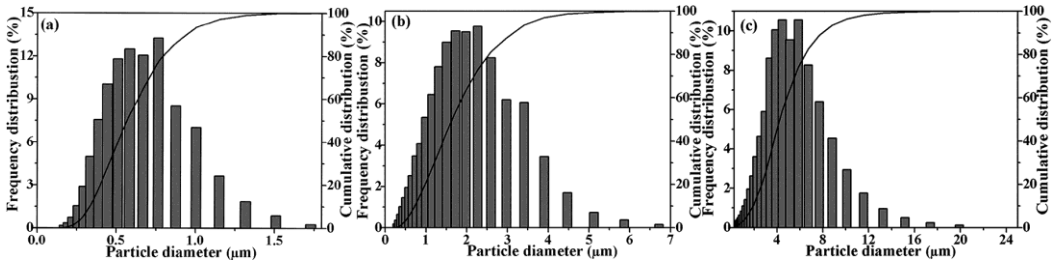

Fig. 2 Particle size distribution of the SnO_2 powders. (a) S2; (b) S3; (c) S4.

The coating of SnO_2 by Ag

During the reduction process, Ag particles are precipitated onto the surface of the SnO_2 particles. The citrate ion has two effects: one is to absorb onto the surface of SnO_2 particles to prevent them from aggregation by the electrostatic force; the other is Ag^+ ion and citrate ion have a tendency to form a complex, which is beneficial to the homogeneous coating of Ag onto the surface of SnO_2 cores.

The morphologies of the as-prepared Ag-SnO_2 composite powders were observed by FE-SEM, as shown in Figure 3. The composite powders show narrow size distribution, which is due to the homogenous reaction in the system. Particle size of the composite powders increases with increasing particle size of SnO_2. Thus, particle size of the composite powders can be adjusted by the SnO_2 particle size. The smaller the SnO_2 particle size, the higher the specific surface area, and thus the more the nucleation sites of Ag.

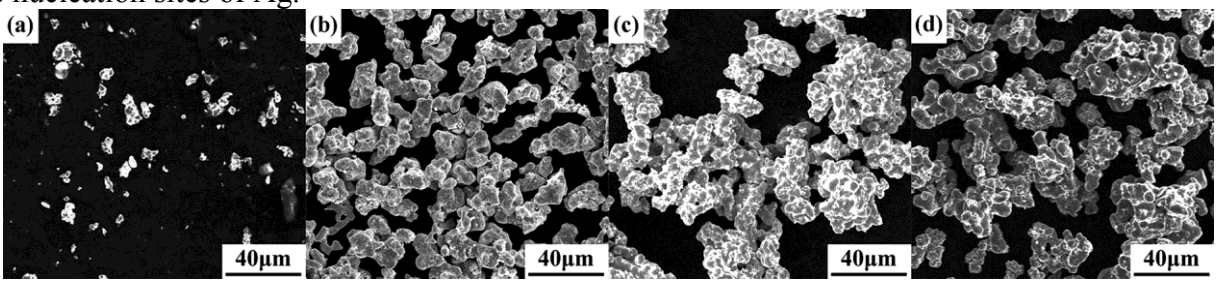

Fig. 3 Morphology of the Ag-SnO_2 composite powders with different particle size of SnO_2: (a) S1; (b) S2; (c) S3; (d) S4.

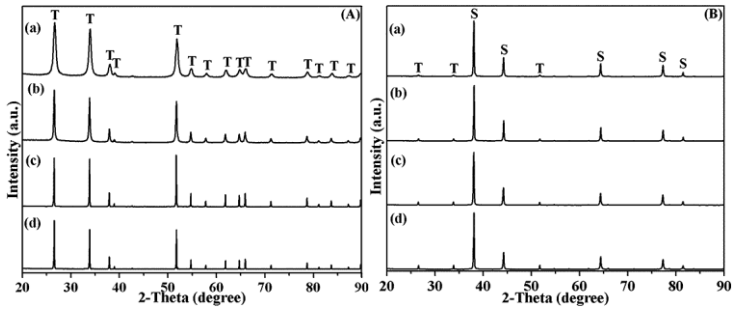

Fig. 4 XRD patterns of (A) the original SnO_2 particles, and (B) the corresponding Ag-SnO_2 composite materials: (a) S1; (b) S2; (c) S3; and (d) S4. Letters T and S represent tin oxide and silver, respectively.

XRD analysis (Figure 4) shows that the original particles are all pure rutile tetragonal structured SnO_2, and the as-prepared Ag-SnO_2 composites are all composed of face-centered cubic Ag and rutile tetragonal structured SnO_2. No other phases were observed.

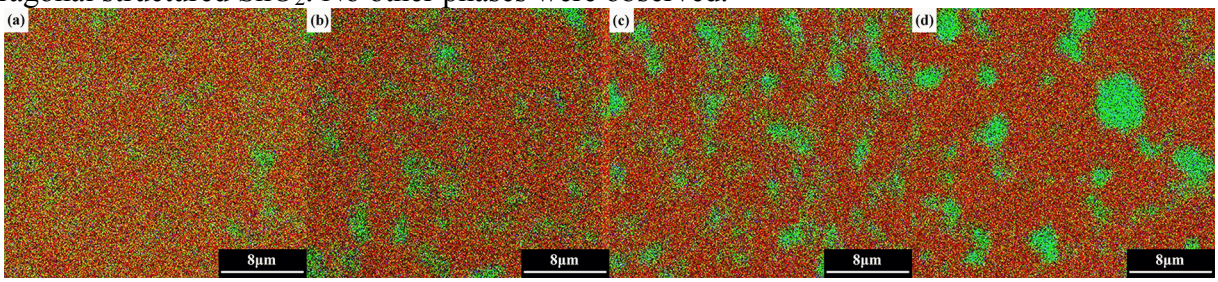

Fig. 5 EDX element mapping shows the element distribution in Ag-SnO_2 electrical contact materials (red-Ag rich zone, and green-Sn rich zone): (a) S1; (b) S2; (c) S3; (d) S4.

Element distributions in the Ag-SnO_2 electrical contact materials were analyzed by EDX, as shown in Figure 5. The second phase SnO_2 particles are all uniformly dispersed in the Ag matrix with low degree of aggregation. The size of Sn rich area is consistent with the initial sizes of the SnO_2 particles.

Properties of the Ag-SnO_2 electrical contact materials

Hardness and electric conductivety are of great importance to the electrical contact materials. The effect of particle size of SnO_2 on hardness and electric conductively were shown in Figure 6.

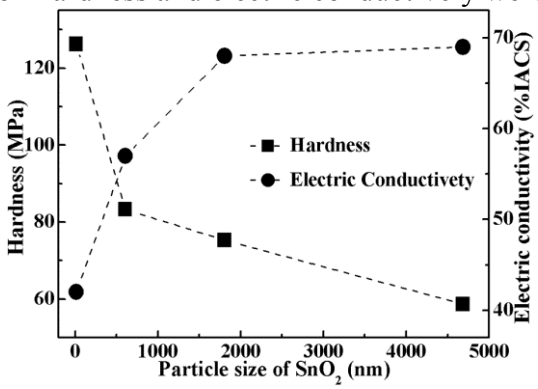

Fig. 6 The influence of particle size of SnO_2 on hardness and electric conductively of the bulk Ag-SnO_2 contact materials

With the increase of SnO_2 particle size, hardness decreases while electric conductivety increases for the Ag-SnO_2 electrical contact materials. For the incoherent interface between SnO_2 and Ag, the flow stress, $\Delta\sigma$, of the Ag-SnO_2 electrical contact materials can be described by the Orowan mechanism [10].

$$\Delta\sigma \propto \frac{G \cdot b}{L} \tag{1}$$

where G is shear modulus, b is the value of Burgers vector, and L is mean free spacing between SnO_2 particles. It can be seen that flow stress increases with the increase of amount of oxide particles in the silver matrix. The strengthening of Ag-SnO_2 electrical contact materials is beneficial to the wear resistance from the point of view applications. However, high hardness is detrimental to mechanical processing.

It is believed that electric conductivity is achieved the transmission of the conduction electrons, which can be weaken by the interface scattering in the Ag-SnO_2 interfaces [11]. The smaller the SnO_2 particle size, the higher the specific surface area, and thus the stronger of interface scattering, due to lower electric conductivity.

Conclusion

Ag-SnO_2 composite powders were successfully prepared by the chemical reductive precipitation of Ag particles onto the surface of SnO_2 particles. Citric acid was introduced as both dispersant for forming SnO_2 suspension, and coordination connection between Ag and SnO_2 particles in the reaction system. Therefore, the silver particle was deposited onto the surface of SnO_2 particles by heterogeneous nucleation. As a consequence, the particle size of the Ag-SnO_2 composite powders decreases with decreasing particle size of SnO_2. It was observed that SnO_2 particles are all uniformly dispersed in the Ag matrix. With the increase of SnO_2 particle size, hardness decreases and electric conductivity increases.

Abstract: This paper investigates a composite cathode $La_{0.2}Sr_{0.8}TiO_{3+\delta}$-$Ce_{0.8}Sm_{0.2}O_{2-\delta}$ (LSTO-SDC) for the direct steam electrolysis in an oxide-ion-conducting solid oxide electrolyzer. The dependences of electrical conductivity of the reduced LSTO on temperature and oxygen partial pressure are studied and further correlated to the electrochemical properties of the cathode in symmetric cell LSTO-SDC/YSZ/LSTO-SDC and solid oxide electrolyzer LSTO-SDC/YSZ/LSM-SDC, respectively. Current efficiencies of the solid oxide electrolyzer with LSTO-SDC cathode were found to be 92.38% and 91.17% with or without reducing gas flowing over them under the applied voltage of 1.8 V at 800 ^{o}C, respectively.

Introduction

Hydrogen is an environmental-friendly fuel, it is regard as the candidate fuel because it has the potential to solve the environmental and energy shortage issues associated with fossil fuel [1-2]. Many processes have been used to promote the sequestration of steam including photosynthesis, heterogeneous catalysis and steam electrolysis [3-4]. The high-temperature steam electrolysis in a solid oxide electrolyzer (SOE) stands out for its possibility to operate in high efficiency and can be further combined with renewable electricity to effectively exploit available heat streams [5]. Solid oxide electrolyzer is the reverse process of solid oxide fuel cell, which can directly convert the electrical energy into chemical energy and recently it has attracted a lot of interests. A solid oxide electrolyzer operates at high temperature which could partially offer energy for molecular dissociation, leads to more favorable kinetics and thermodynamics. Using external electricity, an oxide-ion-conducting solid oxide electrolyzer can electrolyze steam into hydrogen and oxygen. At the cathode, H_2O molecules are electrochemically reduced into H_2 under applied potential, while the generated O^{2-} transports through the electrolyte to the anode where O_2 gas is formed [6].

Composite Ni-YSZ cathode has been preferentially used for the high temperature steam electrolysis in an oxide-ion-conducting solid oxide electrolyzer [7]. However, the composite cathode can only work in an atmosphere with a significant concentration of H_2, or the oxidation of Ni to NiO at high temperature would occur and further cause a loss of electronic conductivity and the failure of the composite cathode. The poor redox cycling is also the critical problem for a Ni-YSZ cathode [8]. Irvine et al. have demonstrated an efficient ceramic $(La_{0.75}Sr_{0.25})_{0.95}Mn_{0.5}Cr_{0.5}O_3$ (LSCM) cathode for the direct steam electrolysis [9]. Recently, we demonstrated that some adverse chemical changes may occur in LSCM cathode under strong reducing potentials when perform high-temperature steam electrolysis, which further degrades the Faradic current efficiency and the

electrode performances [10]. On the other hand, the p-type conduction in LSCM is restricted when high voltage is applied to cathode for electrochemical reduction of steam [11]. Therefore, a cathode that has n-type conduction with sufficient electro-catalytic activity seems more suitable in cathode atmosphere. The $La_xSr_{1-x}TiO_{3-\delta}$ (LSTO) perovskite is an active and redox-stable material that has high n-type conductivity upon reduction atmosphere, which has attracted a lot of attentions in the field of solid oxide fuel cell anode materials [12]. Perovskite $La_{0.2}Sr_{0.8}TiO_{3+\delta}$ would well fit the cathode atmosphere in an oxide-ion-conducting solid oxide electrolyzer.

In this work, a composite cathode $La_{0.2}Sr_{0.8}TiO_{3+\delta}$-$Ce_{0.8}Sm_{0.2}O_{2-\delta}$ is prepared and utilized for the direct steam electrolysis in an oxide-ion-conducting solid oxide electrolyzer. The electrical properties of $La_{0.2}Sr_{0.8}TiO_{3+\delta}$ are studied and then correlated to the cathode performance. High temperature steam electrolysis is then systematically investigated and evaluated with a solid oxide electrolyzer- (cathode) $La_{0.2}Sr_{0.8}TiO_{3+\delta}$-$Ce_{0.8}Sm_{0.2}O_{2-\delta}$/YSZ/$(La_{0.8}Sr_{0.2})_{0.95}MnO_{3-\delta}$-$Ce_{0.8}Sm_{0.2}O_{2-\delta}$ (anode).

Experimental

$La_{0.2}Sr_{0.8}TiO_{3+\delta}$ (LSTO) powders were synthesized by a traditional solid-state reaction method [13]. The phase formations of the LSTO powders were analyzed by X-ray diffraction (XRD, $2\theta=3^{o}\cdot min^{-1}$, D/MAX2500V, Rigaku Corporation, Japan). Subsequently, the sintered samples were reduced at 1400 ºC for 12 h in 5%H_2/Ar. The conductivity test was performed using a DC four-terminal method from 130 to 800 ºC in 5%H_2/Ar atmosphere. The 8YSZ powders were dry-pressed into a green disk with a diameter of 20 mm followed by a sintering in air at 1450 ºC (3 $ºC\cdot min^{-1}$) for 10 h to obtain a 2-mm-thick electrolyte support. The composite electrodes LSTO-SDC and LSM-SDC slurries were prepared by milling the SDC powders with the LSTO and LSM powders at a weight ratio of 35:65 in the alpha-terpineol with the cellulose additive, respectively. The silver paste (SS-8060, Xinluyi, Shanghai, China) was printed onto both electrode surfaces for current collection. Scanning electron microscope (SEM, JSM-6490LV, JEOL Ltd, Japan) was used to observe the microstructure of the as-prepared electrolyzers.

The AC impedance of symmetric cells were tested at the open circuit voltage (OCV) in different hydrogen pressure at 800 ^{o}C using the electrochemical workstation (IM6, Zahner, Germany). The single solid oxide electrolyzers were sealed to a home-made testing jig by using ceramic paste (JD-767, Jiudian, Dongguan, China) for electrochemical measurements including the AC impedance and Current-Voltage (I-V) curve. The direct electrolysis of steam was performed at 1.2, 1.6 and 1.8 V with the as-prepared single solid oxide electrolyzers at 800 ^{o}C, respectively. The output gas from the cathode was analyzed using an online gas chromatograph (GC9790II, Fuli, Zhejiang, China) to detect the concentration of generated hydrogen.

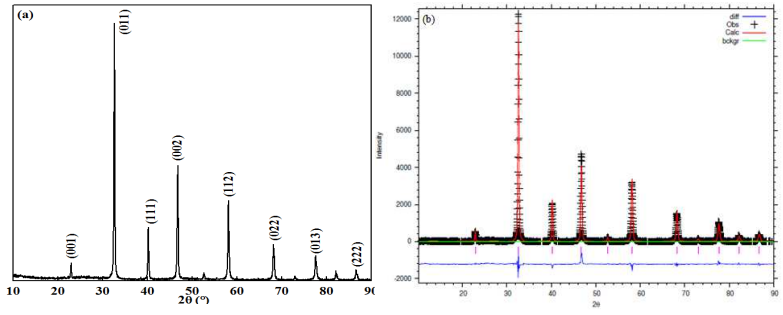

Fig. 1 (a) XRD Patterns and (b) Rietveld Refinement of $La_{0.2}Sr_{0.8}TiO_{3+\delta}$ (LSTO) Powders.

Results and Discussion

Fig. 1(a) shows the XRD patterns of LSTO powders. The results show pure phase according to the references [14], and the XRD patterns are indexed according to its PDF card (LSTO: No.52-1769). These two oxides belong to the same space group; however, the chemical compositions are different. The LSTO refinement gives χ^2, wRp and Rp values of 1.425, 2.23% and 1.21%, respectively, and the cell parameters of LSTO are a=b=c=3.88139 Å, α=β=γ=90 º.

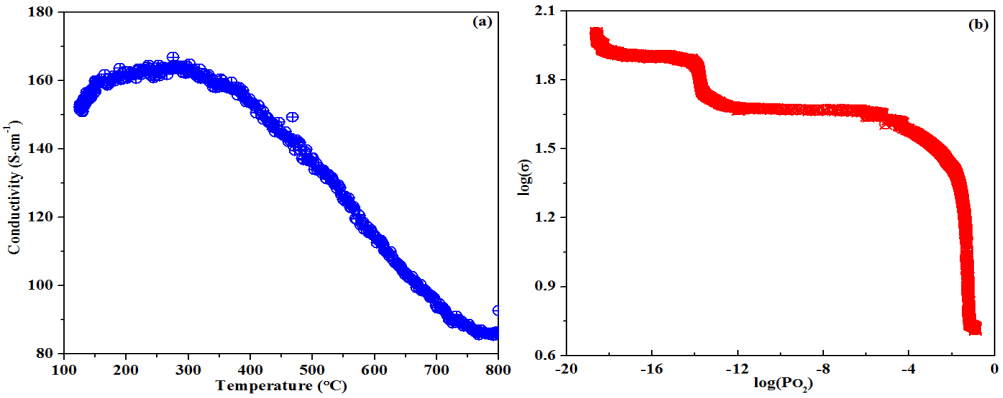

Fig. 2 The Conductivity of LSTO Versus (a) Temperature in 5%H2/Ar and (b) the Oxygen Partial Pressure.

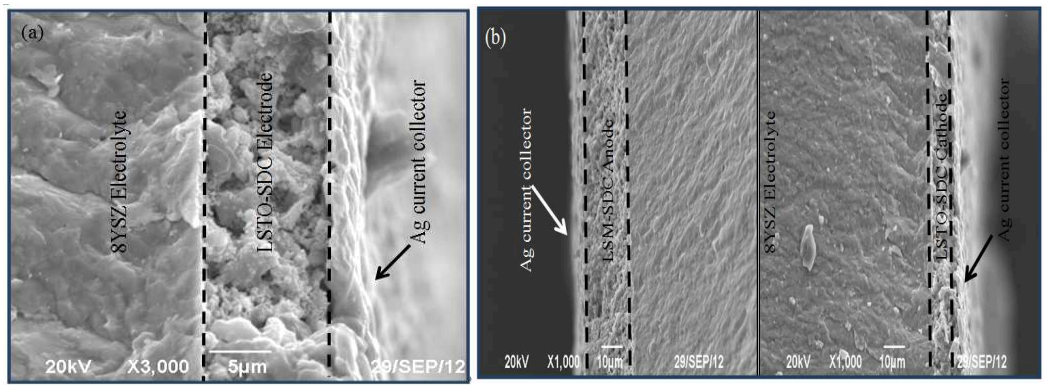

Fig. 3 (a) Microstructure of the Symmetric Solid Oxide Electrolyzer; (b) Microstructure of the Single Solid Oxide Electrolyzer

The reduced LSTO sample is an n-type electronic conductor which is expected to show a typical metallic behavior in H_2/Ar gas; however, an increase in conductivity is observed when the temperature increases from 130 ºC to 247 ºC as shown in Fig. 2 (a). It is attributed to the oxidized and p-type LSTO layer on the sample surface which is produced by the absorption of oxygen on the surface of the reduced sample. The atmospheric oxygen would easily and quickly oxidize Ti^{3+} to Ti^{4+} and causes the loss of conductivity of the reduced sample at low temperatures; however, the oxidized layer would be gradually and sufficiently reduced by H_2 up to the 247 ºC and enhance the conductivity though the conductivity of n-type conductor would decrease with temperature. The maximum conductivity reaches approximately 160 $S \cdot cm^{-1}$ at 247 ºC and drops to about 85 $S \cdot cm^{-1}$ at 800 ºC which is in good accordance with the n-type conductor behavior. Fig. 2 (b) shows the dependence of conductivity of the reduced LSTO on the PO_2. It is observed that the conductivity is increasing versus PO_2, especially at low oxygen partial pressure region. The reduction of Ti^{4+} to Ti^{3+} is promoted to generate higher concentrations of the charge carriers and enhances the conductivity, which further confirms the n-type conduction mechanism.

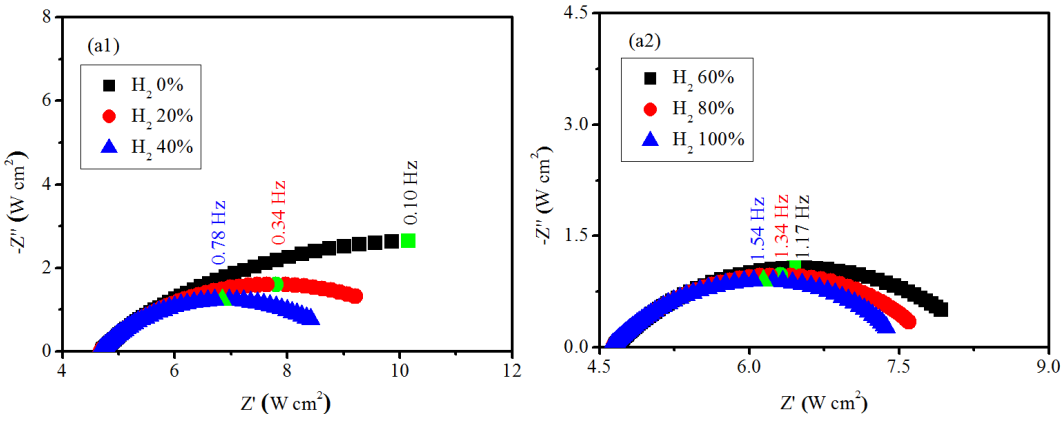

Fig. 4 The AC Impendence of the Symmetric Cells for LSTO Composite Cathode.

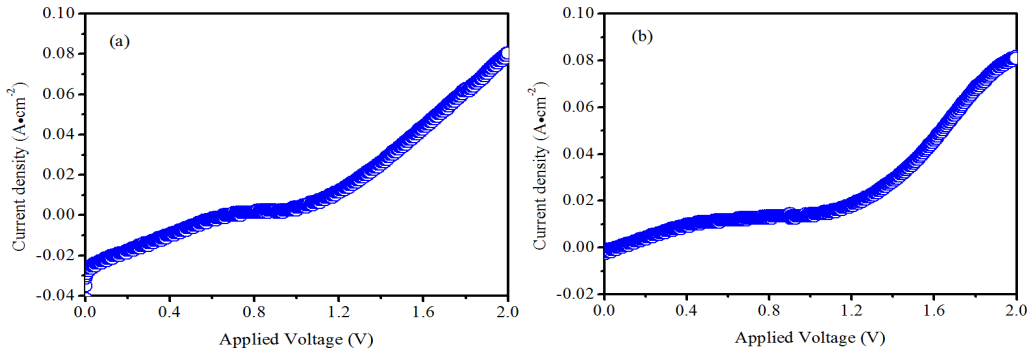

Fig. 5 The I-V Curves of the Electrolyzer with LSTO Cathode at 800 oC in Different Atmospheres (a) 5%H2O/5%H2/Ar and (b) 5%H2O/Ar.

Fig. 3 shows the microstructures of the symmetric cell and the single cell. The adhesion between dense electrolyte and the porous electrodes layers with a thickness of 10-μm seems very well. The outer porous silver current collector layer is only about 2 μm in thickness. Fig. 4 (a) shows the AC impendence of symmetric cell tested in different hydrogen pressure at 800 ºC. The electrode polarization resistance (Rp) of symmetric cell based on LSTO-SDC decreases from approximately 10 $\Omega \cdot cm^2$ to 1.5 $\Omega \cdot cm^2$ with the hydrogen partial pressure ranging from 0% to 100%. The low Rp in a stronger reducing atmosphere may be related to the improved electrocatalytic activity of the composite electrodes. A low oxygen partial pressure was also favorable to increasing electrical conductivity of the reduced LSTO, which also improved the electrode performances. The LSTO is efficiently activated at higher temperature in H_2 atmosphere and could be a good cathode candidate.

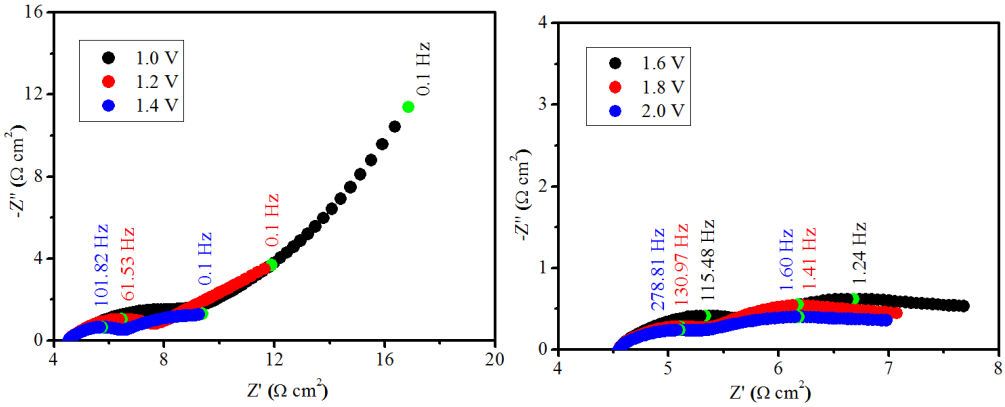

Fig. 6 The AC Impendence of the Electrolysis Cells Based on LSTO with the Flow of 5%H2O/5%H2/Ar at 800 oC.

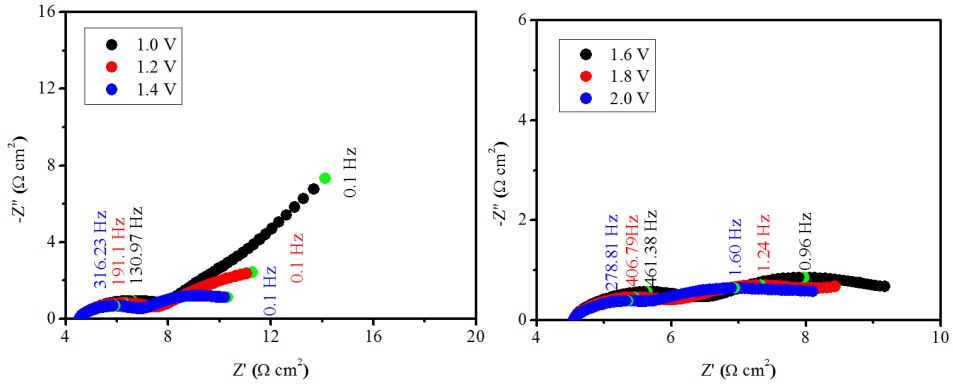

Fig. 7 The AC Impendence of the Electrolysis Cells Based on LSTO with the Flow of 5%H2O/Ar at 800 oC.

Fig. 5 shows the current density with the applied voltage (I-V curve) of the electrolyzer under different testing conditions. The open circuit voltages of the single electrolyzers in 5% H_2O/5% H_2/Ar are 0.9 V as shown in Fig. 5 (a). The relationship between the current density and applied voltage are far from linear, and clear changes in slope can be observed above 1.2 V. The maximum current density reaches 0.0822 A cm^2 at 2.0 V based on LSTO-SDC composite cathodes; As shown in Fig. 5 (b), the current density reached 0.0807 A cm^2 at 2.0 V with LSTO-SDC composite cathodes in 5% H_2O/Ar. It should also be noted that the current densities based on LSTO-SDC in 5% H_2O/5% H_2/Ar is slightly larger than it in 5% H_2O/Ar, which might be attributed to the better catalytic performances and mixed conductivities of the composite electrodes in more reducing conditions. To further study the electrochemical performance of the electrodes, in-situ AC impedance spectroscopy was conducted to investigate the change of cell resistance under different voltages.

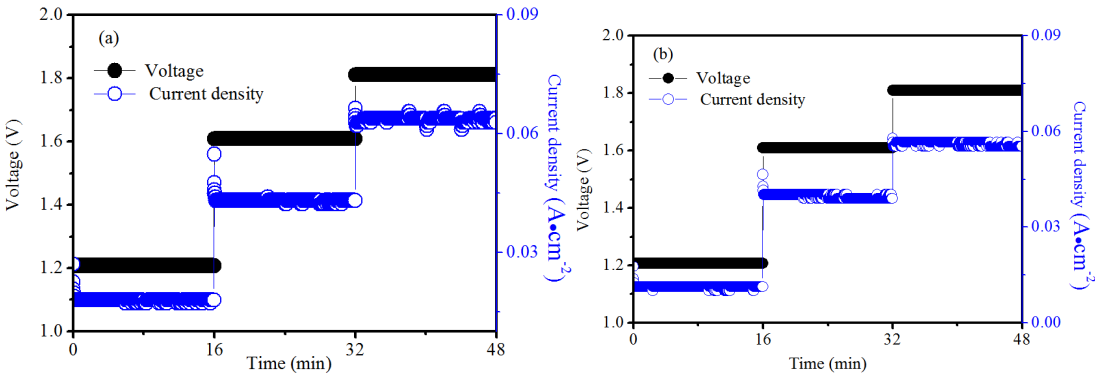

Fig. 8 The Performances of Steam Electrolysis for the Electrolyzer in Different Atmosphere (a) 5%H2O/5%H2/Ar and (b) 5%H2O/Ar at 800 oC.

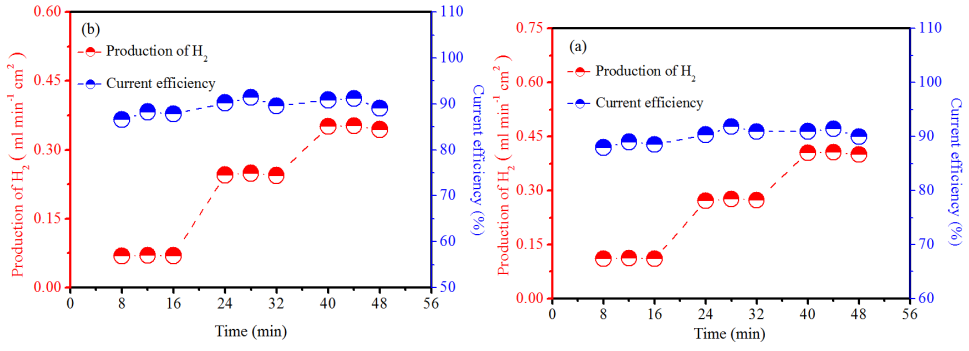

Fig. 9 The Hydrogen Production and Current Efficiency (a) for the Electrolyzer with the flow of 5%H2O/5%H2/Ar; (b) with the Flow of 5%H2O/Ar.

Fig. 6 and 7 show the in-situ AC impendence of solid oxide electrolyzers under a series of external voltages ranging from 1.0 to 2.0 V, at 800 ºC in 5% H_2O/5% H_2/Ar and 5% H_2O/Ar, respectively. As shownin the figures, the electrode polarization resistance Rp is quite large at low voltages, whereas the increasing voltages make the Rp drop considerably at high voltages, which may be attributed to the fact that the applied voltage not only activates the electrode but also electrochemically reduces the composite LSTO-SDC electrode and enhances the mixed conductivity. The Rp is only 3.5 $\Omega \cdot cm^2$ at 1.6 V and further drops to 2.5 $\Omega \cdot cm^2$ at 2.0 V in 5% H_2O/5% H_2/Ar with LSTO-SDC cathode; A promising electrochemical performance with the LSTO-SDC composite cathodes was also obtained in the 5% H_2O/Ar atmosphere for direct steam electrolysis as shown in Fig. 7. Direct steam electrolysis was achieved with the composite cathode, and a comparable performance with electrolyzers in 5% H_2O/Ar was obtained. The electrode polarization resistance with the LSTO-SDC cathode, Rp, is approximately 4.5 $\Omega \cdot cm^2$ at 1.6 V and finally drops to 3.5 $\Omega \cdot cm^2$ at 2.0 V, which is comparable but slightly larger than the values in 5% H_2O/5% H_2/Ar, which is most likely because the direct steam electrolysis produces a less reducing atmosphere that decreases the mixed conductivity of the LSTO-SDC composite electrodes.

As shown in Fig. 8, the current density vessus time with the applied voltage of 1.2, 1.6 and 1.8 V were also recorded to further investigate the process of steam electrolysis. It is clear that the current densities increased with the applied voltage and the performance was stable at a certain potential load. It can also be observed that the current density reached approximately 0.0637 A cm^2 at 1.8 V with the LSTO-SDC electrodes in 5% H_2O/5% H_2/Ar. In addition, the current density with the LSTO-SDC cathodes still reached a comparable 0.0553 A cm^2 in 5% H_2O/Ar for direct steam electrolysis. Fig. 9 shows the hydrogen production rate, and current efficiency with the LSTO-SDC cathodes under different applied voltages for steam electrolysis in 5% H_2O/5% H_2/Ar and 3% H_2O/Ar at 800 ºC, respectively. The production of H_2 reached 0.406 ml min^{-1} cm^2 at 1.8 V with the LSTO-SDC composite electrode in 5% H_2O/5% H_2/Ar. More importantly, direct steam electrolysis was achieved with the LSTO-SDC composite cathodes in the 5% H_2O/Ar atmosphere. The hydrogen generation from the direct electrolysis of 5% H_2O/Ar reaches 0.353 ml min^{-1} cm^2 for the LSTO-SDC composite cathodes. The result suggests that the redox-stable LSTO-SDC leads to the improved cathode performances for direct steam electrolysis and desired short-term stability. The corresponding current efficiency reached 92.38% and 91.17% at 1.8 V with the LSTO-SDC cathodes in 5% H_2O/5% H_2/Ar and 5% H_2O/Ar.

Conclusion

In this work, a composite electrode based on $La_{0.2}Sr_{0.8}TiO_{3+\delta}$ (LSTO) is investigated in an oxide-ion-conducting solid oxide electrolyzer with a configuration of LSTO-SDC/YSZ/LSM-SDC for the direct steam electrolysis at 800ºC. AC impedance spectroscopy and I-V tests demonstrate two main processes from 0 to 2.0 V with steam versus air: the reduction of the LSTO electrode below 1.0 V and the electrolysis of steam above 1.0 V. The applied voltage improves the cathode performance and the current efficiency is 92.38% and 91.17% with or without reducing gas flowing over them under the applied voltage of 1.8 V at 800 ^oC, respectively.

Highly hydroxylated graphite felts used as electrodes for a vanadium redox flow battery

LI Wen-Wen, CHU You-Qun, MA Chun-An

College of Chemical Engineering, Zhejiang University of Technology, Hangzhou 310014, China,

E-mail: chuyq@zjut.edu.cn

Keywords: Vanadium redox flow battery, graphite felt, electrochemical activity

Abstract: The highly hydroxylated graphite felts (GFs) were obtained by treating in mixed acids ($V(HNO_3)/V(H_3PO_4)$=3:1) for different time at 80℃, and used as the electrodes for all vanadium redox flow battery (VRB). The physical, chemical and electrochemical characteristics of these GFs are characterized by X-ray photoelectron spectroscopy, scanning electron microscopy, cyclic voltametry, electrochemical impedance spectroscopy and charge/discharge test. The excellent electrochemical properties of the treated GFs to VRB electrode reactions can be ascribed to the enhancement of the interaction between vanadium ions with –OH groups introduced by acid treatment. Using GFs treated in the mixed acids for 8 h as electrodes, the VRB exhibits excellent performance under a current density of 20 mA/cm^2. The average current efficiency, voltage efficiency and energy efficiency are about 97%, 83.3% and 78%, respectively.

Introduction

Recently, the all vanadium redox flow battery (VRB) has attracted great attention due to its excellent merits, such as long cycle life, deep discharge capability, fast response time, flexible design, low cost, etc. Graphite felts (GFs) are the most commonly used electrode materials for VRB due to their great specific surface area, high strength and broad potential window[1]. But these materials have been proven to show a poor electrochemical activity[2]. Considerable efforts have been devoted in introducing oxygen-containing groups such as hydroxyl, carbonyl and carboxyl for the purpose of improving the electrochemical properties of GFs[3-13]. Despite a large number of literature reports on the modification of the GF surface nature, but it still need further research to enrich the surface modification method to meet the steep demands for the practical application of VRB in large scale energy storage domain.

In this study, we developed a new method to treat GFs in mixed acids $V(H_2SO_4)/V(HNO_4)$=3:1 to get the hydroxylated surface of GFs. The effects of treatments on the surface of GFs were characterized by X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM). And their electrochemical properties to the redox reaction of V(IV)/V(V) were also investigated using cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS) and charge/discharge test of a small-size VRB.

Experimental

PAN-graphite felt with the thickness of 10 mm was purchased from Shanghai XinXing Carbon Co. Ltd., China. HNO_3 (68 wt %) was provided by Zhejiang Zhongxing Chemical Co. China. H_3PO_4 (> 85wt %) was purchased from Guoyao Chemical Co. China.

The raw GFs were heated at 520±10 ℃ for 3 h under air atmosphere to produce R-GF. The R-GF of 1 cm×1 cm was treated in a sealed Teflon-lined stainless steel autoclave containing 70 mL mixed acids $V(HNO_3)/V(H_3PO_4)$=3:1 for different time at 80℃, then the GFs were washed with distilled water until pH of the rinsed water was neutral and dried for 3 h at 60℃. The GFs after acid treating were denoted as AGF-X, where X represents the treating time.

XPS spectra were obtained with an ESCALab220i-XL electron spectrometer from VG Scientific using 300W Al-Kα radiation. The base pressure was about 3×10^{-9} mbar. The binding energies were

referenced to the C1s line at 284.6 eV from adventitious carbon. The spectra were analyzed using Spectrum software (XPSPEAK). The surface morphologies of the GFs were observed using a Hitachi S-4800 scanning electron microscopy (SEM) at an acceleration voltage of 20 kV.

For cyclic voltammetry (CV) and the electrochemical impedance spectroscopy (EIS, 0.01–10^5 Hz, amplitude=5mV) measurements, a three-electrode cell was used with GF as the working electrode, a saturated calomel electrode (SCE) as the reference electrode and graphite plate as the counter electrode. The measurements were performed with an Iviumstat electrochemical workstation (Ivium Technologies BV, The Netherlands) in 3.0 M H_2SO_4 + 0.1 M $VOSO_4$ solution at room temperature.

The constant current charge/discharge test was carried out by using a small-size VRB with symmetrical structure on an Arbin BT2000 battery testing system (Arbin Instruments, USA). Two pieces of GFs with area of 9 cm^2 (3.0 × 3.0 cm) were used as positive electrode and negative electrode, respectively. The chambers of positive electrode and negative electrode were separated by a Nafion 117 cation exchange membrane. The initial anolyte was 40 ml 1.0 M V(VI)+3.0 M H_2SO_4, and catholyte was 40 ml 1.0 M V(III)+3.0 M H_2SO_4. The cells were charged and discharged at the current density of 20 mA/cm^2 and the voltage range was fixed between 1.65 and 0.8 V.

Results and Discussions

SEM analysis. It can be seen from Fig.1 that the impurities on the GF surface were eliminated by treating in the mixed acids. The surface of GF before acid treatment (R-GF) is smoother than those treated in the acids. With the extension of processing time, the increasing of cavities on the surface of GF fibres can be observed. The increasing of cavities could increase the specific surface area of the GFs, which may beneficial to the VRB reactions. But the GF structure was destroyed when the processing time extended to 14h, which may have negative impacts on the electrochemical performance. This indicates that the processing time should not last more than 8 h.

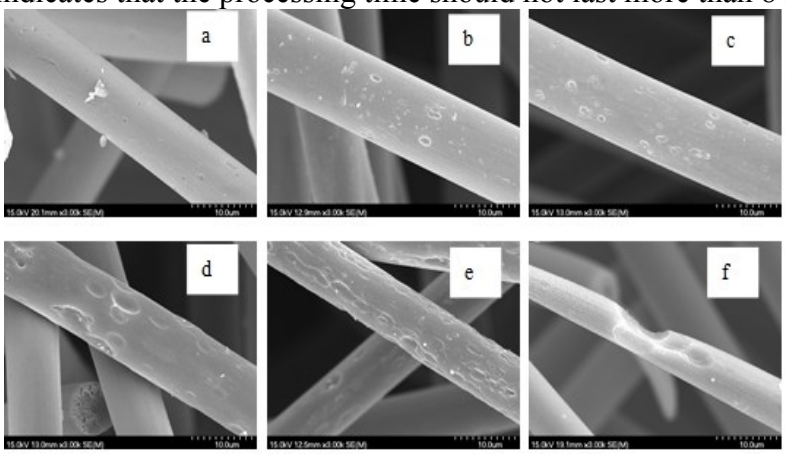

Fig.1. SEM images of R-GF(a), AGF-2(b), AGF-4(c), AGF-6 (d), AGF-8 (e) and AGF-14 (f)

XPS analysis. To elucidating surface nature of GFs before and after treatments, XPS is a suitable technique particularly for monitoring the functional groups in the surface region. With the increase of treatment time, the intensity of the O1s peak at the binding energy of 532 eV increases significantly with concerning to that of the C1s peak at the binding energy of 284.7 eV (shown in Fig. 2), and corresponding O content at the surface of GFs increase gradually from 10.10 at% to 13.28 at% (listed in Table 1).

In the case of O1s deconvolution for R-GF, three main peaks were observed at 531.7, 532.4, and 534.4eV, which correspond to C=O, -OH and H-O-H[14-16]. The C=O groups mainly come from the further oxidization of -OH groups which result from the breakage of C=C bonds on the fragments under strong oxidation [17]. As the increase of the treatment time, almost all the C=C bonds on the fragments are broken and all the carbons from the broken bonds transform into -OH groups.

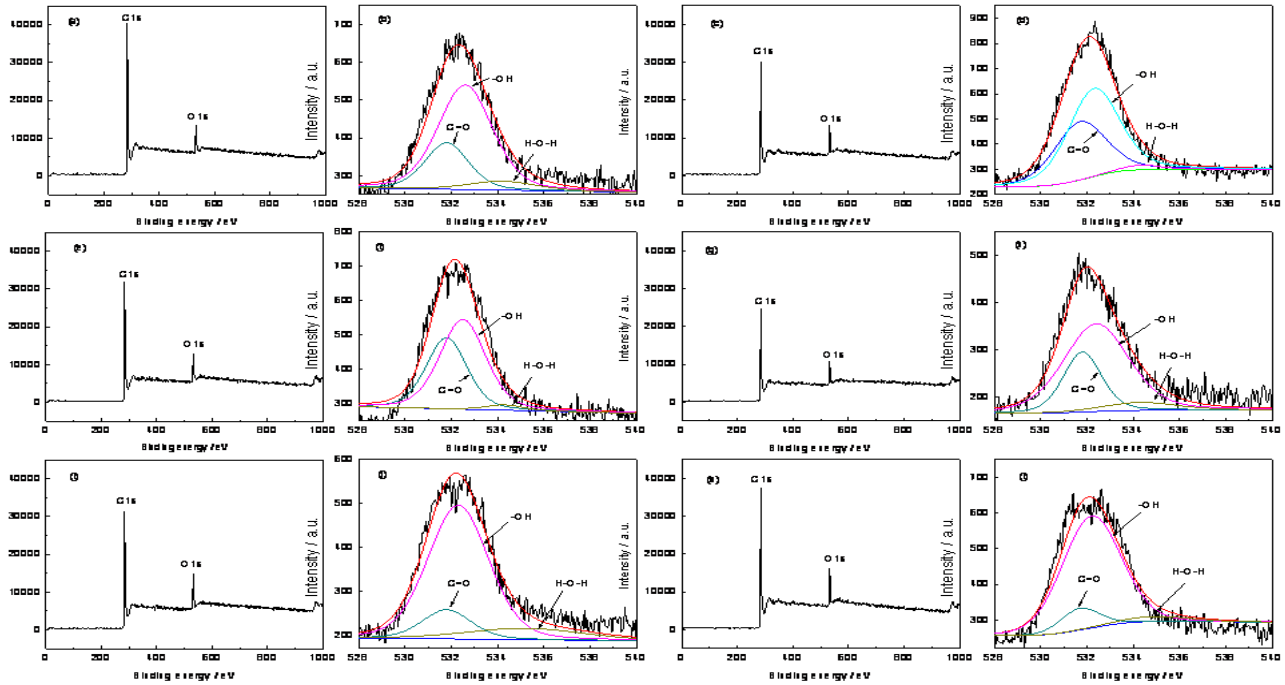

Fig. 2 XPS of (a,b) R-GF, (c,d)AGF-2, (e,f)AGF-4, (g,h)AGF-6, (i,j)AGF-8, and (k,l)AGF-14 h

Table 1 XPS surface elemental analysis parameters of the untreated and treated GFs

Times (h)	Content(at%)					
	C1s	O1s	N1s	C=O	-OH	H-O-H
0	89.90	10.10	-	2.5	6.9	0.7
2	87.71	11.21	1.09	4.4	6.5	0.3
4	86.69	12.10	1.21	4.9	6.9	0.3

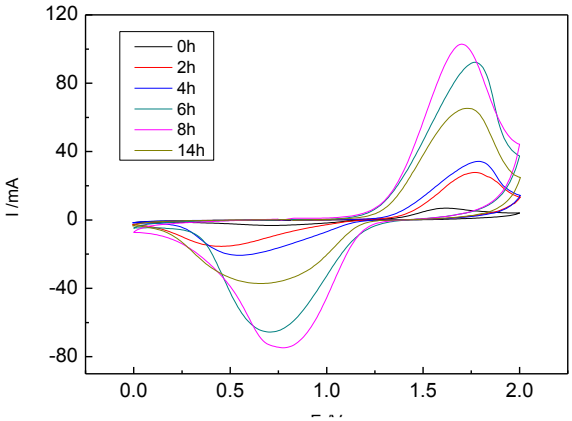

Fig.3 Cyclic voltammograms of the untreated and treated GFs obtained at 10 mVs^{-1}

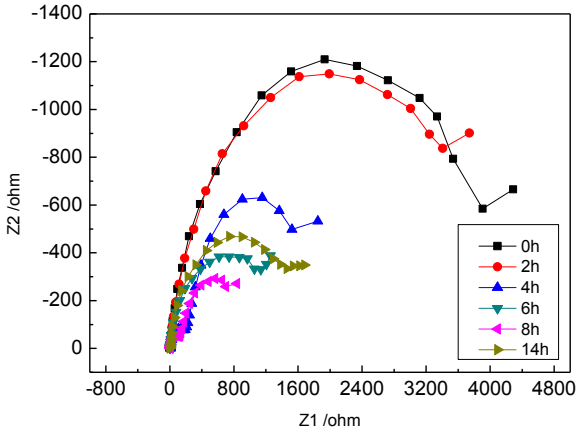

Fig. 4 Nyquist plots of GF electrodes

Cyclic voltammetric behavior. As shown in Fig. 3, the activities of GFs toward V(IV)/V(V) redox reaction have been improved after the treatment in mixed acids. The anodic peak appears at 1.46-1.49 V corresponding to V(IV)/V(V) redox reaction. Much higher current responses were obtained with those treated samples, this can be attributed to the enhanced interaction between the vanadium ion with the -OH groups formed during the acid treatment. Among them, AGF-8 exhibits

the highest activity. Although AGF-14 has the highest -OH group contents, showing poorer activity than AGF-8, this can be ascribed to the structural damage of the GF treated for 14 h.

EIS analysis. A comparison of impedance (Nyquist) plots is shown in Fig.4. The Nyquist plots include a semicircle part and a linear part, indicating that the V(IV)/V(V) redox reactions on these GF electrodes are all mix-controlled by charge transfer and diffusion steps. The semicircle part at high frequencies reflects the charge transfer process and the linear part at low frequencies reflects the diffusion processes in pore channel of GF[19-22]. In addition, it can be seen that the reaction resistance decreases gradually with the prolonging of processing time, and the smallest reaction resistance is achieved with AGF-8. This further proves that the hydroxylation of GF surface is beneficial to the electrode reaction. The increasing of reaction resistance of AGF-14 can also attributed to the structural failure of GF.

Charge-discharge test. Fig.5 and Fig.6 show the charge/discharge characteristics of VRBs using R-GF and AGF-8 as electrodes. It can be seen from Fig.5 that the VRB using AGF-8 (Fig.5a) as electrodes has lower charging voltage and higher discharging voltageusing compared to the VRB using R-GF as electrodes (Fig.5b). This implies that AGF-8 has better electrocatalytic actives for the VRB reactions than R-GF. This is in complete accord with the results obtained by CV and EIS. In addition, both VRBs show no significant performance degradation after 50 times charge/discharge cycles at current density of 20 mA/cm^2. The current efficencies of both VRBs are about 97%, while the VRB using AGF-8 as electrodes has higher voltage efficency and energy efficiency, 83.3% and 78%.

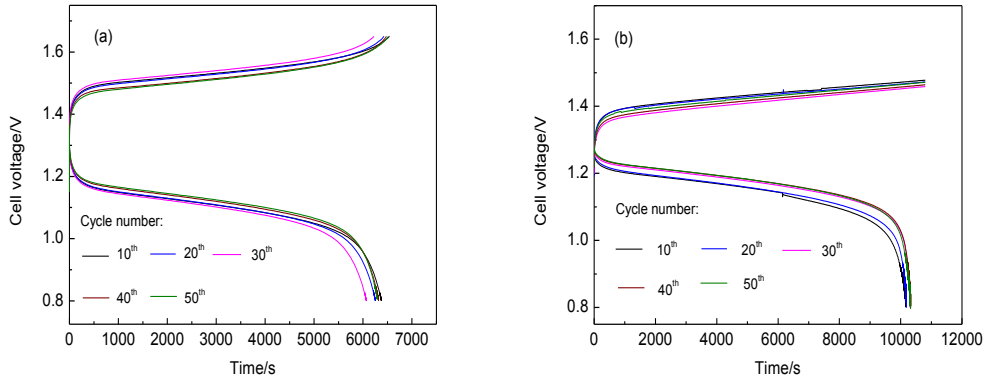

Fig. 5. Charge/discharge curves of VRBs using R-GF(a) and AGF-8(b) at 20 mA/cm^2

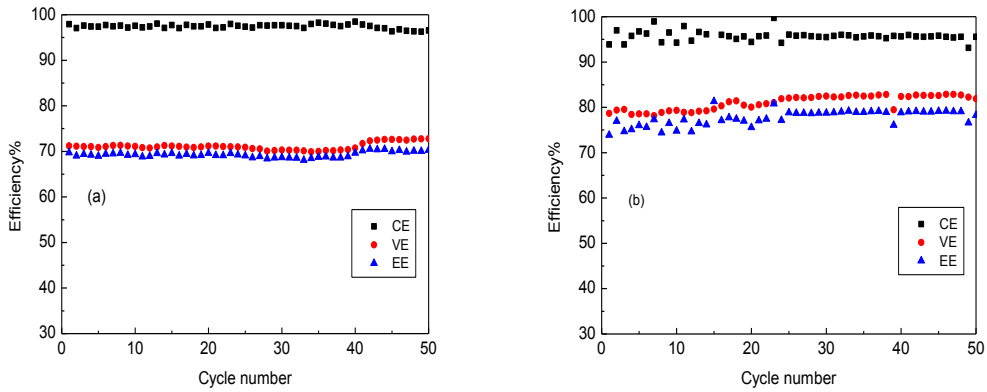

Fig. 6. Charge/discharge performance of VRBs using R-GF(a) and AGF-8(b) at 20 mA/cm^2.

Conclutions

The GF surface was successfully hydroxylated through the treatment in mixed acids V(HNO_3)/V(H_3PO_4)=3:1. The introduction of –OH groups onto GF surface can significantly improve its electrocatalytic activities for VRB reactions. This can be ascribed to the enhancement of interaction between vanadium ions and -OH functional groups formed on the GF surface, which

makes the electron transfer reaction of vanadium ions at the GF surface easier. The appreciate time for treating GF in the mixed acids is 8 h, and the GF structure will be destroyed if the time further prolongs. The VRB using AGF-8(GF treated in the mixed acid for 8 h) as electrodes exhibits excellent performance under a current density of 20 mA/cm^2. The average current efficiency, voltage efficiency are about 97%, 83.3%, and 78%, respectively.

Keywords: Mesoporous carbon, titanium, nanocomposite, self-assembly

Abstract: A series of titanium doped ordered mesoporous carbons (Ti-OMCs) were prepared by employing titanium modified resol as source for the first time. The effect of titanium content and F127 content on the microstructure of Ti-OMCs was investigated by X-ray diffraction (XRD), N_2 sorption isothermal and Transmission electron microscopy (TEM). The results showed that regularity of products decreased with the increase of titanium content. A mesophase transformation from 2-D hexagonal(P6mm) to body-centered cubic ($Im\bar{3}m$) structure can be achieved by decreasing F127 content.

Introduction

Titanium-doped ordered mesoporous carbons (Ti-OMCs) have aroused much interest for their wide potential application in the field of photo-catalysts Li-ion battery, protein immobilization, etc [1,2]. A variety of strategies have been developed to prepare Ti-OMCs, such as impregnating pores of CMK-3 with titanium precursor to form TiO_2/CMK-3 materials [3], synthesis of Ti-OMCs by the aid of evaporation-induced self-assembly (EISA) method [4]. In general, titanium complex is almost doped by physical hybrid, which leads to the poor compatibility between titanium complex and carbon matrix. If heteroatom could be anchored on the backbone of resol through chemical reaction, interface compatibility would be improved. Meanwhile, heteroatom would be well dispersed in the OMC because of the dispersion of modified resol during EISA. Recently, this new route is applied to prepare B doped OMC [5]. Nevertheless, to the best of our knowledge, no metal atom was doped through this novel route, presumably because it's tough to obtain appropriate metal modified resol. Previously, our group reported a facile way to synthesis titanium modified phenolic resin [6], which might be a candidate for fabrication Ti-OMCs. Herein, we prepared a series of Ti-OMCs by employing titanium modified resol as source for the first time. The effect of titanium contents and F127 contents on the mesostructure was investigated by XRD, N_2 sorption and TEM.

Experimental

Preparation of titanium modified resol was according to our previous report [6].

Ti-OMC was synthesized by a modified solvent evaporation induced self-assembly (EISA) method. The final products are denoted as Ti-OMC-X-Y while X represents the molar ratio of titanium and phenol, and Y represents the mass ratio of F127 and carbon source.

Transmission electron microscopy (TEM) images were obtained on JEOL-1400. Nitrogen adsorption experiments were performed at 77 K using a Micromeritics ASAP 2010. Pore size distribution and the BET surface area of samples were calculated by the BET method from the N2 adsorption isotherm data. Powder X-ray diffraction (XRD) patterns were recorded on Rigaku D/MAX-2550 diffractometer using Cu-Kα radiation.

Results and discussion

Influence of titanium content

Fig. 1 shows the small angle XRD (SAXRD) and wide angle XRD (WAXRD) results of samples with different titanium content. As shown in fig 1a, Ti-OMC-0.015-1 revealed obvious diffraction peak, indicating its well-ordered framework. However, the intensity decreased dramatically with the increase of titanium content, which implied the collapse of regular structure. In all the WAXRD spectra, two broad diffraction peaks emerge around 22° and 44°, corresponding to (002) and (001) diffractions of amorphous carbon respectively. Besides, a tiny peak mainly attributed to Ti7O13 (JCPDS 50-0780) was observed only for Ti-OMC-0.037-1. No other typical peaks attributed to titanium species could be detected probably due to excellent compatibility between carbon and titanium or low titanium content. Thus, to obtain Ti-OMCs with well-ordered structure, the molar ratio of titanium/phenol is 0.015 in following study.

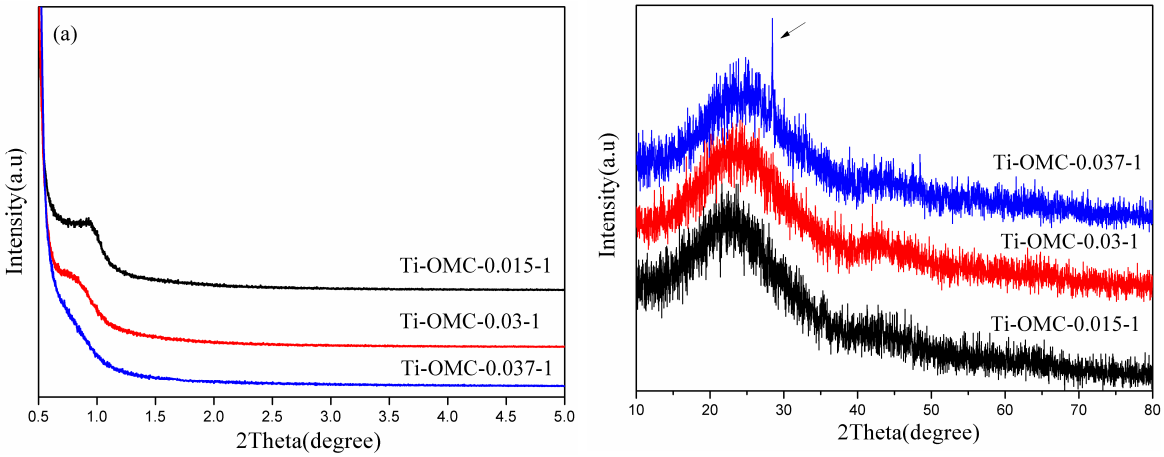

Fig. 1 Small angle XRD (a) and wide angle XRD patterns of Ti-OMCs

Influence of F127 content

The surfactant F127 has been used as the structure directing agent in the synthesis of ordered mesoporous carbon, and previous research shows its content might affect the structure of the final products. In this work, the influence of the amount of F127 on the structure of Ti-OMCs was also investigated. With F127 content decreasing from 1 to 0.5, a slight enhancement in diffraction intensity (Fig 2) is observed. However, the peak disappeared while F127 content is 0.1.

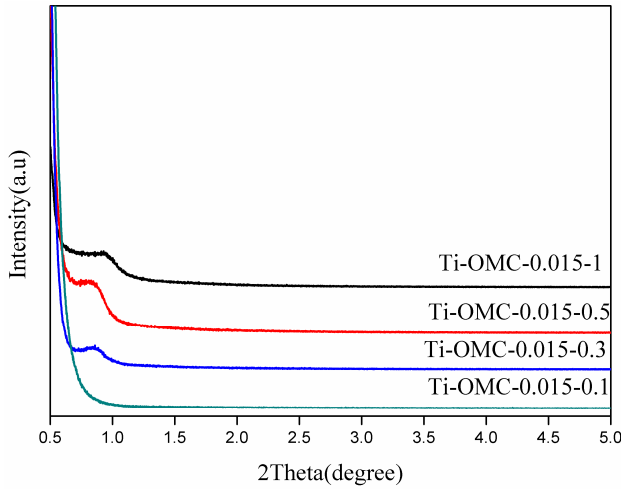

Fig. 2 Small angle XRD patterns of Ti-OMCs prepared with different F127 contents

Figure 3 represents N2 sorption isotherms and pore size distribution curves of samples prepared with different F127 contents. It can be seen that sample Ti-OMC-0.015-1, Ti-OMC-0.015-0.5, Ti-OMC-0.015-0.3 display typical IV isothermals with a sharp capillary condensation step at

P/Po=0.35-0.7, indicating the mesoporous character of these materials. And they all posses samilar pore size at about 3.5nm according to fig. 3(b). However, Ti-0.015-0.1-OMC posesses typical I sorption isothermal, suggesting no mesopores in this sample. This is because F127 content is too low to form polymer aggeration , which is the template of mesopores.

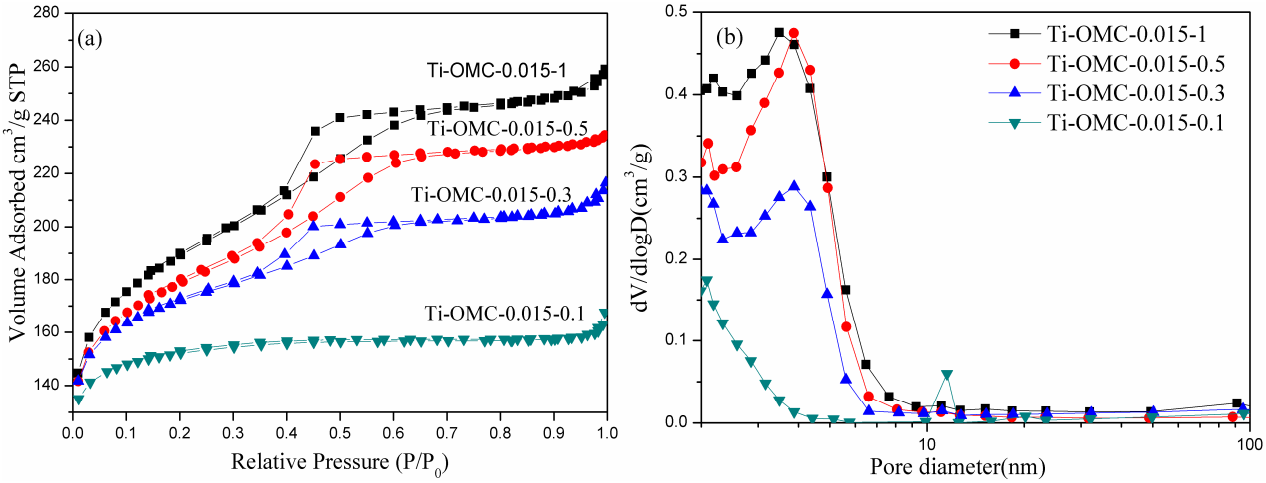

Fig. 3 N_2 adsorption-desorption isothermals of Ti-OMCs (a) and pore size distributions of Ti-OMCs (b)

Fig 4 reveals the TEM images of samples prepared with different F127 contents. Ti-OMC-0.015-1 and Ti-OMC-0.015-0.5 show strip-like channels, which are typical images of 2-D hexagonal structure. However, when F127 content is 0.3, TEM image of body-centered cubic structure is observed in Fig. 4 (c). This phenonemon indicat that a mesophase transformation from 2-D hexagonal(P6mm) to body-centered cubic ($Im\bar{3}m$) structure is occured with the decrease of F127 content. F127 contents can influence both regularity and symmetry structure of Ti-OMCs.

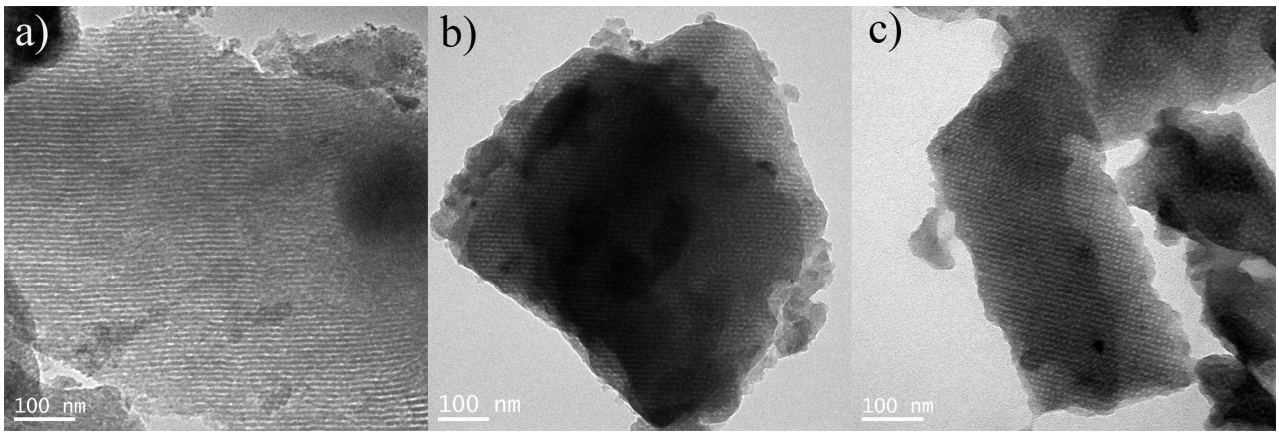

Fig. 4 TEM images of Ti-OMCs. (a) Ti-OMC-0.015-1, (b) Ti-OMC-0.015-0.5, (c) Ti-OMC-0.015-0.3

Conclusion

In summary, a series of Ti-OMCs were prepared by employing titanium modified resol as source for the first time. The results show that regularity of products decreased with the increase of titanium content. A mesophase transformation from 2-D hexagonal (P6mm) to body-centered cubic ($Im\bar{3}m$) structure can be achieved by decreasing F127 content.

Keywords: Li-ion battery, $LiFePO_4$, Ge film, Rate capability.

Abstract: $LiFePO_4$/C-Ge electrodes were prepared with vacuum thermal evaporation deposition by depositing Ge films on as-prepared $LiFePO_4$/C electrodes. The effect of Ge film on the electrochemical performances of $LiFePO_4$/C cells was investigated systematically by charge/discharge testing, cyclic voltammograms and AC impedance spectroscopy, respectively. It was found that Ge-film-surface modified $LiFePO_4$/C showed excellent electrochemical performances compared to that of the pristine one in terms of cyclability and rate capability. At 60℃, $LiFePO_4$/C-Ge film exhibited outstanding cyclability with less than 5% capacity fade after 50 cycles while the pristine one suffers 15%. Analysis from the electrochemical measurements showed that the presence of Ge film on the $LiFePO_4$/C electrode would protect active material from HF generated by the decomposition of $LiPF_6$ in the electrolyte and stabilize the surface structure of active material during the charge and discharge cycle. Electrochemical impedance spectroscopy (EIS) results indicated that Ge film mainly reduced the charge transfer resistance R_{ct} of $LiFePO_4$/C electrode, resulting from the suppression of the solid electrolyte interfacial (SEI) film.

Introduction

With the development of the electric vehicles and hybrid electric vehicles, olivine-structured orthophosphate $LiFePO_4$ has been considered as one of the most promising candidates for cathode materials due to its high theoretical capacity(170mAhg^{-1}), flat voltage profile, high thermal stability as well as environment benignity[1-4]. However, this material suffers from the low intrinsic electronic conductivity (~10^{-8} to 10^{-10} Scm^{-1}) and lithium-ion diffusivity (~10^{-18} cm^{2}s^{-1}), which become major obstacles to extraction of lithium and result in steep falling in capacity at high rates[5-7]. Tremendous efforts have been devoted to improve electronic conductivity and overall electrochemical performance of $LiFePO_4$. The surface coating with a more conductive material such as carbon is well-known as an effective way in improving the rate performance of $LiFePO_4$ cathode[8-10]. For instance, Tang et al.[8] coated $LiFePO_4$ with $Li_{0.34}La_{0.51}TiO_{2.94}$ by rheological phase reaction method, and revealed that the surface modification of $LiFePO_4$ obviously enhanced the rate performance. The samples exhibited high discharge capacity of 109.9mAhg^{-1} at 10C. Sun et al.[9] reported that the surface modified $LiFePO_4$ by three-dimensional carbon networks exhibited better cyclic performance. Zhang et al.[10] revealed that the surface coating with Li_4SiO_4 was a feasible approach for improving the discharge capacity, cycling stability and interfacial resistance of $LiFePO_4$.

In contrast, germanium seems to be more promising surface-modification material due to its favorable electronic conductivity (2.1 S m^{-1}) and ionic diffusivity (1.9x10^{-14} cm^2 s^{-1})[11, 12]. Combining the above ideas, composing $LiFePO_4$ with germanium would be reasonably beneficial for improving rate capability and cyclic reversibility. In this paper, germanium film was deposited on $LiFePO_4$/C electrode by vacuum thermal evaporation. Compared to the pristine $LiFePO_4$/C, the as-prepared LiFePO4/C-Ge film exhibited better electrochemical performances.

Experimental

Preparation and characterization of $LiFePO_4$/C cathode material

Carbon coated $LiFePO_4$ composite materials were first prepared by a carbothermal reduction method. Firstly, $LiCH_3COO \cdot 2H_2O$(AR), $FeC_2O_4 \cdot 2H_2O$(AR), and $NH_3H_2PO_4$(AR) in stoichiometric amounts were thoroughly planetary milled in mortar for 48 h in ethanol containing proper amount of tartaric acid as carbon source. The obtained slurry was dried at 70℃ and then pressed into pellets. These pellets were transferred to a temperature-controlled tube furnace equipped with flowing Ar gas, calcined at 350℃ for 6 h and subsequently sintered at 700℃ for 12 h to obtain $LiFePO_4$/C. The phase analysis of the $LiFePO_4$/C composite was characterized by X-ray diffraction (XRD, Rigaku MiniFlex II) with monochromatized Cu Kαradiation source (λ=0.15405 nm). The morphology was observed by scanning electronic microscopy (SEM, JSM-7500F, Japan). The carbon content in $LiFePO_4$/C was determined by simultaneous thermal analyzer (STA 449 F3) with a heating rate of 10℃/min up to 900℃ in oxygen ambient.

Deposition of Ge film on $LiFePO_4$/C electrode

The cathode electrodes were prepared by homogeneously pasting a slurry containing 80 wt.% active material, 10 wt.% super-P and 10 wt.% polyvinylidene fluoride (PVDF) which was dissolved in N-methyl-2-pyrrolidone on an Al foil and subsequently dried at 110℃ for 12h in vacuum. Ge film was deposited onto the cathode electrode by thermal evaporation at a base pressure of 3×10^{-3} Pa with crystalline Ge as the vaporization source.

Cell fabrication and characterization

The coin cells (R2025) were assembled in an argon-filled glove box (O_2 <3ppm and H_2O<3ppm, Mikrouna, Super 1220/750, China) with Li metal as anode and counter electrode, Celgard 2300 microporous polyethylene membrane as separator and 1M $LiPF_6$ in a mixture of ethyl carbonate (EC) and dimethyl carbonate (DMC) (1:1 in vol. ratio) as electrolyte. Galvanstatic charge/discharge tests were carried out in the voltage range of 2.0-4.5V with a battery cycler (LAND, CT2001A, China). Cyclic voltammograms (CV) and electrochemical impedance spectra (EIS) measurements were performed by the electrochemical workstation (CHI660C). EIS analysis was recorded in a frequency range from 10 mHz to 100 KHz with a sinusoidal perturbation of 5 mV.

Results and discussion

Fig.1 shows XRD pattern of $LiFePO_4$/C powder. All the observed diffraction peaks for as-prepares powder can be indexed well based on an olivine-type phase structure with a space group of Pmnb (JCPDS No. 40-1499), indicating the successful synthesis of phase pure $LiFePO_4$[13,14].

Fig. 2 presents the surface morphology of $LiFePO_4$/C powder examined by SEM, which indicates the homogeneous $LiFePO_4$ particles with the order of ~200 nm are coated by carbon layers. The tartaric acid in reactants is considered to prevent the agglomeration of $LiFePO_4$ and protect $LiFePO_4$ from oxidation during the calcinations. The 3D carbon network would facilitate electron transport effectively among particles and consequently improve the electrochemical performances[9].

The carbon content in $LiFePO_4$/C composite was confirmed by simultaneous thermal analyzer. Fig.3 presents TG curve of as-prepared $LiFePO_4$/C in oxygen ambient. The weight loss between 200 and 700 °C might result from the reaction of carbon and oxygen. Analysis from the TGA measurements reveals that the carbon content was 7.5wt.% approximately.

To examine the effect of Ge film on improving the rate performances, the discharge capacities and the cycle numbers for $LiFePO_4$/C and $LiFePO_4$/C-Ge film at different current densities (0.2C, 0.5C, 1C, 2C, 3C, 1C = 170 $mAhg^{-1}$) between 2.0 and 4.5 V at 25 ℃ were investigated, as shown in Fig.4. It was found that with the deposition of Ge film on the electrode, $LiFePO_4$/C-Ge film (0.2C: 146 $mAhg^{-1}$; 0.5C: 131 $mAhg^{-1}$; 1C: 117 $mAhg^{-1}$; 2C: 104 $mAhg^{-1}$; 3C: 89 $mAhg^{-1}$, respectively) exhibited higher capacity than that of $LiFePO_4$/C (0.2C: 140 $mAhg^{-1}$; 0.5C: 120 $mAhg^{-1}$; 1C: 99$mAhg^{-1}$; 2C: 81 $mAhg^{-1}$; 3C: 65 $mAhg^{-1}$, respectively), especially at higher rates. The enhancement

in rate performances indicated that high conductive Ge film would facilitate Li^+ ion diffusion in the electrode, especially at high rates[15-17].

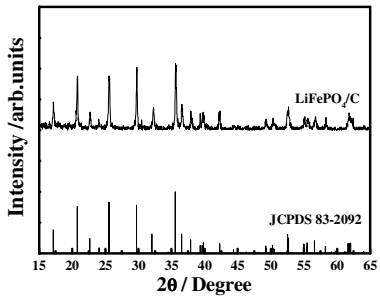

Fig.1 XRD pattern of LiFePO4/C powder

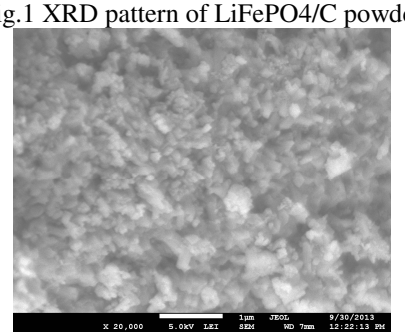

Fig.2 SEM images of LiFePO4/C powder

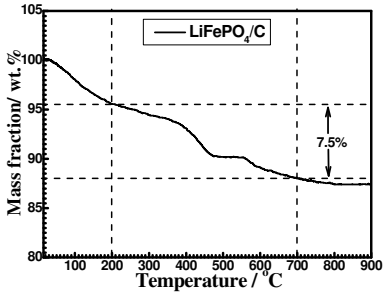

Fig.3 TGA curve of of as-prepared LiFePO4/C powder

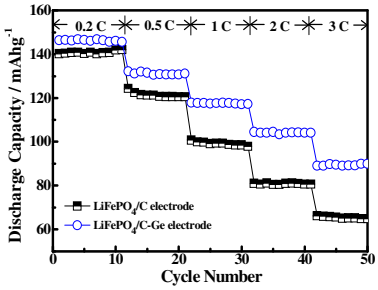

Fig. 4 Rate capabilities of the pristine LiFePO4/C and LiFePO4/C-Ge film at 25℃

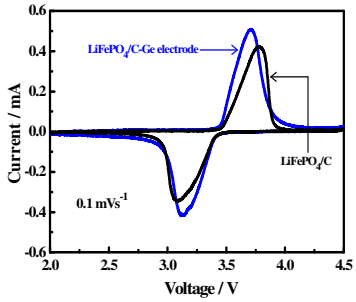

Fig. 5 Cyclic voltammograms of LiFePO4/C and LiFePO4/C-Ge film

Fig.5 show the CV curves of $LiFePO_4$/C and $LiFePO_4$/C-Ge film at a scanning rate of 0.1mV/s in the potential range from 2.0 to 4.5 V. Both curves shows a couple of peaks around 3.4 V, which correspond to the redox reaction of Fe^{2+}/Fe^{3+} couple[18]. The higher intensity of the redox peaks of $LiFePO_4$/C-Ge film than that of $LiFePO_4$/C further indicates that Ge-depositing should facilitate

li-ion transportation in the electrodes[19]. On the other hand, the separation between the anodic and cathodic peaks of $LiFePO_4$/C-Ge film (0.57 V) is lower than that of $LiFePO_4$/C (0.71 V), suggesting the outstanding reversibility of lithium intercalation into and de-intercalation from $LiFePO_4$/C-Ge film[20].

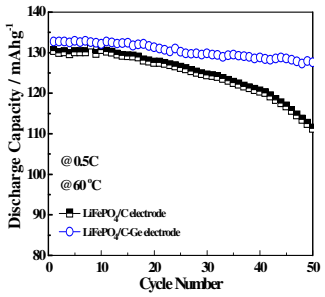

Fig. 6 Cycling performances of $LiFePO_4$/C and $LiFePO_4$/C-Ge film at 0.5C and 60℃;

Fig. 6 shows the capacity cyclabilities of $LiFePO_4$/C and $LiFePO_4$/C-Ge film at 0.5C at 60℃, respectively. It is clear that $LiFePO_4$/C-Ge film shows superior capacity cyclability in comparison with $LiFePO_4$/C. The $LiFePO_4$/C shows initial capacity of 130.5 $mAh \cdot g^{-1}$ and fades faster to 111.3 $mAh \cdot g^{-1}$ after 50 cycles, suffering a more than 15% capacity loss. The fade in capacity mainly results from the dissolution of Fe caused by in LiPF6-based electrolyte[21,22], especially at the elevated temperatures. In $LiFePO_4$/C-Ge film, Ge film provices protection to $LiFePO_4$/C from the erosion of HF[23], keeping crystal structure stable during charge/discharge process and consequently resulting in improved cyclic stability.

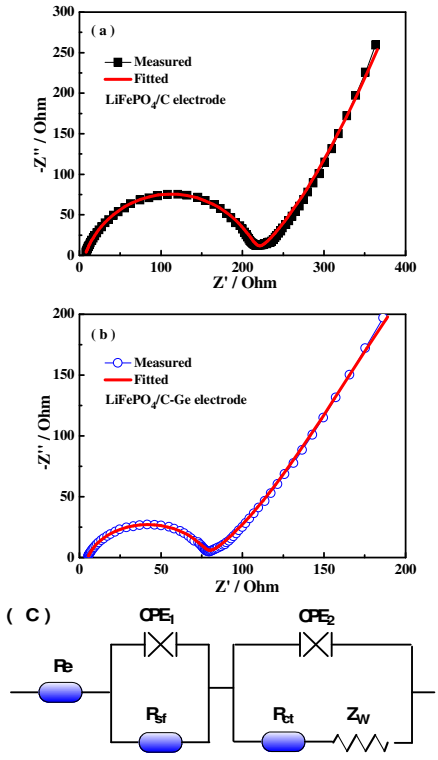

Fig.7 Nyquist plots and equivalent circuit of LiFePO4/C electrode and LiFePO4/C-Ge electrode after 10 cycles at charged state.

Figs. 7(a) and (b) present impedance spectra of the pristine $LiFePO_4$/C and $LiFePO_4$/C-Ge film in the fully discharged state after 50 cycles at 0.5C rate in 60 ℃, respectively. Both EIS profiles are composed of a depressed semicircle at high frequencies and a spike at low frequencies. The depressed semicircle in high frequency region on the real axis is mainly attributed to the charge transfer

process[24] and the sloping line in low frequency region is ascribed to the warburg impedance associated with lithium ion diffusion[25]. It is found that $LiFePO_4$/C-Ge film has smaller charge-transfer resistance (R_{ct} = 72.73Ω) than that of the pristine one (=209.6Ω), which is ascribed to the highly conductive Ge film on the $LiFePO_4$/C electrode and the suppression of SEI layer. The decrease in R_{ct} is expected to overcome the kinetics restrictions and consequently enlarge the depth of Li ion insertion/extraction[26].

Summary

$LiFePO_4$/C-Ge film was synthesized by depositing Ge on $LiFePO_4$/C electrode in vacuum. Compared to the pristine $LiFePO_4$/C, $LiFePO_4$/C-Ge film exhibited superior rate performance and cyclic stability. The obtained results indicate that the presence of Ge film on $LiFePO_4$/C surface plays an important role in reducing polarization of electrode, enhancing lithium diffusion rate and protecting $LiFePO_4$ from the erosion of HF in the $LiPF_6$ based electrolyte.

Key words: contact material; $Ag/SnO_2/TiO_2$; mechanical property; electrical property

Abstract. In order to improve the machinability and electrical performance of the Ag electrical contact materials. A new kind of nano-Ag/SnO_2-TiO_2 electrical contact materials were prepared by liquid phase in-situ chemical route. The distribution state of elements titanium in copper and their effects on the microstructures and properties have been studied. The results of SEM show that SnO_2-TiO_2 powders are small, uniform and with no obvious phenomenon of reunion. At last, Ag/SnO_2-TiO_2 electrical contact materials were prepared by powder metallurgy method and electrical performance were done. Test results show that the electrical properties of Ag/SnO_2-TiO_2 are superior to the electrical properties of Ag/SnO_2. Hence Ag/SnO_2-TiO_2 may become a new contact material which can replace Ag/SnO_2.

Introduction

Ag/CdO contact material is known for its goog switching performance. At present, traditional Ag/CdO materials have been replaced gradually by some new contact material such as Ag/SnO_2 because of its damages to the environment and human health in the process of making and using[1-2].But Ag/SnO_2 materials have innate shortcomings. First, the electrical performance such as contact resistance and temperature rise of Ag/SnO_2 is higher than Ag/CdO, and we have not yet found a satisfactory solution to it at home and abroad. Secondly, because of the large particles and high hardness of SnO_2, so the plasticity and ductility of Ag/SnO_2 is poor and have bad formability. All of the above limited the manufacturing and application of Ag/SnO_2 electrical contact materials greatly. Applying different additives to improve the performance of Ag/SnO_2 contact material is studied by many scholars. The most widely used additions are other metal oxides[3-4].

The deposit of titanium element is very large in China. It have the similar chemical properties and show +4 valence in the usual conditions. It combine with oxygen to form stable oxide TiO_2 easily. The dielectric constant of TiO_2 is high, so it has excellent electrical performance. TiO_2 has the performance of the semiconductor, its electrical conductivity increased rapidly with temperature rising[5-7].

The aim of this study is to develop a new kind of contact material $Ag/SnO_2/TiO_2$ by liquid phase in-situ chemical route and powder metallurgy technology. The new $Ag/SnO_2/TiO_2$ has excellent mechanical properties and electrical property. The new material improved the electrical appliances work performance and improved Chinese electrical products market competitiveness.

Research Steps and Experimental Means

The main work of this research includes experimental raw material and additive amount selection, powder preparation, powder performance characterization and the preparation of electrical contact materials and performance test and so on. The designed composition is shown in table1.

TABLE 1 THE COMPOSITION OF THE NEW MATERIAL

10	Ag	SnO_2	TiO_2
Mass fraction/%	allowance	10	1～3

The morphologies of SnO_2-TiO_2 powders and electrical contact materials were observed by scanning electron microscopy (TDCLS4800).The test parameters of the electrical contact material comprehensive parameter tester were 17V and 20A DC, contact pressure was 80Cn and the space was 2.0 mm. The test conditions and parameters are shown in table 2.

TABLE 2 ELECTRICAL PERFORMANCE TEST CONDITIONS AND PARAMETERS

Test conditions	Environment temperature(℃)	20	Test parameters	Duty ratio（%）		40
	Environmental humidity(%)	60		Interval of measuring contact resistance(time)		1000
	Air pressure(kPa)	101		Minimum arc voltage(V)		10
	Power source type	DC		Minimum arc current(A)		0.7
	Load type	Resistive		Contact from(mm)		1.5
	Operating frequency (time/minute)	60		Contact closure pressure(g)		100
	Test voltage(V)	24		Failure to determine	Great powers welding(g)	100
	Test current (A)	20			Number of consecutive (time)	5

Results and Discussion

Physical Properties

The additive and physical properties of the homemade materials are shown in table 3.

TABLE 3 EXPERIMENT WITH ADDITIVE AND PHYSICAL PROPERTIES OF THE HOMEMADE MATERIALS

Serial number	Material	Additive	Additive amount	Hardness (HV)	Electrical conductivity (%IACS)
1#	Ag/SnO_2(10)-T	—	—	760.4	62.48
2#	Ag/SnO_2(10)-T	TiO_2	1%	774.5	61.19
3#	Ag/SnO_2(10)-T	TiO_2	2%	795.6	60.17
4#	Ag/SnO_2(10)-T	TiO_2	3%	869.4	59.24

From the table, it can be seen that the hardness of the materials are all improved after Ti doped. The higher the Ti content, the greater the materials' hardness. On the contrary,the electrical conductivity decreased with the increase of Ti content.

Microstructure Analysis

The SEM images of SnO_2-TiO_2 powders with different content of TiO_2 are shown in Fig. 1.

From Fig.1 we can learn that the SnO_2 particles exhibit larger size and nonuniform. But the SnO_2 particles doped Ti^{4+} exhibit small size and almost uniform distribution.The small white particles exhibit smaller size(about a few nanometers), the large gray particles are dozens of nanometers because of a few soft reunion phenomenon while gel-drying process. Furthermore, SnO_2 particles doped 2% Ti^{4+} are more fruity compared to other ones. Ti^{4+} doping is beneficial to enhance the strength of the contact materials due to the excellent wettability and fine distribution. This also strongly accounts for the markedly improved mechanical properties and processing performance of Ag/SnO_2[8-10].

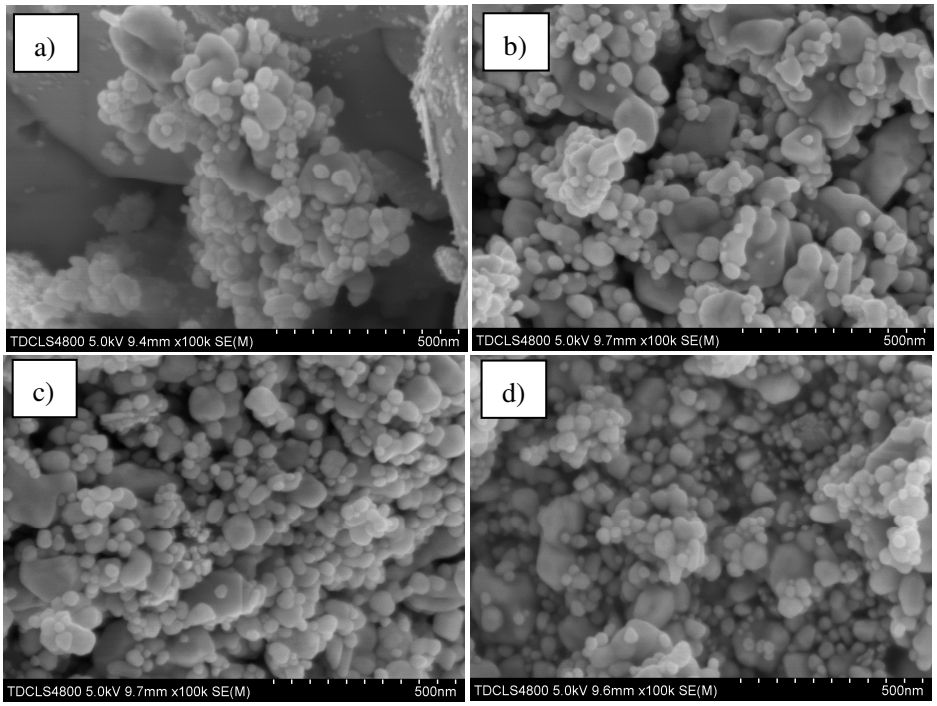

Fig.1 The SEM Images of Oxide Powders with Different Content of TiO_2

(a) 0%;(b)1%;(c)2%;(d)3%

The SEM images of composite materials with different SnO_2-TiO_2 content are shown in Fig. 2.

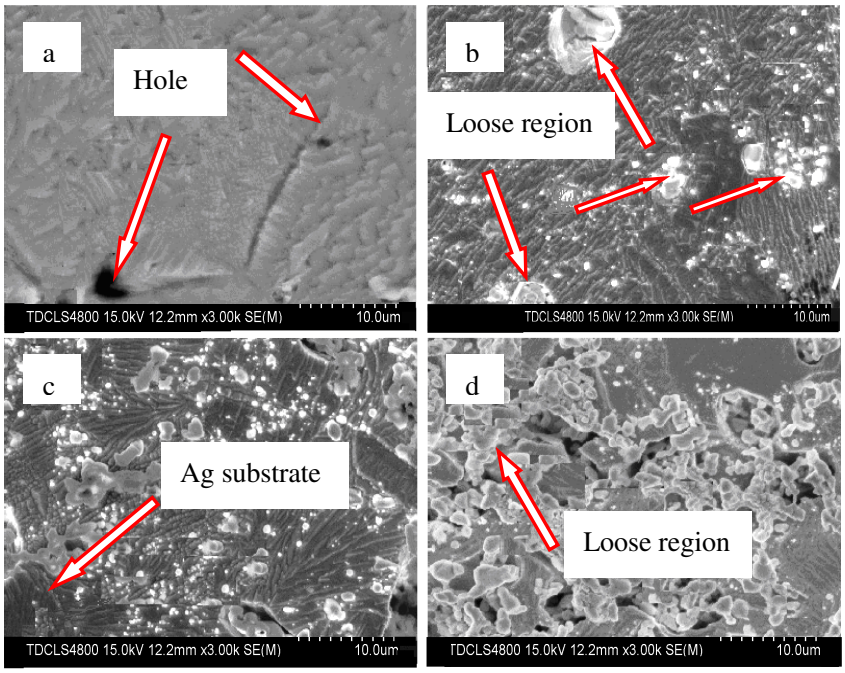

Fig.2 SEM Images of Composite Materials with Different SnO_2-TiO_2 Content (a)10%;(b)11%,(c)12%;(d)13%

From Fig.2 we can learn that the white area on the surface of the sample is the reunion of oxide particles.The defects such as holes and loose increased with the increase of SnO_2-TiO_2 content.There is a big loose zone when the content of SnO_2-TiO_2 is 13%. However,When the oxide content increased from 11% to 12%, there are not obvious defects such as holes and loose region. Comprehensive 3.1 and 3.2 we can learn that when the SnO_2-TiO_2 content is 12%, the microstructure and physical properties of the materials is best.

Electrical Performance Test Results

The morphologies of the contactor which through electrical performance test were observed by scanning electron microscopy (TDCLS4800). The SEM images of Ag/SnO_2(10) and Ag/SnO_2-TiO_2(12) after arc erosion are shown in Fig. 3.

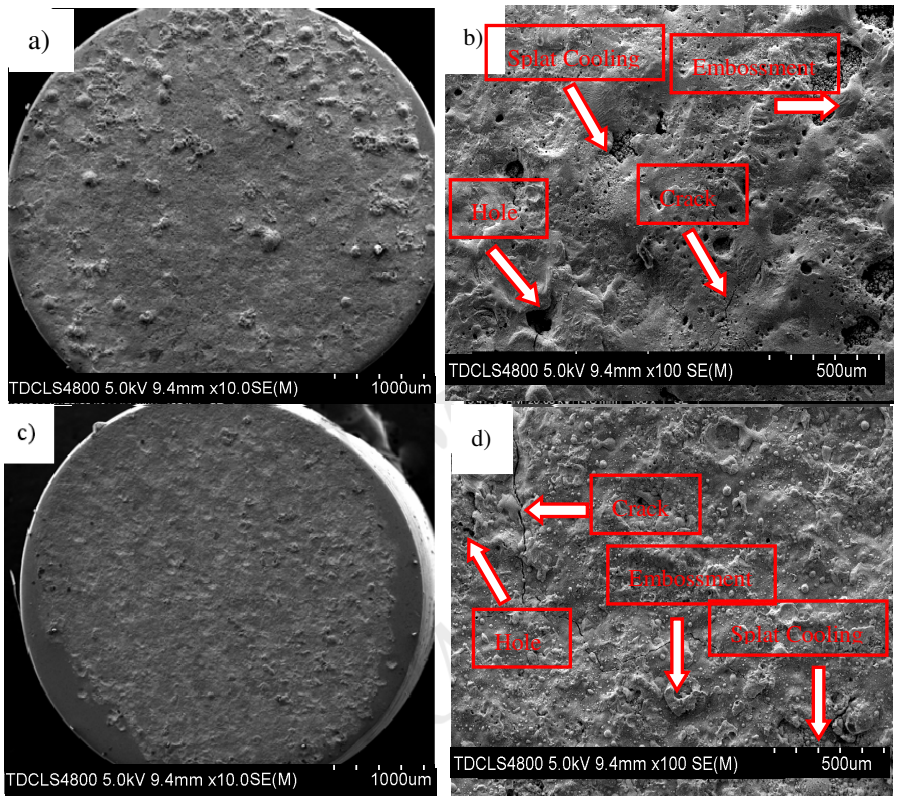

Fig.3 SEM Images of Homemade Materials after Arc Erosion (a)ag/sno$_2$(10); (b)Enlarge figure of Fig.3(a);(c) Ag/SnO_2-TiO_2(12);(d)Enlarge figure of Fig.3(c)

Comparative Fig.3(a) and Fig.3(c)we found that the ablation area is larger and there are more trunk and potholes on the surface of Ag/SnO_2(10) sample than that of on the surface of Ag/SnO_2-TiO_2(12). It can be seen that Ti coating on SnO_2 particles improves the wet ability of Ag to SnO_2 and prevents the temperature arising owing to the formation of SnO_2 insulation layer and thus significantly improves the electrical properties, such as the electrical life,anti-fusion welding ability, electrical arc resistance of the materials. Because the electrical conductivities of Ag/SnO_2 contact materials depend strongly on the condition of the interface between SnO_2 and Ag[11-12].

Temperature Rise Test

The conditions of the test are as follows:electric current(40A), on-load factor(100%), environment temperature(22℃), connection wire specifications(10mm^2/m). The temperature rise of terminals were measured using thermocouple. The results are shown in table 4.

TABLE 4 RESULTS OF TEMPERATURE RISE BETWEEN HOMEMADE CONTACT AND EXISTING CONTACT AT HOME AND ABROAD

Measurement Locations		Measured maximum temperature rise (K)		
		Ag/SnO_2-TiO_2 (Homemade contact)	Ag/SnO_2-In_2O_3 (Foreign contact)	Ag/SnO_2 (Domestic contact)
Terminals	Inlet A	21.6	18.7	23.6
	Inlet B	25.4	21.9	26.0
	Inlet C	22.2	21.1	22.6
	Outlet A	20.7	20.2	21.7
	Outlet B	21.4	23.7	22.6
	Outlet C	20.1	18.9	21.8

Summary

Ti doped is beneficial to enhance the density and strength and improve mechanical properties and processing performance of the contact materials due to the excellent wettability and fine distribution. This also strongly accounts for the markedly improved electrical properties of Ag/SnO_2.

Keywords: Hydrothermal stripping, nano-β-$Ni(OH)_2$, cathode materials, electrochemical performances

Abstract: A novel hydrothermal stripping technique synthesis route, in which the nickel-loaded organic phase of naphthenic acid was directly stripped by water at 140-240 °C for 2.0 h to recover nickel as hydroxide precipitates, has been firstly developed. The nickel hydroxide powders synthesized by this route was the spherical β-$Ni(OH)_2$ and had a small particle size in the range of 20-100 nm shown by XRD and TEM test. The results of electrochemical performances show that the nanometer β-$Ni(OH)_2$ cathode materials have much higher discharge specific capacity, excellent capacity retention and cycle performances.

Introduction

Nickel hydroxide ($Ni(OH)_2$) is a very important cathode material in a number of alkaline rechargeable batteries, which are the most widely used in many applications ranging from power tools to portable electronics and electric vehicles [1-8]. Many synthesis methods have been proposed for controlling the physical and chemical characteristics of $Ni(OH)_2$ by controlling the structure, morphology and particle size. Recently, β-$Ni(OH)_2$ with a small crystalline size and spherical shape has attracted enormous interest due to their novel physical properties and excellent electrochemical performance, and its synthesis has been the focus of significant interest in materials chemistry [9-17]. The nanometer spherical β-$Ni(OH)_2$ can be synthesized by different techniques such as solid-state reaction, precipitation and hydrothermal method, etc [6-12].

Hydrothermal stripping synthesis is a promising method for synthesizing oxide ceramic powders for high-performance applications [18-26]. Compared with the previous works, the hydrothermal stripping synthesis as reported in this paper has some advantages: effectively reaction control, which will help control the product morphology and particle size at low-temperature, environmentally friendly and low costly processes, in which the product was formed and the organic phase was released and can be reused. The nanometer spherical β-$Ni(OH)_2$ synthesized by this route has good electrochemical performances.

Experimental

The hydrothermal stripping synthesis route is started with water and organic phase. The nickel-loaded organic phase of naphthenic acid (RCOOH) was prepared by solvent extraction from an aqueous nickel sulfate solution. In each stripping experiment the water and organic phase were transferred into a stainless steel autoclave, heated to the experimental temperature. After being cooled, the precipitates were segregated by centrifugation and washed several times with distilled water. Then the samples were dried at 80℃ for 2.0 h in an oven and the samples were numbered as A, B, C, D and E according to different synthesis conditions (See Table 1).

Table 1 Samples synthesized from nickel-loaded organic phase of naphthenic acid

Samples	**A**	**B**	**C**	**D**	**E**
Temperature /[°C]	**80**	**140**	**200**	**240**	**240**
Time /[h]	**2.0**	**2.0**	**2.0**	**2.0**	**4.0**

The crystal phase structure of sample was investigated using an X-ray diffractometer (XRD) (BDX-3300 made by Peking University Instrument Co, China). A Transmission Electron Microscope (TEM) (100CX-II made by JEOL, Tokyo, Japan) and Field Emission Gun Scanning Electron Microscope (SEM) (100CX-II made by JEOL) were used to characterize the sample with respect to their morphology and particle size. Simulated battery was prepared to study the electrochemical performance of the nickel hydroxide electrode with 60 mass% β-$Ni(OH)_2$, 10% CoO and 30% Ni powder.

Results and discussion

Structure analysis

Fig. 1 shows the XRD patterns of the samples synthesized from nickel-loaded naphthenic acid (RCOOH) at different temperature. It can be found from the XRD patterns that sample B, C and D exhibits the standard XRD characteristics of β-$Ni(OH)_2$ phase (JCPDS 14-0117), and sample A has several clutter peaks due to unidentified crystalline phase. The fact that pure water is used as the reactant means the sample is uncontaminated.

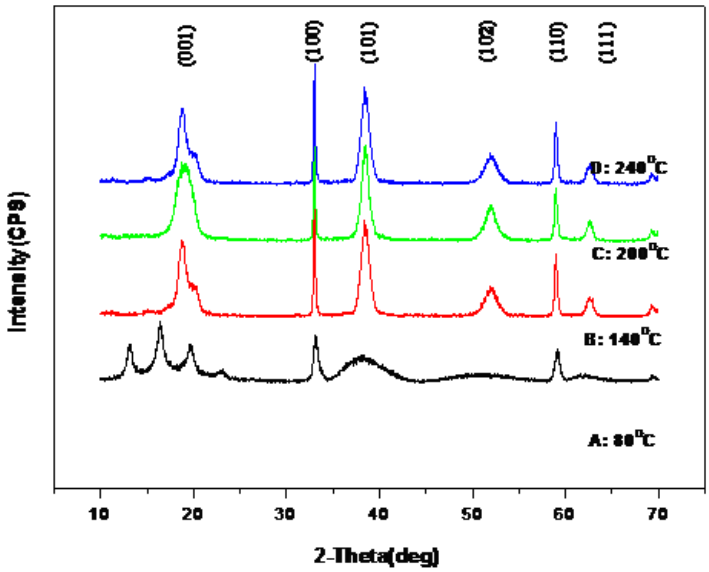

Fig. 1. XRD patterns of samples

Morphology and particle analysis

The typical TEM images in Fig. 2 show that the samples are the uniform distribution of spherical β-$Ni(OH)_2$ without agglomeration, of which the particle size was smaller than that of literature reported [20-22] and synthesized by precipitation transformation (2). It can be seen from Fig. 2 that the average particle size was related with the stripping temperature and time, and the size becomes larger with the increase of temperature (B, C and D) and time (D and E). The average particle size of sample C, which was synthesized at 200 ℃ for 2.0 h, is measured to be about 34 nm by observation. As a contrast, the size of C is 33.61 nm, which was estimated from the Cherrer's formula according to the full width at half-maximum (fwhm) of the diffraction peaks (Seen Fig. 1).

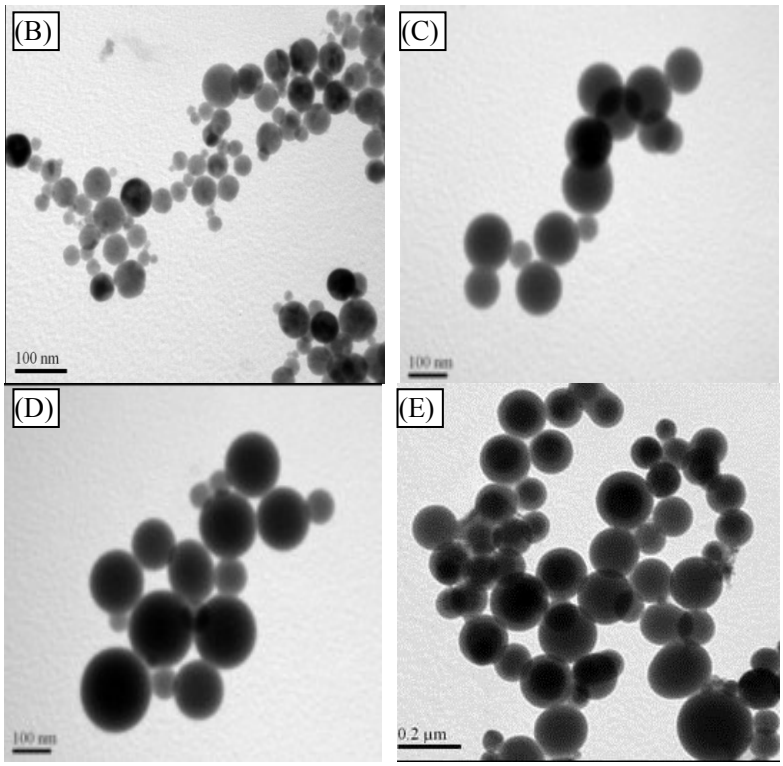

Fig. 2. TEM images of (B), (C), (D) and (E)

Electrochemical performance

Fig. 3 (a) displays the typical charge-discharge voltage profiles of the samples synthesized by hydrothermal stripping. The fact that charging potential plateaus is lower and the discharging potential plateau is higher suggests that the charge–discharge process can be taken place more easily and more reversibly on the nanometer β-$Ni(OH)_2$ electrode.

Cycle performance is an important index for MH-Ni batteries. Fig. 3 (b) displays the typical cycle performance of the samples synthesized by hydrothermal stripping method. At a constant current rate of C/5, the cell prepared with nano-$Ni(OH)_2$ shows the discharge capacity of 289 $mA{\cdot}hg^{-1}$. This shows hat the nanometer β-$Ni(OH)_2$ cathode materials have much higher discharge specific capacity . As seen in Fig. 3 (b), the nanometer β-$Ni(OH)_2$ sample at C/5 manifests a good cycling performance with initial discharge capacity of 289$mA{\cdot}hg^{-1}$, and discharge capacity of 285 $mA{\cdot}hg^{-1}$ after 58 cycles. The 1.7% loss of specific capacitance after 58 cycles indicates that the repetitive charge-discharges do not induce noticeable degradation of the nanometer β-$Ni(OH)_2$. The spherical nanometer particles, which has larger real superficial area, can provide more chances for the β-$Ni(OH)_2$ to contact the electrolyte solution, therefore proton diffusion is enhanced, which in turn will accelerate the electrode reaction. The charge–discharge process can be taken place more easily and more reversibly on the β-$Ni(OH)_2$ electrodes than that on the microsized β-$Ni(OH)_2$ electrode.

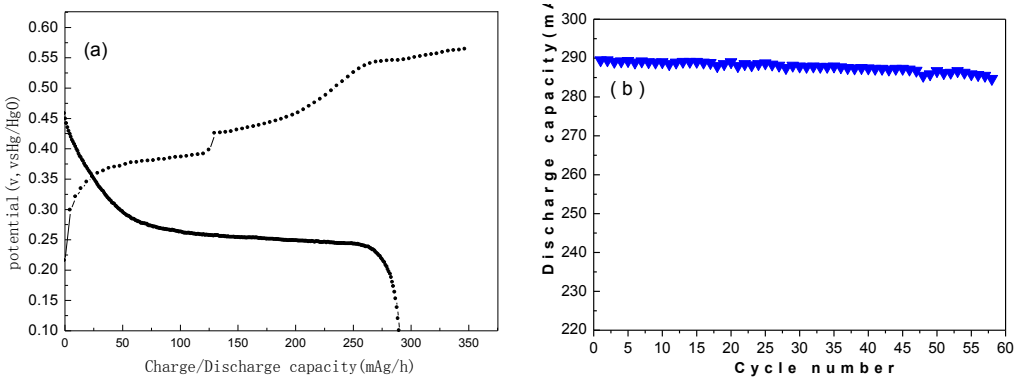

Fig.3. Charge and discharge curves (a) and cycle performance (b) of samples

Conclusions

In summary, the spherical nanometer β-$Ni(OH)_2$ were successfully synthesized by the hydrothermal stripping route, in which the nickel-loaded organic phase was directly stripped by pure water at 140-240 °C for 2.0-4.0 h. The nanometer β-$Ni(OH)_2$ sample at C/5 manifests a good cycling performance with initial discharge capacity of 289mAh·g^{-1}, and discharge capacity of 285 mAh·g^{-1} after 58 cycles. The excellent performances of the present samples in our work are due to the spherical and smaller β-$Ni(OH)_2$ particles. This can makes it feasible as a promising additive material for Ni/MH battery. Hydrothermal stripping route is an effective and green solution-phase synthetic method for synthesizing nanometer β-$Ni(OH)_2$ cathode materials and other high quality materials.

Keywords: Hybrid battery-supercapacitor; $(LiFeO_4+AC)/Li_4Ti_5O_{12}$; High rate; High capacity; Long life

Abstract:A hybrid battery-supercapacitor $(LiFePO_4+AC)/Li_4Ti_5O_{12}$ using a $Li_4Ti_5O_{12}$ anode and a $LiFePO_4$/activated carbon(AC) composite cathode was built. The electrochemical performances of the hybrid battery-supercapacitor $(LiFePO_4+AC)/Li_4Ti_5O_{12}$ were characterized by constant current charge-discharge, rate charge-discharge, electrochemical impedance spectra, internal resistance, leakage current, self-discharge and cycle performance testing. The results show that $(LiFePO_4+AC)/Li_4Ti_5O_{12}$ hybrid battery-supercapacitors have rapid charge-discharge performance, high energy density, long cycle life, low resistance, low leakage current and self-discharge rate, which meet the requirements of practical power supply and can be applied in auxiliary power supplies for hybrid electric vehicles. At 4C rate, the capacity loss of $(LiFePO_4+AC)/Li_4Ti_5O_{12}$ hybrid battery-supercapacitors in constant current mode is no more than 7.71% after 2000 cycles, and the capacity loss in constant current- constant voltage mode is no more than 4.51% after 1500 cycles.

Introduction

Due to the lack of energy and increasingly serious pollution, hybrid electric vehicles (HEVs) has become a research hotspot in automotive industry [1,2]. But neither secondary batteries (low power density) nor supercapacitors (low energy density) as a single power source can be applied in HEVs [3-9]. Therefore, the demand for electrochemical energy storage devices with high energy density and high power density is urgent. Hybrid battery-supercapacitor is a kind of combination of secondary battery and supercapacitor. It has high energy density as the secondary battery and also high power density as the supercapacitor [10-13]. This makes it one of the most possible auxiliary power supplies for hybrid electric vehicles (HEVs). The authors previously synthesized a composite cathode material containing $LiFePO_4$ and activated carbon (AC) abbreviated as LAC, by an in-situ synthesis method, and then assembled a hybrid battery-supercapacitor device with a $Li_4Ti_5O_{12}$ anode to form the $LAC/Li_4Ti_5O_{12}$ system. Although the hybrid battery-supercapacitor $LAC/Li_4Ti_5O_{12}$ showed the advantages of high rate capability and high capacity [11], the in-situ synthesis requires high system stability. It's hard to control product performance, stability and consistency, particularly accurate content of $LiFePO_4$ in composite materials. The shortage of in-situ synthesis increase difficulty in industrial production. One possible solution to this problem is to synthesize products by a direct mixing technique. The direct mixing technique synthesizes the composite materials via high-speed mechanical mixing, which is simple and can control accurate content of each component in composite materials.

In this paper, we used a composite material from $LiFePO_4$ and AC, as the composite cathode, and then assembled a hybrid battery-supercapacitor device with $Li_4Ti_5O_{12}$ anode to form the system. The

electrochemical properties of ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitors were investigated. The study summed up ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitors application characteristics and rules. These results may provide the theoretical basis and practical reason for the need of practical application for HEVs.

Experimental

Synthesis of electrode materials

$Li_4Ti_5O_{12}$ powder was prepared via a solid-state reaction as described in Ref. [11].

Cells assembly

Cathodes were prepared with $LiFePO_4$ (STL, China) and AC (GH-6, China). The conductive additives used were colloidal graphite (F-0, China) and conductive carbon black (SuperP, TIMCAL) termed SP hereinafter. The binder used was LA132 (Indigo, China). Anodes were prepared in the same way, using $Li_4Ti_5O_{12}$ as active material. The electrodes formulations are summarized in Table 1.

TABLE 1. FORMULATIONS OF THE ELECTRODES TESTED.

Electrode	Active material	Conductive additives	Binder
15% LFP + AC	$LiFePO_4$ 15% + AC 60%	F-0 12% + SP 6%	LA132 7%
22.5% LFP + AC	$LiFePO_4$ 22.5% + AC 52.5%	F-0 12% + SP 6%	LA132 7%
30% LFP + AC	$LiFePO_4$ 30% + AC 45%	F-0 12% + SP 6%	LA132 7%
LTO	$Li_4Ti_5O_{12}$ 86%	F-0 6% + SP 4%	LA132 4%

The cells were assembled in an argon-filled dry box by pressing a $LiFePO_4$/AC cathode, a Celgard 2400 polypropylene membrane, and a $Li_4Ti_5O_{12}$ anode. Al foil was used as electrode current collectors. The electrolyte was a 1.0M $LiPF_6$ solution in the mixture of ethylene carbonate, dimethyl carbonate and ethylene methyl carbonate (1:1:1 by weight). The cells were packaged with aluminum-plastic membrane and shaped. The final size of hybrid battery-supercapacitor is 4.5mm × 30mm × 48mm (thickness × width × length, Fig. 1). For comparison, the capacitors of AC/AC and AC/$Li_4Ti_5O_{12}$ and the battery $LiFePO_4$/$Li_4Ti_5O_{12}$ were also assembled in the same way.

Fig. 1. Hybrid battery-supercapacitor obtained.

Performance evaluation

Rate capability and cycle performance of the hybrid battery-supercapacitor and capacitor were tested on a Repower Battery Tester (China). Cycle performance tests were divided into two modes: constant current mode (CC mode) and constant current-constant voltage mode (CC-CV mode). In CC mode, the hybrid battery-supercapacitors were charge-discharge cycled over a cell-voltage window of between 2.6V and 1.0V at a constant current. In CC-CV mode, for each cycle, after resting for 5 minutes, the hybrid battery-supercapacitors were charged with constant current to 2.6V and with constant voltage at 2.6V till charge current declined to 5mA. Then, they were rested for 5 minutes. After that, they were discharged to 1.0V at a constant current. Electrochemical impedance spectra were investigated by a Solartron 1260/1287 (UK) in the frequency range of 10^{-1}–10^5Hz. Internal resistance of the cells was investigated by a BK-300 Precision Internal Resistance Tester (1000Hz,

20mA, China). Leakage current and self-discharge behaviors of the cells were characterized using an Arbin instrument (USA). All the tests were carried out at 20 ℃.

Results and discussion

Physical properties of electrode materials

The particle size distribution of $LiFePO_4$, AC and $Li_4Ti_5O_{12}$ is depicted in Fig. 2. As is seen in this figure, the average particle size of $LiFePO_4$, AC and $Li_4Ti_5O_{12}$ is 3.27, 12.11 and 0.303μm, respectively. The BET of $LiFePO_4$, AC and $Li_4Ti_5O_{12}$ is listed in Table 2.

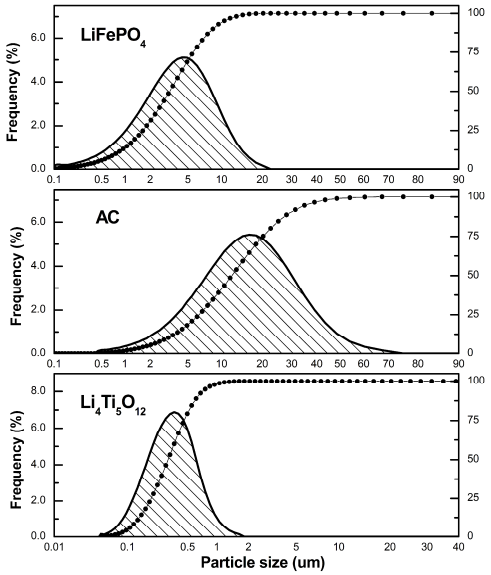

Fig. 2. The particle size distribution of $LiFePO_4$, AC and $Li_4Ti_5O_{12}$.

TABLE 2. THE PARTICLE SIZE DISTRIBUTION AND BET OF $LIFEPO_4$, AC AND $LI_4TI_5O_{12}$.

	D_{10}(μm)	D_{50}(μm)	D_{90}(μm)	$D_{(4,3)}$(μm)	BET($m^2 \cdot g^{-1}$)
$LiFePO_4$	0.765	3.27	8.43	4.06	2.41
AC	3.09	12.11	29.40	14.53	581.7
$Li_4Ti_5O_{12}$	0.128	0.303	0.638	0.352	10.67

Charge/discharge behavior of hybrid battery-supercapacitor

Fig. 3 shows a whole charge-discharge process of ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitors with different $LiFePO_4$ contents. The whole charge-discharge process of ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ battery-supercapacitor includes six steps that are A～B，B～C，C～D，D～E，E～F and F～G [11]. Step B～C is the middle stage of the charge process, which is also the slow charge process during which the capacity is increased but the voltage is kept constant. It belongs to the process of Li-ion extraction/oxidation in $LiFePO_4$ and Li-ion insertion/reduction in $Li_4Ti_5O_{12}$, and presents Faradaic energy storage. Step C～D is the final stage of the charge process, i.e. the slow charge process during which the capacity increases linearly with voltage, which is the characteristic charge process of electric double-layer electrostatic adsorbing PF_6^{-1} in AC and Li-ion insertion/reduction in $Li_4Ti_5O_{12}$, and presents energy storage of electric double-layer electrostatic adsorption. Step A～B is the early stage of charge, i.e. slow charge process capacitor shows a non-linear increase with voltage, which has the characteristics of B～C and C～D stages. The steps D～E，E～F and F～G are the reversible discharge processes of C～D，B～C and A～B steps respectively. In two modes, with the increase of $LiFePO_4$ content in composite cathodes, the platform region of hybrid battery-supercapacitors correspondingly adds and the platform performance strengthens. Compared with CC and CC-CV modes, discharge capacity of CC-CV mode is slightly

larger than that of CC mode under the same conditions, which is resulted from adding the process of constant voltage charge.

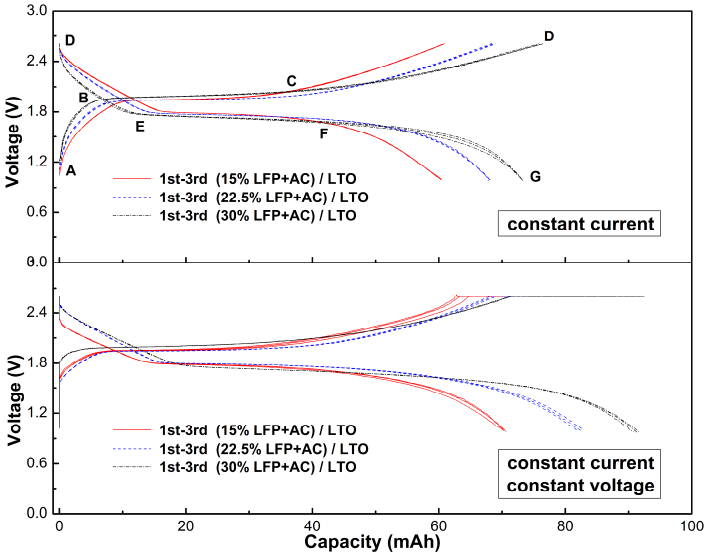

Fig. 3. Charge-discharge curves of the hybrid battery-supercapacitor.

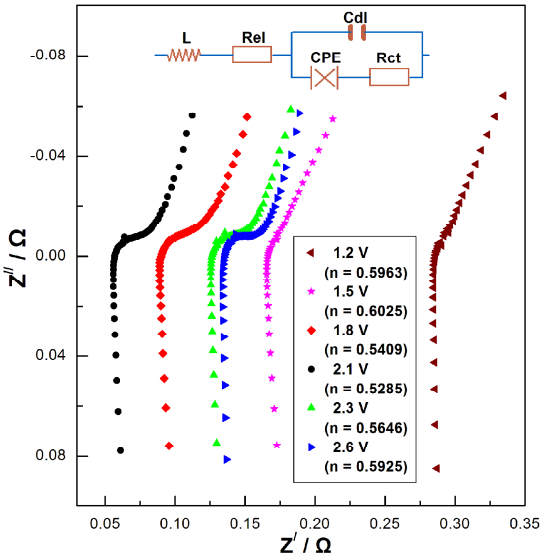

Fig. 4. EIS of the hybrid battery-supercapacitor at various potentials.

Electrochemical impedance spectra (EIS) of hybrid battery-supercapacitor

Fig. 4 shows EIS of hybrid battery-supercapacitor (22.5%$LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ at various potentials. It is apparent that Nyquist plots at various potentials are very similar, which is composed of two parts: an almost vertically straight line & semicircle in the high frequency range and a slash in the low frequency range. The equivalent circuit is made of a connector's inductance (L), an electrolyte resistance (Rel), a charge-transfer resistance (Rct), a double-layer capacitance (Cdl), and a constant phase element (CPE). CPE reflects capacitance characteristics of the hybrid battery-supercapacitor. With the increase of potential, n of CPE increases firstly (from 1.2V to 1.5V), then decreases (from 1.8V to 2.1V) and finally increases again (from 2.3V to 2.6V). These results indicate that with the increase of potential the hybrid battery-supercapacitor shows firstly the capacitance characteristics, then transfers to the battery characteristics and finally shows capacitance characteristics again. This demonstrates that energy storage process in the hybrid battery-supercapacitor is gradually transferred from energy storage of electric double-layer electrostatic adsorption to Faradaic energy storage, then to energy storage of electric double-layer electrostatic adsorption. These facts illustrate that the Nyquist plot of ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery–supercapacitor is consistent with the charge-discharge cycle curve.

Energy density of hybrid battery-supercapacitor

Table 3 shows the results of the energy densities of the hybrid battery-supercapacitors in CC and CC-CV modes. In two modes, the mass and volume energy densities of ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitors with various $LiFePO_4$ contents all exceed 10.9 $Wh \cdot kg^{-1}$ and 16.8 $Wh \cdot kg^{-1}$, respectively. The energy densities of the hybrid battery-supercapacitors are significantly higher than that of AC/$Li_4Ti_5O_{12}$ hybrid capacitor and AC/AC electric double-layer capacitor, also higher than that of commercial supercapacitors (1~10 $Wh \cdot kg^{-1}$). Moreover, the energy density of hybrid battery-supercapacitor is enhanced when the content of $LiFePO_4$ is added in composite cathode. When the content of $LiFePO_4$ in composite cathode is 30 wt% in CC-CV mode, the mass and volume energy densities of ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitor reach 15.56 $Wh \cdot kg^{-1}$ and 24.02 $Wh \cdot kg^{-1}$, respectively. The Energy densities of the hybrid battery-supercapacitors will be increased (especially for volume energy density) if the monomer cell is assembled. These results demonstrate ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitors have high energy density at 4C rate.

TABLE 3. ENERGY DENSITIES OF HYBRID BATTERY-SUPERCAPACITORS AT 4C RATE.

Type		Energy density	
		($Wh \cdot kg^{-1}$)	($Wh \cdot L^{-1}$)
AC/AC (DLC306)		4.17	6.44
AC/AC		2.31	3.56
AC/LTO		5.77	8.91
CC mode	(15%LFP+AC)/LTO	10.92	16.85
	(22.5%LFP+AC)/LTO	12.07	18.63
	(30%LFP+AC)/LTO	12.98	20.02
CC-CV mode	(15%LFP+AC)/LTO	12.36	19.08
	(22.5%LFP+AC)/LTO	14.81	22.86
	(30%LFP+AC)/LTO	15.56	24.02

Resistance characteristics of hybrid battery-supercapacitor

Table 4 shows the results of alternating current resistance of the hybrid battery-supercapacitors. After formation process, alternating current resistances of all devices decrease. With the increase of $LiFePO_4$ content in composite cathodes, the alternating current resistances of the hybrid battery-supercapacitors slightly increase, also slightly higher than AC/$Li_4Ti_5O_{12}$ hybrid capacitor and AC/AC electric double-layer capacitor.

TABLE 4. ALTERNATING CURRENT IMPEDANCE OF THE HYBRID BATTERY-SUPERCAPACITORS.

Type		Before formation (mΩ)	After formation (mΩ)	2000 cycles(4C) (mΩ)
AC/AC (DLC306)		12.6	12.2	29.3
AC/AC		27.3	27.3	30.3
AC/LTO		32.9	32.8	32.8
CC mode	(15%LFP+AC)/LTO	27.6	27.3	33.8
	(22.5%LFP+AC)/LTO	29.9	28.8	34.0
	(30%LFP+AC)/LTO	33.4	32.4	40.0
CC-CV mode	(15%LFP+AC)/LTO	27.9	27.1	32.5
	(22.5%LFP+AC)/LTO	29.5	28.7	33.5
	(30%LFP+AC)/LTO	33.3	33.0	39.8

Leakage current

Leakage current can be used as an important evaluation index of energy storage devices performance. In Fig. 5, all devices were charged with constant voltage for 72 hours. The constant voltage is 2.6V for ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitor and $LiFePO_4$/$Li_4Ti_5O_{12}$ battery, 2.7V for AC/AC electric double-layer capacitor, and 2.8V for AC/$Li_4Ti_5O_{12}$ hybrid capacitor. As shown in the figure, the hybrid battery-supercapacitors present good leakage current performance, which is the same as other energy storage devices.

Self-discharge

Fig. 6 shows self-discharge performance of all devices. After charging with constant voltage for 0.5 hour, all devices were placed in an open-circuit state for 72 hours. The constant voltage is 2.6V for ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitor and $LiFePO_4$/$Li_4Ti_5O_{12}$ battery, 2.7V for AC/AC electric double-layer capacitor, and 2.8V for AC/$Li_4Ti_5O_{12}$ hybrid capacitor. As shown in the figure, the order of voltage drop is AC/AC > $LiFePO_4$/$Li_4Ti_5O_{12}$ > ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ > AC/$Li_4Ti_5O_{12}$. With the increase of $LiFePO_4$ content in composite cathodes, the self-discharge curve

of the hybrid battery-supercapacitors is gradually closer to that of $LiFePO_4/Li_4Ti_5O_{12}$ battery. These results demonstrate $(LiFePO_4+AC)/Li_4Ti_5O_{12}$ hybrid battery-supercapacitors have low self-discharge performance.

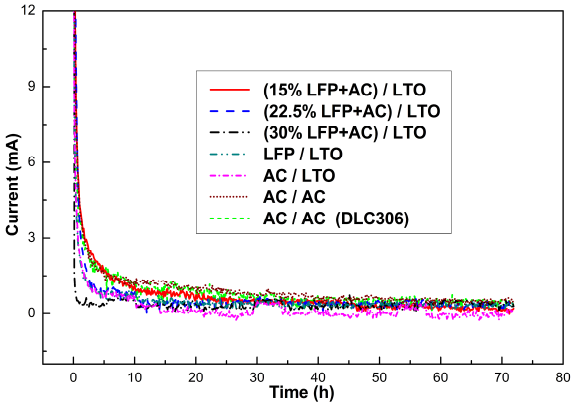

Fig. 5. Leakage current curves of all devices.

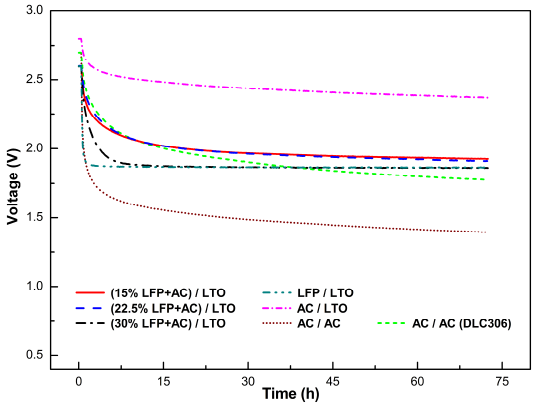

Fig. 6. Self-discharge curves of all devices.

Cycle life performance of hybrid battery-supercapacitor

The results for cycle life of the hybrid battery-supercapacitors at 4C rate are shown in Fig. 7. As is seen in the figure, the capacity losses of AC/AC electric double-layer capacitors are less than 3.00% after 2000 cycles, which demonstrates that they have excellent cycling performance. However, their discharge capacities are low. In contrast, $AC/Li_4Ti_5O_{12}$ hybrid capacitor has larger capacity, but its capacity retention remains poor. It is obvious that AC/AC electric double-layer capacitors and $AC/Li_4Ti_5O_{12}$ hybrid capacitor have not high capacity and long life performances at high rate. $(LiFePO_4+AC)/Li_4Ti_5O_{12}$ hybrid battery-supercapacitors in two modes provide high coulombic efficiencies closed to 100%. In CC mode, when the content of $LiFePO_4$ in composite cathode is 15, 22.5 and 30 wt%, after 2000 cycles the capacity loss of $(LiFePO_4+AC)/Li_4Ti_5O_{12}$ hybrid battery-supercapacitor is 6.04%, 7.48% and 7.71%, respectively. Clearly, all the value is no more than 7.71%. However, if in CC-CV mode, after 1500 cycles the capacity loss will be 2.71%, 4.51% and 3.60%, respectively, and noticeably, all the value is no more than 4.51%. The results show that $(LiFePO_4+AC)/Li_4Ti_5O_{12}$ hybrid battery-supercapacitors have high capacity and good cycle life performance at high rate.

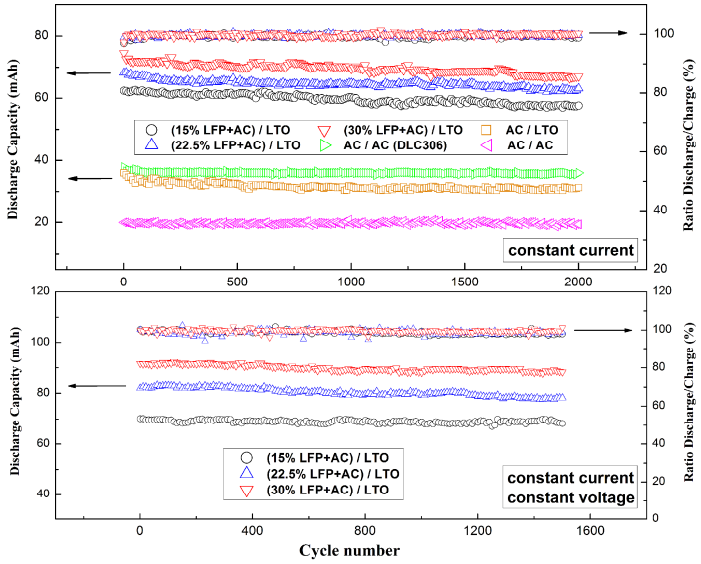

Fig. 7. Discharge capacity and discharge/charge ratio vs. cycle number for hybrid battery-supercapacitors at 4C rate.

Conclusions

The hybrid battery-supercapacitors ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ have the advantages of high rate, high capacity and long life. At 4C rate, when the content of $LiFePO_4$ in composite cathode is 30 wt% in CC-CV mode, the mass and volume energy densities of the monomer ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitor reach 15.56 $Wh \cdot kg^{-1}$ and 24.02 $Wh \cdot kg^{-1}$, respectively, which is significantly higher than that of AC/$Li_4Ti_5O_{12}$ hybrid capacitor and AC/AC electric double-layer capacitor. The capacity loss of ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitors in CC mode is no more than 7.71% after 2000 cycles, and the capacity loss in CC-CV mode is no more than 4.51% after 1500 cycles. Moreover, low resistance, leakage current and self-discharge rate of the hybrid battery-supercapacitors are in accordance with the requirements of practical power supply, and expected to further optimize and improve their electrochemical performance. In a word, ($LiFePO_4$+AC)/$Li_4Ti_5O_{12}$ hybrid battery-supercapacitors have rapid charge-discharge performance, high energy density, long cycle life, low resistance, low leakage current and self-discharge rate, which can be applied in auxiliary power supplies for HEVs.

Keywords: recrystallization modeling, texture, polycrystalline aluminium, oriented growth

Abstract: In many metallic materials the dominating recrystallization mechanism can be described by the oriented growth behavior. Phenomenological laws state that only these nuclei grow intensively which have a given misorientation with the deformed matrix. This description is frequently verified in f.c.c. metals and generally reported misorientations are between 30^0 and 50^0 rotations around the <111> axis. Basing on the above ideas the recrystallization model was formulated and applied to the study of recrystallization textures in rolled polycrystalline aluminium.

Introduction

Texture development in f.c.c. metals was studied and described in literature using various models (eg. [1-5]. In many of these models the stored energy and residual stresses play the essential role (e.g., [3-6]). However, a relatively simple orientation relationship between growing nuclei and deformed matrix was found in aluminium, which can explain the formation of its recrystallization texture. Preferred misorientations, Δg, between nuclei and deformed grains, correspond to high mobility of grain boundaries. They are traditionally described as a rotation $\omega_0 \cong 40^o$ around one of <111> axes. Therefore, the velocity of grain boundary, u, between a nucleus and the deformed matrix depends very strongly on misorientation Δg. This relation was reported in [7] and [8]. Based on the above assumptions, a successful recrystallization model was formulated [9,10]. It was also shown that predicted results are much improved if the so called *compromise condition* and, consequently, the *compromise function* are used. Let us describe now in more details the recrystallization model used in the present calculations.

Recrystallization Model

Boundary Migration Rate

Each deformed grain is statistically consumed by many nuclei but at very different rates. The crystal misorientation Δg_{ij} between the nucleus i and the deformed grain j is expressed by the rotation axis $\mathbf{r}_{ij}$ and the misorientation angle ω_{ij}. Obviously, in general the determined rotation axis $\mathbf{r}_{ij}$ does not exactly coincides with one of <111> axes; let us assume that it is deviated of the angle α_{ij} from the nearest <111> axis. Similarly, the ω_{ij} misorientation angle does not equal exactly to ω_0 (corresponding to the maximum migration rate). Therefore,

basing on the results presented in [7] and [8] the boundary migration rate, u_{ij} (ω_{ij}, α_{ij}) between the nucleus *i* and deformed grain *j*, was approximated as:

$$u_{ij}(\omega_{ij},\alpha_{ij}) = u_{max}\, e^{\frac{-(\omega_{ij}-\omega_0)^2}{\Delta\omega^2}} \cdot e^{\frac{-\alpha_{ij}^2}{\Delta\alpha^2}} \tag{1}$$

The first exponential function in the above equation describes the relation of the migration rate on the misorientation angle ω_{ij}, assuming that the maximum migration rate corresponds to ω_0. In the second exponential function the effect of deviation of a current rotation axis $\mathbf{r}_{ij}$ from the nearest 'ideal' <111> of α_{ij} angle is taken into account. In the above formula the following constants were adjusted from experimental data [9,10]: ω_0=40^0, $\Delta\omega$=13.7^0, $\Delta\alpha$, $\Delta\alpha$=7.5^0 and u_{max}=4.56 mm/min corresponds to the maximum value of the boundary migration rate.

Compromise Function

The compromise function is defined as a volume fraction of all deformed grains, which can be potentially 'consumed' by a nucleus of a given orientation:

$$S(g_i) = \frac{\sum_j V_j}{V_0} \tag{2}$$

where V_j is the volume of the *j-th* deformed grain and the following condition has to be fulfilled: the i-th nucleus can grow into j-th grain with the migration rate exceeding some minimal value, i.e., $u_{ij} \geq u_{min}$. The value u_{min}=0.001 mm/min used.

Calculation of Recrystallization Texture

The deformation matrix is presented as *N*=5000 grains of the same volume with crystal orientation distribution corresponding to the deformation texture. We generate *M*=6859 nuclei with crystal orientations contained in the range of Euler angles space corresponding to the cubic crystal and sample orthorhombic symmetries, i.e.: $: 0 \leq \phi \leq \pi/2,\ 0 \leq \varphi_2 \leq \pi/2$ oraz $0 \leq \varphi_1 \leq \pi/2$ (i.e., every 5^0 with respect to each Euler angle). Next, we define a step function *c(g)*, basing on the compromise function, which decides whether a given nucleus with orientation g_i will grow or not:

$$c(g_i) = \begin{cases} 1, & if \quad S(g_i) \geq s_0 \\ 0, & if \quad S(g_i) < s_0 \end{cases} \tag{3}$$

where s_0 is the assumed level of compromise [3].

The volume ΔV_{ij} of the *j-th* deformed grain consumed by the *i-th* nucleus is:

$$\Delta V_{ij} = \frac{u_{ij}}{\sum_{k=1}^{M} u_{kj}} \cdot V_j \tag{4}$$

where V_j is the initial volume of the j-th grain and the summation on *k* is done on growing nuclei (those which fulfill the compromise condition).

The total volume of the deformed matrix, 'consumed' by *i-th* nucleus is:

$$\Delta V(g_i) = \sum_{j=1}^{N} V_{ij} \tag{5}$$

where N is total number of deformed grains. And finally, the recrystallization texture is calculated as:

$$f(g_i) = a \cdot n(g_i) \Delta V(g_i) \cdot c(g_i) \tag{6}$$

where: $n(g_i)$ is the volume fraction of nuclei with g_i orientations and *a* is a normalization constant.

Results

The example result of our calculations is shown in Fig. 1.

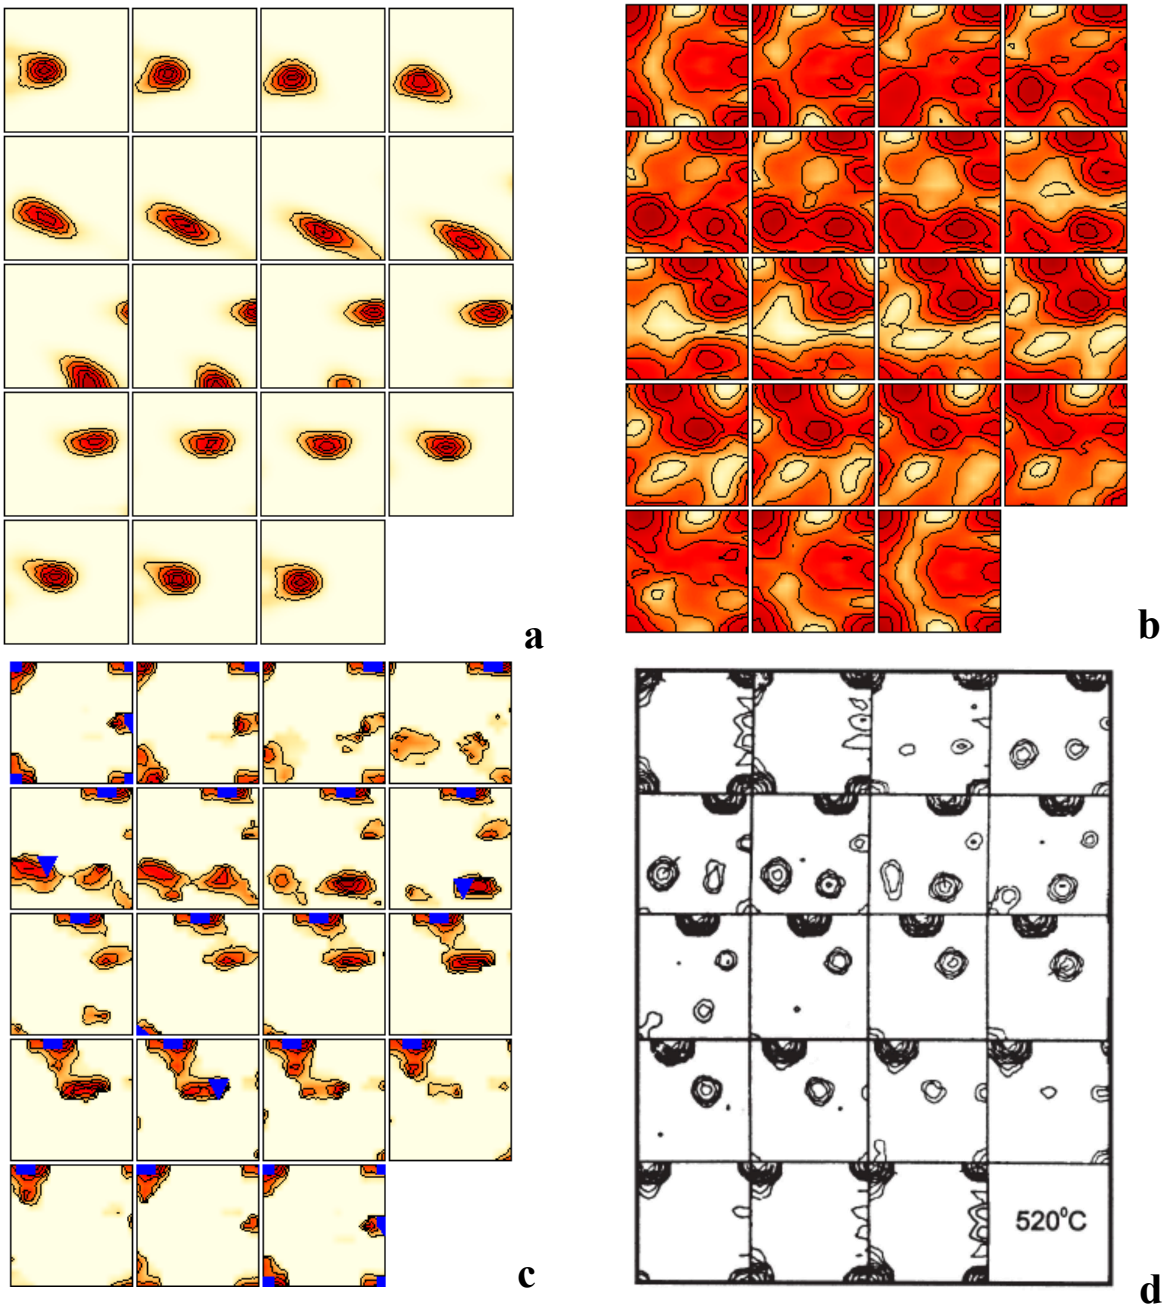

***Fig. 1**. a) Rolling texture of aluminium (reduction 60%, max. intensity: 18), b) calculated compromise function S(g); max. intensity: 0.67, c) predicted recrystallization texture; max. intensity: 11; texture components marked: cube (■), S (▼), rotated Goss (◣), d) experimental recrystallization texture of aluminium annealed at 520^0; max. intensity: 70 (after [4]).*

The starting rolling texture of aluminium (60% rolling reduction) is shown in Fig. 1a, while the compromise function, S(g), calculated on the basis of the deformation texture, is shown in Fig. 1b. The recrystallization texture (Fig. 1c) was calculated assuming the compromise threshold s_0=0.45 and is compared with experimental recrystallization texture of aluminium (Fig. 1d). We observe surprisingly good agreement between the calculated and experimental recrystallization textures - the same texture maxima appear in the two compared orientation distribution functions. Three ideal orientations are marked in recrystallization texture (Fig. 1c): the dominating cube component (0^0, 0^0, 0^0), S component (26^0, 58^0,19^0) and also rotated Goss component (0^0, 90^0, 45^0). It should be noted that already the shape of the compromise function is very similar to the experimental

recrystallization texture of aluminium. Therefore, we conclude that the compromise condition is a very important factor in recrystallization textures modeling.

Conclusions

The concept of preferred growth, defined by specific misorientations between nuclei and matrix, leads to a very good prediction of aluminium recrystallization texture. The compromise condition was included in our calculations in order to obtain a better texture prediction. The question is why this relatively simple approach, used in the presented calculations, leads to so good result in the case of aluminium. One argument can be based on the fact that there is principally one preferred misorientation relation found in f.c.c. metals (40^{o}<111>), while more complex descriptions of the oriented growth relations are reported for other metals (e.g., for b.c.c. metals).

Keywords: weapon-grade uranium; depleted uranium; heat power; numerical analysis

Abstract: In order to exactly master effect of uranium material's heat power on safety and reliability of nuclear weapon, weapon-grade uranium(WgU) and depleted uranium(DU) were regarded as research object in this paper. According to their component, decay heat power of WgU and DU per kilogram was calculated through dynamic decay cascade and decay law of uranium. Decay heat power of WgU and DU was respectively 1.8152 and 0.4075 milliwatt per kilogram. Main nuclide influencing on decay heat power of WgU and DU is uranium-234(U-234).

Introduction

All kinds of nuclear weapon all have at least several kilogram fission materials. Uranium and plutonium are major fission material，these material mainly are weapon-grade plutonium(WgPu) and WgU. In addition DU also exists in definite radioactivity[1]. These materials can emit a great of energy during radioactivity decay and nuclear fission, at the same time the energy can be used to elevate temperature of their surrounding material. On the one hand it can lead to detonate explosive, on the other hand it can lead to deform surrounding material[2]. These will affect performance of whole nuclear explosive device. In order to exactly grasp effect of heat-producing power of nuclear material on store safety and reliability of nuclear explosive device, heat power of these materials must be firstly known. This paper regards uranium as research object and analyzes heat power of WgU and DU. Because uranium can produce alpha decay reaction, spontaneous fission, gamma decay reaction, and so on, but heat power of spontaneous fission is far less than other nuclear reactions[3]. Therefore decay heat power of uranium will be considered in this paper.

Component and decay law of WgU and DU

Component of WgU and DU

Uranium-235(U-235) content is only 0.7% in natural uranium. Concentration of U-235 must reach certain value in order to realize self-sustaining chain reaction. Critical mass of uranium is very big and already can't be made nuclear weapon when its concentration is fewer than 20%. According to use way of uranium, uranium is defined as different grade[4]. When U-235 content is less than 0.711%，uranium is termed depleted uranium. U-235 Content is equal to 0.711% in natural uranium. U-235 content is from 0.711% to 20% in low enrichment uranium. U-235 content is equal or greater than 20% in high enrichment uranium. Generally it is defined as weapon-grade uranium when U-235 content is excess 90%. Component of WgU and DU and atomic mass of their isotopes are shown in Table one[5-6].

TABLE 1 COMPONENT AND THEIR MASS PERCENT ABOUT WGU AND DU

Nuclear material	Isotope	Mass percent (%)	Atomic mass(u)
WgU	uranium-234	1%	234.040975
	uranium-235	93.3%	235.043944
	uranium-238	5.5%	238.050816
DU	uranium-234	0.2%	234.040975
	uranium-235	0.4%	235.043944
	uranium-238	99.4%	238.050816

Decay law of WgU and DU

Most nuclide can become steady nuclide by continuous disintegration. For simple dynamic decay cascade lies in A→B→C, disintegration of nuclide A complies with the law of exponential decay, as well as nuclide B constantly decays nuclide C, on the other hand nuclide B constantly gains supplement from nuclide A. So change of nuclide B with time is shown in below formula:

$$\frac{dN_B}{dt} = \lambda_A N_A - \lambda_B N_B$$

It can be gained by integral about above formula:

$$N_B = N_{A0} \frac{\lambda_A}{\lambda_B - \lambda_A} (e^{-\lambda_A t} - e^{-\lambda_B t})$$

Thus it can be seen, change law of nuclide B is not only correlative with its disintegration constant λ_B, but also is correlative with disintegration constant λ_A of matrix A. In the same way it can be gained that change law of nuclide C is not only correlative with its disintegration constant λ_C, but also is correlative with disintegration constant λ_A of matrix A and disintegration constant λ_B of nuclide B.

For continuous disintegration, whole disintegration can reach perennial balance after enough time if radioactive half-life of matrix A is far long than radioactive half-life of its nuclide. In other words activity of matrix A is equal with its nuclide[7]. Therefore some nuclide must be considered besides main nuclide when radioactivity intensity of uranium is calculated.

Decay cascade of isotopes in WgU and DU are shown in Figure one.

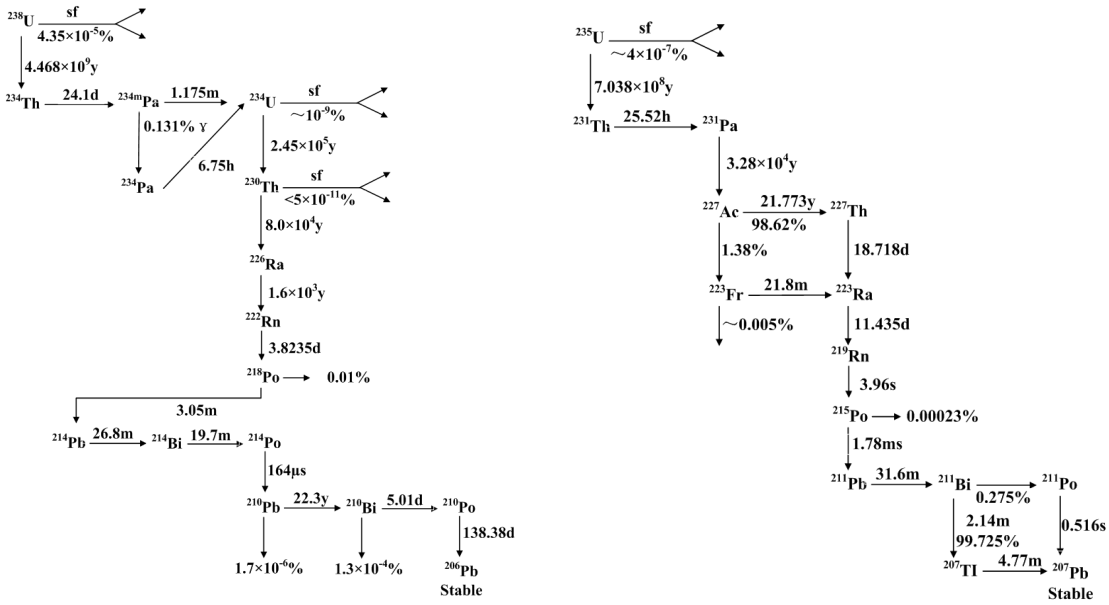

Fig.1 Decay cascade of isotopes in WgU and DU

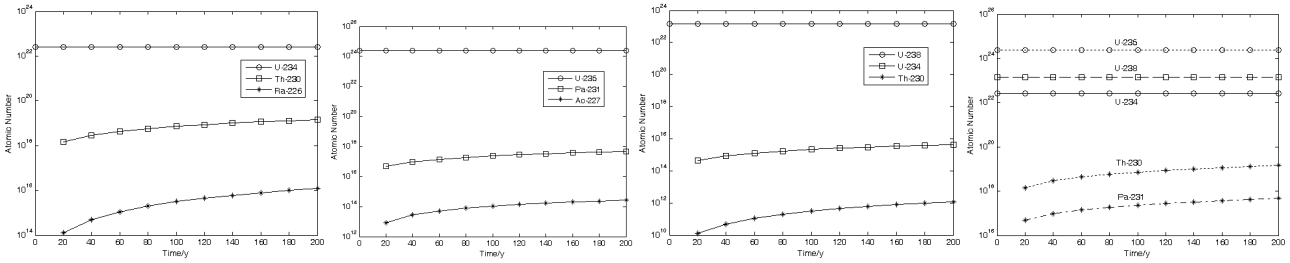
Atom number calculation of WgU and DU isotope

If initial component content of WgU and DU are shown in Fig.1, atomic number of each nuclide in per kilogram WgU and DU can be calculated by below formula:



$N_i(0)=percent\%/m_i$

Where i=1,2,3,4,5.

From disintegration process of U-235 we can get that radioactive half-life is 7.038×10^8 years from U-235 to thorium-231(Th-231), radioactive half-life is 25.52 hours from Th-231 to protactinium-231(Pa-231), radioactive half-life is 3.28×10^4 years from Pa-231 to actinium-227(Ac-227), radioactive half-life is 21.773 years from Ac-227 to thorium-227(Th-227), it need about 30 days from Th-227 decaying to steady nuclide plumbum-207(Pb-227). It is thus clear that we only need calculate atomic number from U-235 decaying to Th-227. Because it only need 25.52 hours from Th-231 to Pa-231, atomic number after Th-231 decaying won't be considered.

Atom number calculation of WgU isotope

According to decay cascade of isotopes, we can gain atomic number of isotopes in WgU and total atomic number versus time are shown in Fig.2(a)-2(d).

(a) (b) (c) (d)

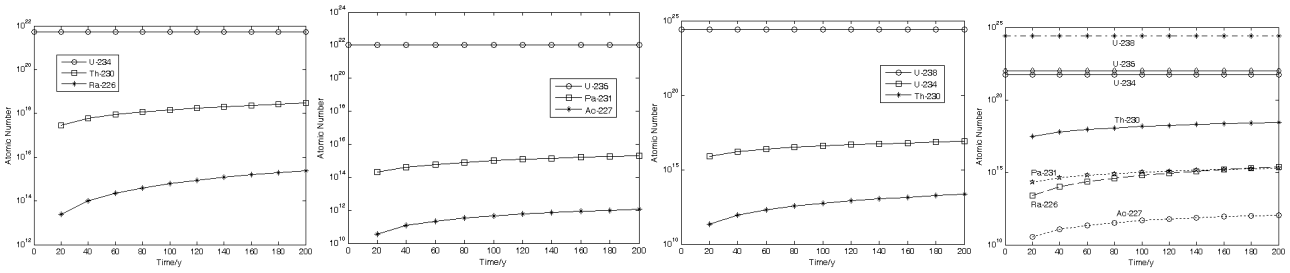


Fig.2 Atomic number of WgU and its isotopes versus time

From computational formula of decay heat power for isotope, we can get that decay heat power is not only relative to its disintegration energy, but also is relative to radioactive half-life and atomic number. Decay heat power varies inversely with radioactive half-life isotope and directly with atomic number. It is thus clear that atomic number is more its decay heat power is maybe bigger.

From Fig.2(a) it can be seen that main nuclide influencing decay heat power on U-234 is itself. From Fig.2(b) and Fig.2(c) can be seen that main nuclide influencing decay heat power on U-235 and U-238 is also respectively itself. From Fig.2(d) it can be seen that main nuclide influencing decay heat power on WgU is U-234, U-235 and U-238. At the same time that it can be seen that atomic number of U-235 is most, atomic number of U-234 is least. This explains that atomic number of isotopes is related to isotope content and they are direct ratio. Moreover from above figures we can find that decay atomic number of various isotopes are almost constant in two hundred years.

Atom number calculation of DU isotope

According to decay cascade of isotopes, we can gain atomic number of isotopes in DU and total atomic number versus time are shown in Fig.3(a)-3(d).

(a) (b) (c) (d)

Fig.3 Atomic number of DU and its isotopes versus time

From above figures we can find that decay atomic number of various isotopes in uranium isotope are almost constant in two hundred years. Among them, it can be seen that atomic number of U-238 is most; atomic number of U-234 is least. This explains that atomic number of isotopes is related to isotope content and they are direct ratio.

Calculation about decay heat power of WgU and DU

According to dynamic decay cascade, atomic number of nuclide is more its radioactive half-life is longer. So heat power of latter nuclide is less contributed to total heat power and they can be ignored. When calculating decay heat power of WgU and DU, the several earlier disintegrations are calculated.

Suppose atomic number of matrix is $N_i(0)$ at begin and disintegration coefficient of j grade nuclide is λ_{ij} during dynamic decay cascade process for i matrix. Disintegration formulas are shown as below:

$$\begin{cases} N_{i1}(t) = N_i(0)e^{-\lambda_{i1}t} \\ N_{i2}(t) = \lambda_{i1}N_i(0)\left(\dfrac{e^{-\lambda_{i1}t}}{\lambda_{i2}-\lambda_{i1}} + \dfrac{e^{-\lambda_{i2}t}}{\lambda_{i1}-\lambda_{i2}}\right) \\ N_{i3}(t) = \lambda_{i1}\lambda_{i2}N_i(0)\left[\dfrac{e^{-\lambda_{i1}t}}{(\lambda_{i2}-\lambda_{i1})(\lambda_{i3}-\lambda_{i1})} + \dfrac{e^{-\lambda_{i2}t}}{(\lambda_{i1}-\lambda_{i2})(\lambda_{i3}-\lambda_{i2})} + \dfrac{e^{-\lambda_{i3}t}}{(\lambda_{i1}-\lambda_{i3})(\lambda_{i2}-\lambda_{i3})}\right] \\ \cdots\cdots\cdots\cdots \\ N_{ij}(t) = \lambda_{i1}\lambda_{i2}\cdots\lambda_{ij-1}N_i(0)\left[h_{i1}e^{-\lambda_{i1}t} + h_{i2}e^{-\lambda_{i2}t} + \cdots + h_{ij}e^{-\lambda_{ij}t}\right] \end{cases}$$

Where each h_{ij} can be gained by below formulas:

$$\begin{cases} h_{i1} = 1/\left[(\lambda_{i2}-\lambda_{i1})(\lambda_{i3}-\lambda_{i1})\cdots(\lambda_{ij}-\lambda_{i1})\right] \\ h_{i2} = 1/\left[(\lambda_{i1}-\lambda_{i2})(\lambda_{i3}-\lambda_{i2})\cdots(\lambda_{ij}-\lambda_{i2})\right] \\ \cdots\cdots\cdots\cdots \\ h_{ij} = 1/\left[(\lambda_{i1}-\lambda_{ij})(\lambda_{i2}-\lambda_{ij})\cdots(\lambda_{ij-1}-\lambda_{ij})\right] \end{cases}$$

We can gain j order decay heat power of matrix nuclide M_{ij} in i branch by below formula:

$P_{ij}=E_{ij}A_{ij}=E_{ij}\lambda_{ij}N_{ij}$

Calculation about decay heat power of WgU

According to above formula, we can calculate decay heat power of each isotope in WgU. Then we can get total decay heat power of WgU per kilogram by accumulation. Decay heat power of WgU and its isotopes versus time are shown in Fig.4.

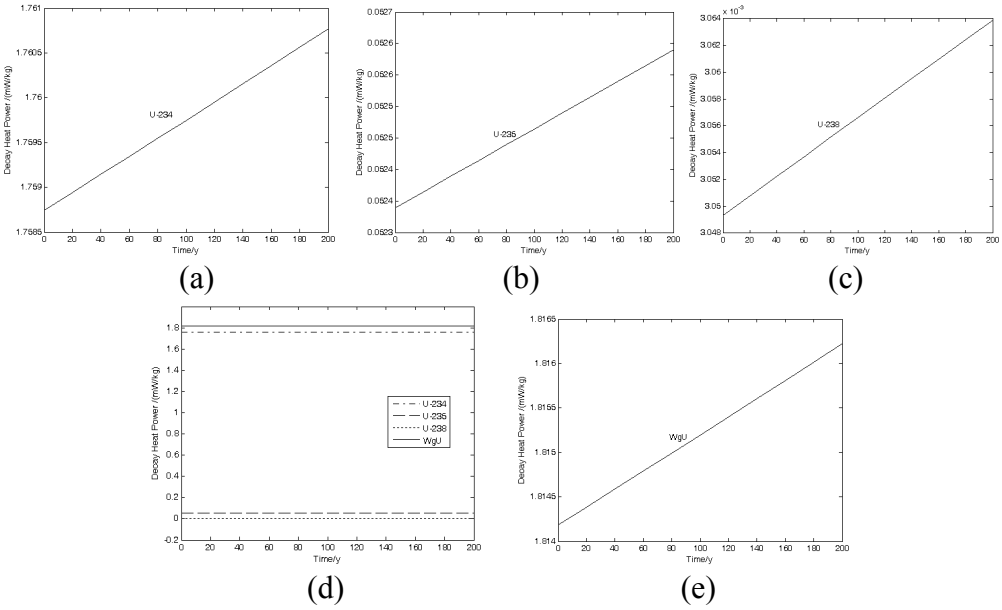

Fig.4 Decay heat power of WgU and its isotopes versus time

From Fig.4(a) it can be seen that decay heat power of U-234 increases linearly with time, but it's change is very small and is only 0.0021 milliwatt per kilogram in two hundred years. Therefore decay heat power of U-234 can be regarded as constant and is 1.76 milliwatt per kilogram. From Fig.4(b) and Fig.4(c) they can be seen that decay heat power of U-235 and U-238 both are constant and are respectively 0.0525 and 0.003058 milliwatt per kilogram. From Fig.4(d) it can be seen that U-234 contributes to decay heat power of WgU is maximum, but contribution of U-238 can be neglected. From Fig.4(e) it can be seen that decay heat power of WgU increases linearly with time, but it's change is very small and is only 0.002 milliwatt per kilogram in two hundred years. Therefore decay heat power of WgU can be regarded as constant and is 1.8152 milliwatt per kilogram.

Calculation about decay heat power of DU

According to above formula, we can calculate decay heat power of each isotope in DU, then we can gain total decay heat power of DU per kilogram by accumulation. Decay heat power of DU and its isotopes versus time are shown in Fig.5.

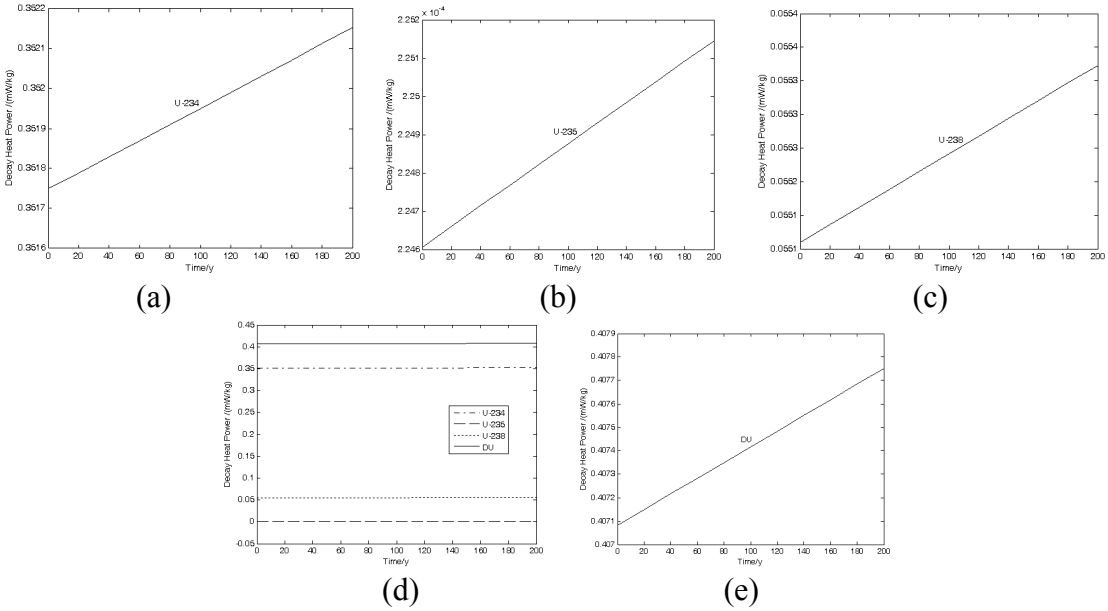

Fig.5 Decay heat power of DU and its isotopes versus time

From Fig.5(a) it can be seen that decay heat power of U-234 increases linearly with time, but it's change is very small and is only 0.0005 milliwatt per kilogram in two hundred years. Therefore decay heat power of U-234 can be regarded as constant and is 0.352 milliwatt per kilogram. Similarly from Fig.5(b) and Fig.5(c) they can be seen that decay heat power of U-235 and U-238 both are constant and are respectively 0.000225 and 0.0553 milliwatt per kilogram. From Fig.5(d) it can be seen that U-234 contributes to decay heat power of DU is maximum, but contribution of U-235 can be neglected. From Fig.5(e) it can be seen that decay heat power of DU increases linearly with time, but it's change is very small and is only 0.002 milliwatt per kilogram in two hundred years. Therefore decay heat power of DU can be regarded as constant and is 0.4075 milliwatt per kilogram.

Conclusions

(1) Decay heat power of WgU is approximately 1.8152 milliwatt per kilogram. Among them, contribution of U-234, U-235 and U-238 is respectively 1.76, 0.0525 and 0.003058 milliwatt per kilogram.

(2) Decay heat power of DU is approximately 0.4075 milliwatt per kilogram. Among them, contribution of U-234, U-235 and U-238 is respectively 0.352, 0.000225 and 0.0553 milliwatt per kilogram.

(3) U-234 contributing to decay heat power of WgU and DU is maximum. However U-238 contributing to decay heat power of WgU can be neglected. U-235 contributing to decay heat power of DU can be neglected. These explain that U-235 and U-238 contributing to decay heat power of uranium is related to their content in nuclear material.

(4) If some nuclear weapon has ten kilogram uranium, decay heat power of uranium is only ten milliwatt more. So small power is equivalently that 10 milliwatt electric lamp can emit heat. It is thus clear that decay heat power of uranium contributing to nuclear weapon can be neglected.

Keywords: Hydrogen

Abstract: The adsorption and dissociative adsorption of a hydrogen molecule on Fe_{tet1}- terminated Fe_3O_4 (111) surfaces are investigated within the framework of density function theory. The surface Fe_{tet1} atom site with the parallel mode of hydrogen molecule is found to be the most stable equilibrium adsorption state. The most possible dissociative adsorption pathway of a hydrogen molecule needs an energy barrier of 2.85 or 2.87 eV at the surface O_a or O_c atom site, and generates a water molecule, remarkably in agreement with Otsuka.K's conclusion on the reaction condition and hydrogen storage mechanism of Fe_3O_4 from microscopic point of view. The calculation of the electronic properties of the termination states with the adsorption and dissociative adsorption of a hydrogen molecule shows strong interactions between atomic hydrogen and Fe_3O_4 (111) surface.

Introduction

Magnetite Fe_3O_4, a promising alternative to hydrogen storage proposed by Otsuka et al [1-3], has attracted extensive attention. Basing on the old steam-iron process to produce hydrogen-rich fuel gas [4], it achieves the hydrogen storage-release processes by a simple redox reaction as following procedure:

Step1: Chemical hydrogen storage (reduction)

$$Fe_3O_4+4H_2 \rightarrow 3Fe+4H_2O \quad (1)$$

Step2: Hydrogen recovery (oxidization)

$$3Fe+4H_2O \rightarrow Fe_3O_4+4H_2 \quad (2)$$

Due to the fact that the standard experimental methods, such as low-energy electron diffraction, X-ray photo-electron spectroscopy and Auger electron spectroscopy, are not able to detect the positions of hydrogen atoms, experimental researches on the adsorptions of hydrogen atoms and molecules at Fe_3O_4 surface are very limited. The theoretical calculations are even less. X. Sun et al [5] confirmed that the adsorption of an atomic hydrogen on Fe_3O_4 (100) is chemical sorption and induces the reappearance of half-metal behavior in the surface structure around the Fermi level by a density-functional theory (DFT) calculation. To understand the surface structure and activity which are essential for the catalytic mechanism of water gas shift (WGS) and Fischer-Tropsch synthesis (FTS) processes, Y. Tao et al [6] investigated the dissociation of hydrogen molecules on Fe_{tet}- and Fe_{oct}- terminated Fe_3O_4 (111) surfaces at different coverage values based on DFT and drew the conclusion that the most favored adsorption of a hydrogen molecule on Fe_{tet}- terminated surface is homolytic and dissociative on two non-adjacent O atoms with more dangling bonds, which is not consistent with the conclusion obtained by the redox reaction.

In this work, we report a DFT study on atomic and molecular hydrogen adsorption on Fe_{tet1}-terminated Fe_3O_4 (111) surfaces to understand the reaction condition and hydrogen storage mechanism of Fe_3O_4 from microscopic point of view. The Linear synchronous transit/quadratic synchronous transit (LST/QST) methods are used to search for the transition states. The activation energies and energy barriers are calculated to determine the dissociative adsorption pathway. In

addition, the density of the states of Fe_{tet1}- terminated Fe_3O_4 (111) surface including the adsorption and dissociative adsorption of a hydrogen molecule are analyzed in detail to understand the interaction between atomic hydrogen and Fe_3O_4 (111) surface.

Computation Models and Methods

All calculations are performed using the plane-wave pseudopotential method based on DFT. This method is implemented in the CASTEP (Cambridge Sequential Total Energy Package) [7] code. The Perdew-Burke-Ernzerhof (PBE) version of the generalized gradient approximation (GGA) [8-11] is used for the exchange and correlation effects. The interaction between valence electron and ion core is described by ultrasoft pseudopotential [12], and the electronic wave functions are expanded in a plane wave basis set with an energy cut-off of 340 eV to ensure convergence [13]. Brillouin zone integration is carried out using K- point sampling, which is generated by the Monkhorst-Pack scheme [14]. For Fe_3O_4 bulk model and 1×1 Fe_3O_4 (111) surface slab model, the K- point grid are 2×2×2 and 2×2×1, respectively. The density-mixing scheme based on the Pulay algorithm [15] is used for self-consistent-field (SCF) calculation. The SCF tolerance is set at 1×10^{-6}eV/atom. The spin polarization of Fe atom in Fe_3O_4 is considered in the calculations as a spin polarization has significant effect on magnetic system [16,17]. The pseudopotentials are obtained by including a partial core charge in the treatment of the exchange and correlation in spin-polarized calculation to account for the nonlinear core corrections [18].

Fe_3O_4 has a cubic inverse spinel structure with a lattice parameter of 8.394 Å [19]. Fe_3O_4 (111) surface is a predominant natural growth face and may be more active for reactions than other surfaces [20, 21]. There are six non-equivalent terminations along Fe_3O_4 (111) stacking sequence. Fe_{tet1}- and Fe_{oct2}- terminated surfaces, which have the least dangling bonds, are proposed to be the most stable terminations. The calculated energy difference of the two terminated surfaces is only 0.03eV [22] indicating the possibility of their coexistence. In this work, the Fetet1- terminated surface is chosen to investigate the adsorption of hydrogen atoms and molecules. For each calculation, a periodic eight-layer slab model in which the top four layers of atoms are relaxed and the bottom four layers of atoms are fixed in their optimized bulk positions is constructed and separated from its neighboring image in the direction normal to the surface by a vacuum spacing of 10 Å. The adsorbed hydrogen atom or molecule is on the one side of the slab and fully relaxed with the top four layers of atoms.

The adsorption energies of surfaces with an adsorbed hydrogen molecule and atom, E_{ads-H_2/Fe_3O_4} and E_{ads-H/Fe_3O_4}, are defined as:

$$E_{ads-H_2/Fe_3O_4} = E_{H_2/Fe_3O_4} - (E_{Fe_3O_4} + E_{H_2}) \tag{3}$$

and

$$E_{ads-H/Fe_3O_4} = E_{H/Fe_3O_4} - (E_{Fe_3O_4} + E_H) \tag{4}$$

Where E_{H_2} and E_H are the total energies of a hydrogen molecule and atom, respectively; $E_{Fe_3O_4}$ is the total energy of Fe_3O_4 (111) slab without adsorbed species; and E_{H_2/Fe_3O_4} and E_{H/Fe_3O_4} are the total energies of surfaces with an adsorbed hydrogen molecule and atom, respectively. With this definition, a negative value of E_{ads} indicates that the adsorption is an exothermic (stable) reaction, and a positive value indicates the adsorption is an endothermic (unstable) reaction. The calculated adsorption energies do not include zero point energy corrections.

Results and Discussion

The Optimization of Fe_{tet1}- Terminated Fe_3O_4 (111) Clean Surfaces

The total energies of an isolated hydrogen atom and molecule are calculated in an orthorhombic cell of 10×10×10 Å3. The bond length r(H-H) and bond dissociative adsorption energy E_{BDE} of a hydrogen molecule are 0.0747 nm and 433.9 kj/mol, which are in good agreement with the experimental values of 0.0740 nm[23] and 436.1 kj/mol[24]. The calculated lattice constant of bulk Fe_3O_4 and magnetic moments are 0.8350 nm and 4.0 uB in comparison with the experimental value of 0.8394 nm [19] and 4.1 uB [25]. The deviation of the calculated values from the experimental values is only around 1%. The results allow us to be confident in making the next calculations, namely the interactions of hydrogen atoms with Fe_3O_4 (111) surface and the interactions of hydrogen molecules with Fe_3O_4 (111) surface.

The model of Fe_{tet1}- terminated Fe_3O_4 (111) surfaces is constructed as shown in Fig.1 It consists of eight layers of atoms in which Fe_{tet1} atom bonds with three O atoms in the next layer consisting of four O atoms and forms three Fe_{tet1}-O bonds which have nearly the same bond lengths. It is clearly seen that both Fe_{tet1} atom and the four O atoms are exposed nearly in the surface plane. The possible adsorption sites Fe_{tet1}, O_a, O_b, O_c and O_d are also shown in Fig. 1.

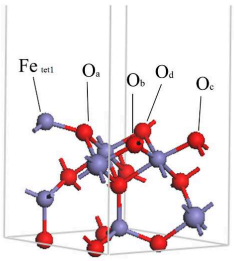

Fig. 1 The optimized configurations of Fe_{tet1}- and Fe_{oct2}- terminated Fe_3O_4 (111) clean surfaces and the presentation of the possible adsorption sites.

Adsorption of a Hydrogen Atom on Fe_{tet1}- terminated Fe_3O_4 (111) Surfaces

The calculated adsorption energies, adsorption heights and distances of H atom adsorbed on the possible adsorption sites on Fe_{tet1}- terminated surfaces are listed in Table 1. The results indicate that the surface O_c atom site is the most stable adsorption site. The adsorption energies are -3.15eV, and the distances are 0.0980 nm.

TABLE 1. THE CALCULATED ADSORPTION ENERGIES (E_{ADS}), ADSORPTION HEIGHTS (H) AND DISTANCES (D) OF A HYDROGEN ATOM ADSORBED ON THE POSSIBLE ADSORPTION SITES IN FE_{TET1}-TERMINATED SURFACE.

Models	H[nm]	D[nm]	E_{ads}[eV]
On-Fe_{tet1}	0.1585	0.1585	-1.79
On-O_a	0.0822	0.0983	-2.93
On-O_b	0.0635	0.0985	-2.81
On-O_c	0.0979	0.0980	-3.15
On-O_d	0.0759	0.0984	-2.83

Adsorption of a hydrogen molecule on Fe_{tet1}- terminated Fe_3O_4 (111) surfaces

In the adsorption of a hydrogen molecule on Fe_{tet1}- terminated Fe_3O_4 (111) surfaces, parallel and vertical types are considered for each possible adsorption site. Parallel type is the side-on type that an adsorbed hydrogen molecule is parallel to an adsorption atom site (denoted as E-), and vertical type is the end-on type that an adsorbed hydrogen molecule is vertical to an adsorption atom site (denoted as S-). They are depicted in Fig. 2. For Fe_{tet1}- terminated surface, there are ten adsorption models, denoted as E1-O_a, E1-O_b, E1-O_c, E1-O_d, E1-Fe_{tet1}, S1-O_a, S1-O_b, S1-O_c, S1-O_d, S1-Fe_{tet1}.

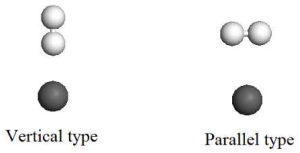

Fig. 2 Parallel type and vertical type of a hydrogen molecule adsorbed on an adsorption site. The white spheres represent hydrogen atoms, and the gray spheres represent adsorption atom sites.

The calculated adsorption energies, H-H bond lengths, distances between H' atom of the adsorbed hydrogen molecule and the adsorption sites, and distances between H" atom of the adsorbed hydrogen molecule and the adsorption sites are given in Table 2 Obviously, the adsorptions of an hydrogen molecule on the possible adsorption sites in the surface are physical adsorptions, less stable than those of a hydrogen atom. In the case of model E1-O_c, the optimized adsorption energy is positive and the hydrogen molecule is inclined to keep away from the surface. In the each case of model E1-O_a, E1-O_b, E1-O_d and E1-Fe_{tet1}, the hydrogen molecule is adsorbed in oriented arrangement with respect to the surface. The H-H bond lengths in the above four adsorption models change slightly, ranging from 0.0756 to 0.0769 nm. In the each case of model S1-O_c and S1-O_d, the hydrogen molecule is inclined to keep away from the surface, and the adsorption energy is positive, indicating the adsorption model is unstable. In the case of model S1-Fe_{tet1}, the H-H bond length elongates to 0.0771 nm, and the adsorption energy is the lowest (-0.38 eV), indicating model S1-Fe_{tet1} is the most stable.

TABLE 2. THE CALCULATED ADSORPTION ENERGIES (E_{ADS}), BOND LENGTHS OF H-H BOND (D_{H-H}), DISTANCES BETWEEN H' ATOM OF THE ADSORBED HYDROGEN MOLECULE AND THE ADSORPTION SITES ($D_{M-H'}$), AND DISTANCE BETWEEN H" ATOM OF THE ADSORBED HYDROGEN MOLECULE AND THE ADSORPTION SITES ($D_{M-H"}$) FOR FE_{TET1}- TERMINATED SURFACE.

Dissociative adsorption of a hydrogen molecule on Fe_{tet1}- terminated Fe_3O_4 (111) surfaces

To study the dissociative adsorptions of an hydrogen molecule on Fe_{tet1}- terminated Fe_3O_4 (111) surfaces, the most stable adsorption model of an hydrogen molecule calculated in section 3.3 is considered as the initial reactant, and the possible final geometric models of the dissociative adsorption are proposed as the products. The LST/QST methods are used to search for the transition states. The activation energies and energy barriers are calculated to determine the possible dissociative adsorption pathway.

Three possible dissociative adsorption models are proposed after performing a quantitative calculation of the adsorption energies of different dissociative adsorption models: (a) dissociative adsorption of a hydrogen molecule on the surface O_a atom site; (b) dissociative adsorption of a hydrogen molecule on the surface O_c atom site; (c) dissociative adsorption of a hydrogen molecule on both the surface O_a and O_c atom sites. The optimized geometric configurations are depicted in Fig. 3.

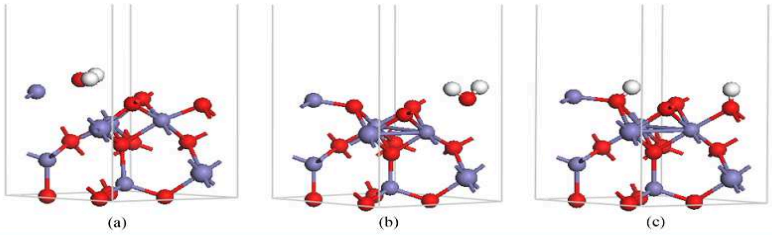

Fig. 3 The optimized geometric configurations: (a) dissociative adsorption of a hydrogen molecule on the surface O_a atom site; (b) dissociative adsorption of a hydrogen molecule on the surface O_c atom site; (c) dissociative adsorption of a hydrogen molecule on both the surface O_a and O_c atom sites. The gray spheres represent H atoms, the blue spheres stand for Fe atoms and the red spheres refer to O atoms.

The calculated total energies, adsorption energies, distances between the two H atoms of the adsorbed H_2, distances between H' atom of the adsorbed H_2 and the adsorption sites, and distance between H" atom of the adsorbed H_2 and the adsorption sites are listed in Table 3 for the three possible dissociative adsorption models. It is found that the adsorption energies of the three models are much higher than those of adsorption models calculated in section 3.3. The value range of the adsorption energies indicates these dissociative adsorptions are chemisorptions. In the dissociative adsorption of a hydrogen molecule on O_a (or O_c) atom site, the original O-Fe^{3+} and H-H bond are broken, and the two H atoms are both adsorbed on O_a (or O_c) atom site to form a water molecule as the bond length and bond angle (0.098nm and 107.9°) are in the range of those at the ground state (Normally for a water molecule, O-H bond length is between 0.957 Å ~1.00 Å and H-O-H bond angle is between 104.52° ~109.5°). In the dissociative adsorption of a hydrogen molecule on both O_a and O_c atom sites, the hydrogen molecule dissociates into two separate hydrogen atoms which are adsorbed on O_a and O_c atom sites respectively. The total energy and adsorption energy are the lowest, indicating the dissociative adsorption is the most stable. It is unclear, however, whether the dissociative adsorption is ease to occur. The possible dissociative adsorption pathways are then analyzed for this purpose.

The optimized S1-Fe_{tet1} adsorption model is chosen as the initial state (IS) since it is the most stable adsorption model for a hydrogen molecule adsorbed on Fe_{tet1}- terminated surface, and the three possible dissociative adsorption models are considered as the final states (FS). The complete LST/QST methods are used to search for the transition states. The activation energies and energy barriers are calculated to determine the most possible dissociative adsorption pathway of a hydrogen molecule. The calculated results are shown in Table 4 and the geometry of the calculated dissociative adsorption pathways are plotted in Fig.4 in which the IS, transition states, and FS are shown as insets. In S1-Fe_{tet1} adsorption model, the hydrogen molecule adsorption is physical adsorption with the H-H bond length 0.0771 nm (see the illustration in section 3.3). Only one transition state along each pathway occurs. The hydrogen molecule moves to the surface, and the distance between the two hydrogen atoms is elongated to 0.1337, 0.1433 and 0.2495 nm in each transition state respectively. The calculated energy barrier of S1-Fe_{tet1}--O_a and O_c dissociative adsorption pathway is 5.201 eV, higher than those of S1-Fe_{tet1}--O_a (2.850 eV) and S1-Fe_{tet1}--O_c (2.871 eV) dissociative adsorption pathways. Hence, S1-Fe_{tet1}--O_a and S1-Fe_{tet1}--O_c dissociative adsorption pathways have priority over S1-Fe_{tet1}--O_a and O_c dissociative adsorption pathway under an external condition. In the two most possible dissociative adsorption pathways, water molecules are generated on Fe_{tet1}- terminated surface, remarkably in agreement with Otsuka.K's conclusion on the reaction condition and hydrogen storage mechanism of Fe_3O_4 from microscopic point of view.

TABLE 3. THE CALCULATED TOTAL ENERGIES (E_{TOTAL}), ADSORPTION ENERGIES (E_{ADS}), DISTANCES BETWEEN THE TWO H ATOMS OF THE ADSORBED H_2 (D_{H-H}), DISTANCES BETWEEN H' ATOM OF THE ADSORBED H_2 AND THE ADSORPTION SITES ($D_{H'-O}$), AND DISTANCES BETWEEN H" ATOM OF THE ADSORBED H_2 AND THE ADSORPTION SITES ($D_{H"-O}$) FOR THE THREE POSSIBLE DISSOCIATIVE ADSORPTION MODELS OF A HYDROGEN MOLECULE ON FE_{TET1}- TERMINATED FE_3O_4 (111) SURFACE.

Electronic structures of a hydrogen molecule adsorption and dissociative adsorption on Fe_{tet1}-terminated Fe_3O_4 (111) surface

The density of states (DOS) of a Fe_{tet1}- terminated Fe_3O_4 (111) surface and free H_2, the partial density of states (PDOS) of Fe(III) atoms and O atoms are presented in Fig. 5a. The valence bands ranging from -7.5eV~2.5eV are mainly composed of the 2p states of O atoms and 3d states of Fe(III) atoms, the valence bands ranging from -20eV~-18eV are mainly contributed by the 2s states of O atoms and 3d states of Fe (III) atoms, and the valence bands ranging from -18eV~-15eV are mainly caused by the 3d states of Fe (II) atoms. Fe (II) atoms have no effect on the adsorption of hydrogen molecule and are not considered. The DOS values of a free H_2 are near the Fermi level. The DOS of a Fe_{tet1}- terminated Fe_3O_4 (111) surface in which an adsorbed H_2 is vertical to Fe_{tet1} atom site (S1-Fe_{tet1} model) and the adsorbed H_2, the PDOS of Fe(III) atoms and O atoms are presented in Fig. 5b. The DOS values of the adsorbed H_2 move from the Fermi level to lower energy region. The DOS of the surface has a weak peak near -7.5eV which is contributed by the 1s states of the atoms of H_2 and 3d states of Fe (III) atoms, indicating the H_2 is adsorbed on Fe_{tet1} atom site. The DOS of a Fe_{tet1}-terminated Fe_3O_4 (111) surface in which an H_2 is dissociated and adsorbed on O_a (or O_c) atom site and the adsorbed H_2, PDOS of Fe(III) atom and O atom are presented in Fig.5c (or Fig. 5d). The valence bands ranging from -24 eV and -22 eV are mainly dominated by the 1s states of H atoms and 2s states of O atoms, and the valence bands ranging from -11 eV and -8 eV are mainly dominated by the 1s states of H atoms and 2p states of O atoms, indicating the dissociated H atoms are adsorbed on the surface O atoms. The electronic structure of Fe_{tet1}- terminated Fe_3O_4 (111) surface is obviously changed with the adsorption and dissociative adsorption of H_2. The 1s states of H atoms form a series of hybrid peaks with the 3d states of Fe (III) atoms, 2s and 2p states of O atoms, indicating that there are interactions between H atoms and Fe_{tet1}- terminated Fe_3O_4 (111) surface.

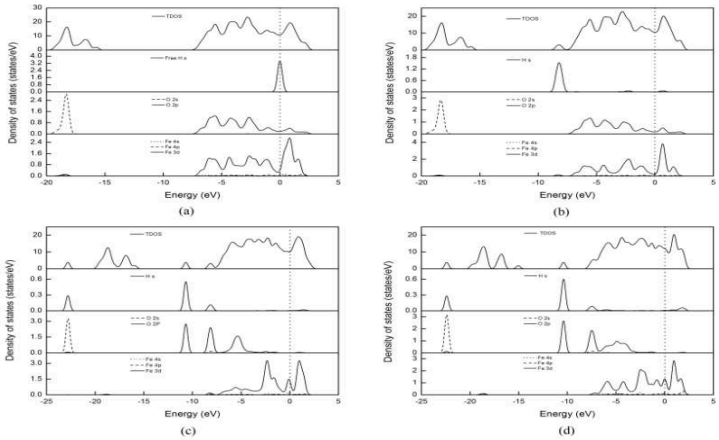

Fig. 5 (a) The DOS of a free H_2 and clean Fe_{tet1}- terminated Fe_3O_4 (111) surface; (b) The DOS of S1-Fe_{tet1} model; (c) The DOS of O_a dissociative adsorption model; (d) The DOS of O_c dissociative adsorption model.

Summary

A detailed density functional study is performed on the adsorption and dissociative adsorption of an H_2 on Fe_{tet1}- terminated Fe_3O_4 (111) surfaces. Our results show clearly that S-Fe_{tet1} model is the most stable adsorption configurations for an H_2 on Fe_{tet1}- terminated Fe_3O_4 (111) surfaces with adsorption energy of -0.38eV. The dissociative adsorption pathway of an H_2 is from S1-Fe_{tet1} to O_a or O_c via a transition state with adsorption energy of -0.77 eV or -0.73eV. Water molecules are generated on Fe_{tet1}- terminated surface, remarkably in agreement with Otsuka.K's conclusion. Finally, the density of states of an H_2 adsorption and dissociative adsorption on the termination surface is calculated, indicating that the models of dissociative adsorption of H_2 on Fe_3O_4 (111) surface are more tempting.

Keywords: heating rate; grain boundary premelting; phase-field crystal; liquid film width

Abstract. The effect of heating rates on the premelting of grain boundary (GB) is investigated by the phase-field crystal method. The microstructure evolution of premelting under different heating rates are discussed, and the film width of GB is quantitatively calculated in terms of the excess mass method. Results show that the liquid film appears as the melting point (T_m) is approached from below and that the film thickness is affected by heating rate. In heating process, at the same temperature (close to T_m), the liquid film width is larger when the temperature increases with lower rate. In insulation process, the liquid film thickness increase until to its equilibrium value with holding time prolonging. For low-angle GBs, the higher heating rate the system has during heating stage, the lager equilibrium value of liquid film will be reached during insulation stage. For high-angle GBs, the liquid film thickness has the same equilibrium value during the insulation process although the heating rate is different during heating process.

Introduction

The grain boundary (GB) is the area where numerous phase transformations easily occur, leading to dramatic changes on the mechanical and physical properties of polycrystalline materials [1,2]. The liquid film at GB is preformed at temperatures below the melting point, which is called GB premelting[3]. The presence of premelting significantly affects the strength and fracture properties of polycrystalline materials. The premelting of GB are research hot spots in materials [4, 5]. Heating rate is an important factor of the GB premelting. Observing GB directly by experimental methods is difficult because it is only a few atoms thick. Hence, solving GB problems through computer simulation presents unique advantages. Keblinnski et al. [6] proved through molecular dynamics simulation that a GB disorder layer exists at different temperatures above and below the melting point. Tang et al. [7] characterized the morphology of the film between the subsolidus during premelting transition. Kikuchi and Cahn [5] approximately estimated the thermodynamic properties of GB premelting using a lattice gas model and a cluster variation approximation.

Although the above methods have been used to confirm and simulate the GB premelting, they did not quantitatively study the relationship between the width of GB premelting layer and atomic GB structure because of the limitation imposed by these models. Phase-field crystal (PFC) inspired from the density functional theory [8] has shown unique advantages of resolving the atomic scale density-wave structure of polycrystalline materials [9-11]. The film width can be quantified and its relationship with atomic GB structure can be clarified by studying the thermodynamic properties of premelted GB because the order parameter of PFC is the periodic local number density of atoms. In this work, we used PFC to study the microstructure evolution of premelting under different heating rates and mainly discussed the effect of heating rates on the film width of GB.

Theoretical Modeling

PFC model

PFC model describes periodic structure on atomic length and diffusive timescales by introducing a free energy that is functional of the local-time-averaged density field ρ(**r**,*t*). We consider the simplest PFC model defined by the dimensionless free-energy functional [9]:

$$F = \int d\vec{r}\left\{\frac{\rho}{2}\left[r + (\nabla^2 + 1)^2\right]\rho + \frac{1}{4}\rho^4\right\} \tag{1}$$

where F is the dimensionless free energy; ρ represents the atomic density field; r is variable related to temperature, the larger value of r corresponds to the higher temperature.

The density is uniform in the liquid. The free energy function reaches the minimum through $\rho(x, y)$. In this instance, we will use the one-mode approximation for the density field. Then, the density for two-dimensional hexagonal structure can be written as: $\rho_s(x, y) = \overline{\rho} + A_t[\cos(qx)\cos(qy/\sqrt{3}) - 1/2\cos(2qy/\sqrt{3})]$. where A_t is density wave amplitude function of hexagonal phase. Substituting the expression into Eq. (1) and minimizing with A_t and q .we can obtain $A_t = 4/5(\overline{\rho} \pm 1/3\sqrt{-15r - 36\overline{\rho}^2})$,where the $\pm$ signs are for positive and negative $\overline{\rho}$, respectively, and $q = \sqrt{3}/2$. The phase diagram of this model has been discussed previously in Ref. [9], and we know that the phase diagram is symmetric in $\overline{\rho}$.

Numerical methods and the choice of simulation parameters

The standard equation of motion of the PFC model is

$$\frac{\partial \rho}{\partial t} = \nabla^2\left(\frac{\delta F}{\delta \rho}\right) = (1 + r)\nabla^2\rho + 2\nabla^4\rho + \nabla^6\rho + \nabla^2\rho^3 \tag{2}$$

Eq. (2) reflects the fact that the density field ρ is a locally conserved quantity and they achieve their equilibrium state through self-diffusion. The Eq. (2) can be efficiently solved by using a semi-implicit Fourier spectral formulation.

The simulation is performed in a system of size $512\Delta x \times 512\Delta y$ with periodic boundary conditions, where $\Delta x = \Delta y = \pi/4$ and the time step $\Delta t = 0.1$. The initial condition used to simulate GBs begin with two large grains, which are rotated by angle $\theta/2$ in opposite directions, are placed into a supercooled liquid. This work mainly studied the relationship between heating rate and liquid film width. Several misorientation angles are selected: 6.2°, 9.6°, and 32.5°. We set $\rho_0 = -0.1969$. In the first simulation stage, r is set as -0.3 until the system reaches to the equilibrium state of solid. Then, the temperature coefficient is increased from $r = -0.3$ to $r = -0.1$ (the melting point (T_m) of pure substance with $\rho_0 = -0.1969$ is $r = -0.09$) with different heating rates ($k = 4\times10^{-6}$, $k = 4\times10^{-7}$, $k = 4\times10^{-8}$) and then keep the system at $r = -0.1$ for 150,000 time steps. As time is prolonged, various premelting phenomena occur in the system .

Simulation Results and Discussions

Effect of heating rate on the premelting and melting of low-angle GBs

Fig. 1 and 2 show separately the structure of a low-angle GB at misorientation angle 9.6° for $r = -0.1$ under different heating rates and its density distributions. Low-angle GB consists of individual dislocations separated by distances that are larger than a few lattice spacing. The dislocations are surrounded by individual 'liquid pools'. The lower the heating rate is, the larger 'liquid pools' has in the GB region [Fig. 1(b)]. The density distribution curves present the vibration form. The peak value of the atomic density of the GB region is lower than the atomic density inside the system, which indicates that 'liquid' appears at this time and that atoms appear disordered. The vibration amplitude of density curves increases as the atom location gradually close to the GB. The

reason for this result is that the Burgers vectors of adjacent dislocations at the GB are different, the atoms

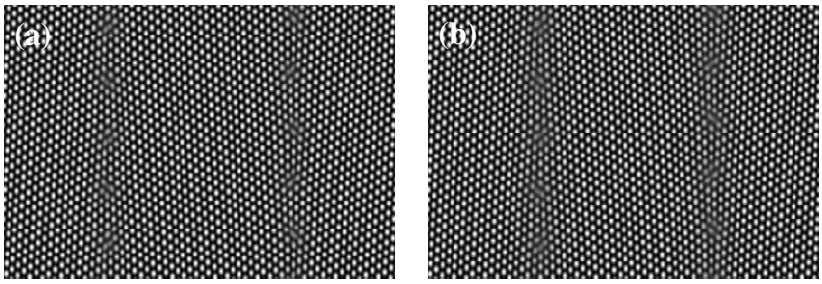

Figure 1. Snapshots of a low-angle grain boundary at misorientation angle 9.6° for $r = -0.1$ under different heating rates (a) $k = 4\times10^{-6}$; (b) $k = 4\times10^{-8}$.

around the dislocation have different degrees of deviation from its original equilibrium position and they are distributed uniformly on both sides of GB. The vibration amplitude of atomic density with heating rate

$k = 4\times10^{-8}$ is lower than that with $k = 4\times10^{-6}$ in near-GB and GB region [Fig. 2(b)]. This is indicated that the arrangement of atoms in GB region is more disordered and the width of liquid film may higher with lower heating rate.

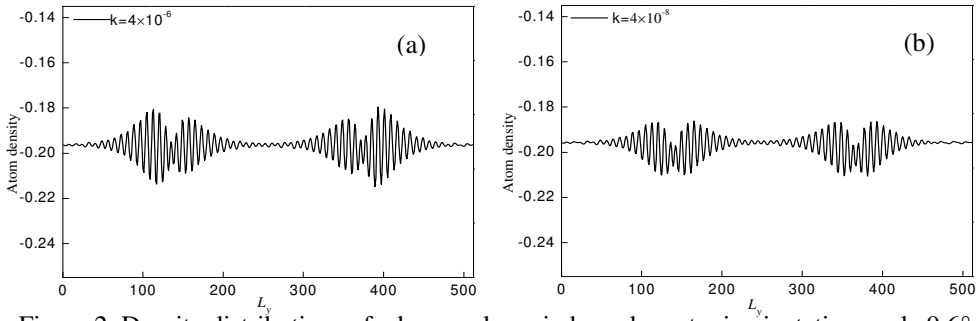

Figure 2. Density distributions of a low-angle grain boundary at misorientation angle 9.6° for $r = -0.1$ under different heating rates (a) $k = 4\times10^{-6}$; (b) $k = 4\times10^{-8}$.

We use excess mass theory of Mellenthin [12] to calculate the liquid film thickness of GB. An excess mass per unit length of GB can be defined by subtracting the mass of the homogeneous solid at the same chemical potential from the actual mass contained in the system. The total mass is fixed in the system and the film thickness can be extracted with good precision from measured the chemical potential $\mu(\rho)$. The liquid film thickness can be defined as follow:

$$w = \frac{L_y\left[\mu - \mu_s(\rho)\right]}{\mu_l(\rho) - \mu_s(\rho)} \tag{5}$$

where $\mu_l(\rho)$ and $\mu_s(\rho)$ are respectively the chemical potential of bulk liquid and bulk solid phases at the same condition, and μ is the total chemical potential in the system. L_y is the boundary length perpendicular to the GB, and the lattice constant $a = 2\pi / q$.

Fig. 3 shows the variation in liquid film width of low-angle GB $\theta = 9.6°$ with temperature r . As the temperature rises, the liquid film width increase flatly when the temperature is far below T_m and then increases rapidly when the temperature is close to T_m . Temperature almost has no effect on the liquid film width when the temperature is relatively low because low-angle GB is formed by the dislocation networks and its structure is complex. At low temperature, atomic diffusion is relatively slow. As a result, the heating rate elicits minimal effect on the liquid region on the GB and the three curves almost coincide. When temperature is close to the T_m , the liquid film width rapidly increases. Furthermore, at the same temperature (close to T_m), the liquid film width is larger when the heating rate is smaller. Because the thermal motion of atom aggravates near the melting point and atoms can

diffuse fully with low heating rates. So, when the system reaches to the same temperature with lower heating rate, the liquid film width is larger.

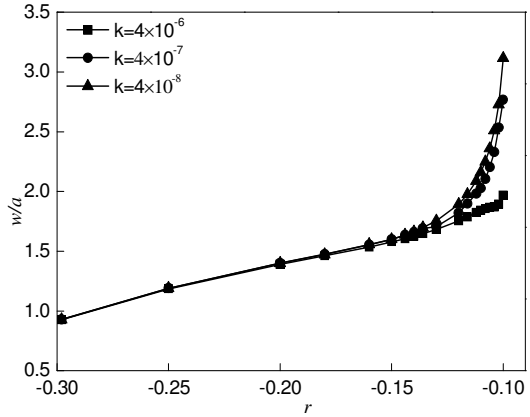

Figure 3. Film thickness w as a function of temperature r under different heating rates at misorientation angle 9.6°.

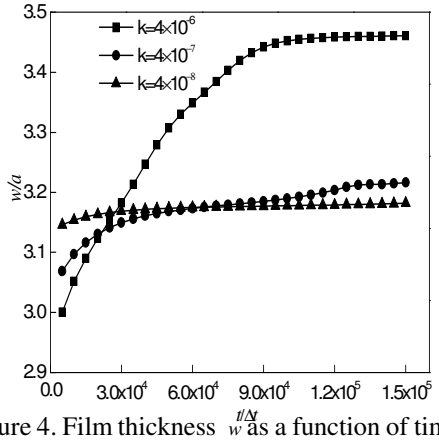

Figure 4. Film thickness w as a function of time t after Different heating rates for $\theta = 9.6^\circ$ at $r = -0.1$

Fig. 4 shows the curves of liquid film thickness w versus holding time t during heat preservation stage after different heating process. We can observe that as the holding time is prolonged, the liquid film thickness increase until to its equilibrium value, and then the liquid film thickness is no longer increase with holding time and keep its equilibrium value. This is due to the diffusion of atoms is in the dominant position in the initial stage of heat preservation, and the driving force of diffusion decreases with the holding time prolonging. The migration of liquid-solid interface gradually stabilizes and the liquid film thickness tends to stop increasing. In the initial stage of insulation, the film thickness in the system with high heating rates is less than that in the system with low heat rates. This finding is consistent with the change of film width in the heating stage. As time is prolonged, the film thickness in the system with high heating rates exceeds that of the system with low heating rates. This is because atoms cannot diffuse sufficiently in the system with high heating rates during the heating process, and dislocations on the GB lead to lattice distortion, allow storage of high distortion energy and increase the internal energy of the system, indicating that the system is unstable. In the consequent insulation stage, the system would be changed to reduce the free energy. The strain energy of dislocation becomes the diffusion driving force. The system with high heating rates during the heating stage has higher diffusion driving force during the insulation stage than that with low heating rates, allowing the "liquid pool" to obtain high driving force to merge and the liquid film thickness to have a dramatically increase during the insulation stage. The higher heating rate the system has during heating stage, the lager equilibrium value of liquid film will be reached during insulation stage.

Effect of heating rate on the premelting and melting of high-angle GB

Fig. 5 and 6 show separately the structure of a high-angle GB at misorientation angle 32.5° for $r = -0.1$ under different heating rates and its density distributions. The liquid film constructed by the fuzzy lattice structure forms the connected "pipe." The liquid film is rather homogeneous, that is, it has approximately the same width at each point. The film width increases with heating rate decreasing [Fig. 5(b)]. In the density distribution curve, no vibration trend can be found in the high-angle GB, but obvious valley is formed. With increasing heating rate, the atomic average density in bulk crystal region is smaller, whereas that in the region of GB is larger. We can observe that the liquid film thickness is larger when the temperature increases to the same value $r = -0.1$ with a smaller rate [Fig. 6].

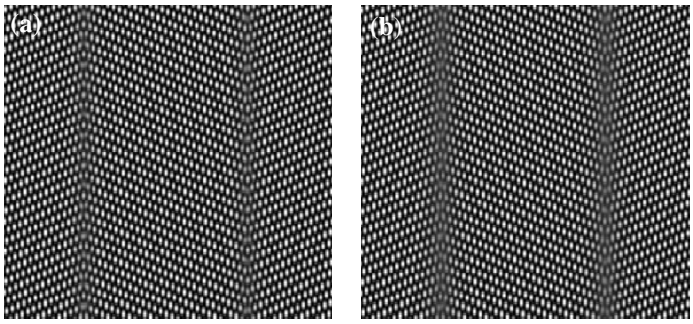

Figure 5. Snapshots of a high-angle grain boundary at misorientation angle 32.5° for $r=-0.1$ under different heating rates (a) $k=4\times10^{-6}$; (b) $k=4\times10^{-8}$.

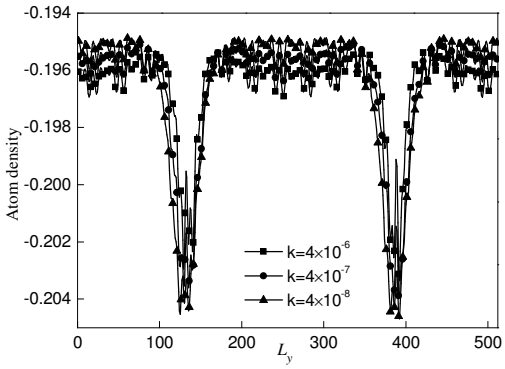

Figure 6. Density distributions of a high-angle grain boundary at misorientation angle 32.5° for $r=-0.1$ under different heating rates.

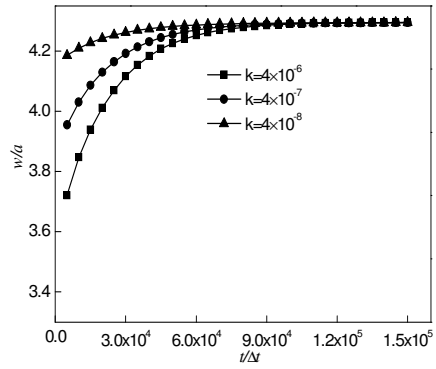

Figure 7 Film thickness w as a function of time t under different heating rates with misorientation angle $\theta=32.5^{\circ}$.

The curve of film width w versus temperature r for high-angle GB $\theta=32.5^{\circ}$ under different heating rates is similar to Fig. 3. At the beginning, the film width flatly increases with temperature, and heating rates exhibit no obvious effect on the film width. When the melting point is reached, the film width rapidly increases, and at the same temperature, the liquid film width is larger when temperature rises with lower heating rate.

Fig. 7 depicts the curves of film thickness w of high-angle GBs versus holding time t during the insulation stage after different heating process. The same point with Fig. 4 is that as the holding time prolonging, the liquid film thickness increase until to its equilibrium value, and then keeps the equilibrium value with holding time prolonging. The difference from Fig. 4 is that the liquid film thickness has the same equilibrium value during the entire insulation process although the heating rate is different during heating process. For high-angle GBs, the liquid is distributed homogeneously along the GB, thereby providing the convenience channel for the thermally activated motion of atoms so that atoms can fully diffuse during the heating process. As the liquid film thickness is lager in the system with lower rate during heating process, atoms can use the larger channel to diffuse, and the liquid film thickness in the system is still larger before achieving the equilibrium value; that is, the three curves have no intersections in this stage. However, the system can store more distortional energy with higher rate during heating process, which can lead the atoms to diffuse quickly, and in the stage before liquid film width achieving stability, the increasing rate of liquid film width is larger in the system. The final state is that the system with different heating rates reaches to the same value of equilibrium liquid film width.

Conclusions

The PFC model is used to study the effect of heating rate on the GB premelting. The liquid film thickness is calculated by excess mass theory. Our results show that the liquid film appears as the melting point is approached from below, and the liquid film width of GB is related to heating rate and misorientation angle. In the heating process, the liquid film width increase flatly when the

temperature is far below T_m, and then increases rapidly when the temperature is close to T_m.At the same temperature(close to T_m), the liquid film width is large when the temperature increases with low heating rate. In the insulation process, the liquid film thickness increase until to its equilibrium value, and then the liquid film thickness is no longer increase with holding time. For low-angle GBs, the higher heating rate the system has during heating stage, the lager equilibrium value of liquid film will be reached during insulation stage. For high-angle GBs, the liquid film thickness has the same equilibrium value during the insulation process although the heating rate is different during heating process.

Keywords: first-principles, Ce/N co-doped TiO2, electronic properties, photocatalytic activity

Abstract. Density function theory is performed in order to investigate the effect of Ce/N co-doping on geometry structure, electronic and optical properties of anatase TiO2. Comparing the energy band and density of states of pure TiO2 and Ce/N doped anatase TiO2. We can conclude that, the valence band of pure TiO2 is main composed of O 2p states and the conduction is mainly composed of Ti 3d states. For N-doped TiO2, the topmost part of the valence band is mainly occupied by N 2p states which is higher than that of the O 2p states which can narrowed the band gap. Ce doping will introduce 4f states which is involved in the conduction band. These may lead the conduction band move down. As for Ce and N co-doped, the top of the valence band is mainly occupied by an admixture N 2p, O 2p and the bottom of the conduction band is predominantly occupied by an admixture of Ce 4f ,Ti 3d. The strong interaction between the dopants and the ions lead the band gap get narrower. We predict that Ce+N doping is one of the best choices for enhancing the photoelectrochemical activity of TiO2.

Introduction

TiO2 photo catalysts has received more and more attention as a promising material due to its wide range of potential application. such photolysis of water, as solar cells, photocatalytic degradation of organic compounds , purifying water and air. Many researches have proved that TiO2 is the most preferable photocatalytic semiconductor because of its low price, non-toxicity, chemical stability and photocatalytic activity. However, as a large band gap (3.2eV for anatase and 3.0eV for rutile), TiO2 can be activated only by UV light which accounts for a small part(~4%) of solar energy. Therefore, many studies have been done to improve photocatalytic activity of TiO2 under visible-light irradiation. An effective method is doping the TiO2 with non-metal or metal elements.

Among non-metal doped TiO2 materials, doping with nitrogen atom is considered to be one of the most effective methods and it has been studied thoroughly via both experimental and theoretical methods. For example, Asahi et al. discovered that band gap energy of TiO2 was narrowed when TiO2 doped with N , which is further studied by other theoretical and experimental[1] tools to support their views. However Irie et al.suggested that the isolated N-2p states are above the valence-band maximum of TiO2, which is consistent with several recent experimental studies. The localized N-2p states act as the trap for photo generated carriers and decreases the photo-generated current which consequently limits the efficiency of N-doped TiO2 in the photocatalytic process. On the other hand, many attempts have been made to improve the photocatalytic activity of TiO2 by preparing Ce-doped TiO2. Tong et al.[2] figure out doping Ce^{4+} effectively improves the photocatalytic activity under both UV light irradiation and visible light irradiation with an optimal doping concentration of 0.2% and 0.4%, respectively. Fu et al.[3] studied the electronic and optical properties of Ce^{3+}-doped TiO2, and indicated that the Ce incorporation leads to a decrease of Ti 3d states and enhancement of 4f states in the bottom of conduction band. Recently, some researchers attempted to improve the photocatalytic activity of TiO2 by preparing Ce and N co-doped TiO2. Zhang et al.[4] studied the electronic properties of Ce/N-Coped TiO2, and found that Ce+N doping results in band gap narrowing and also leads to a red-shift of the absorption edge of TiO2.

In order to explain the reason of the enhanced photocatalytic activity and red shift of optical absorption, in this report the crystal structures, band structures and density of states between pure anatase TiO2 and Ce, N-doped anatase TiO2 are studied using the plane-wave ultrasoft pseudopotential method of density functional theory(DFT).

Model and Method of Calculation

The doped system consists of 2×2×1 anatase TiO2 super cell with 48 atoms in total. The Ce-doped configuration was constructed by replacing one Ti atom with one Ce atom, and similarly N-doped configuration was constructed when the O atom was replaced by N atom with a doing molar concentration 6.25%. For co-doping(Fig .1), One Ti atom was replaced by Ce atom while one O atom near the Ce atom was replaced by one N atom with a doping molar concentration of 3.125% .

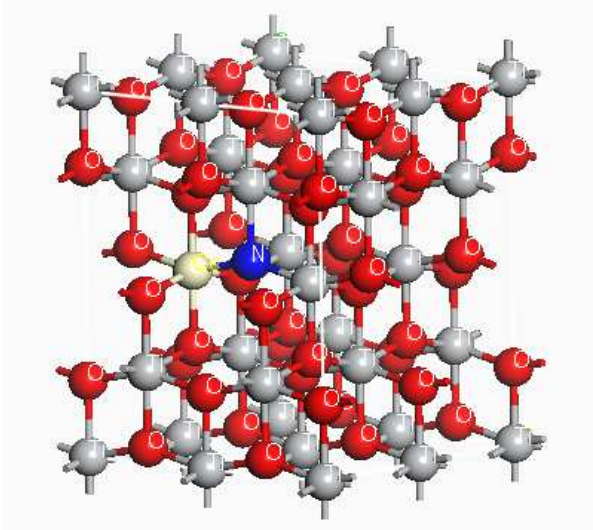

Fig. 1 Super cell models of Ce/N-co-doped TiO2

All of the calculations have been performed using Cambridge Serial Total Energy Package (CASTEP) module in Materials Studio 6.0.The electronic exchange-correlation energy is treated within the framework of the generalized gradient approximation (GGA) with the Perdew-Burke-Ernzerhof (PBE). The planewave expansion is truncated by the cutoff energy of 380ev. Monkhorst-Pack grid parameter for K-point simpling was 3×3×2 for all models. The convergences are set as 1.0×10^{-3} Å for maximum displacement tolerances, 8.5×10^{-3} eV/Å for maximum force, 0.01GPa for maximum stress and 5×10^{-7} eV/atom. The valence electrons configuration for the O,Ti,N, and Ce was $2s^2\ 2p^4$,$3s^2\ 3p^6\ 3d^2\ 4s^2$,$2s^2 2p^3$ and $4f^1\ 5s^2\ 5p^6\ 5d^1 6s^2$, respectively. Considering the influence of the doping on the lattice, the first step is geometrical optimization.

Results and Discussion

Optimized Structure Properties. After optimizing the geometry, we got the lattice parameters of pure TiO2 (a=3.802 Å ,and c=9.721 Å) which are close to the experimental data (a=3.782 Å and c=9.502 Å [5]). In order to study further , we also got the average bond lengths of pure TiO2 and doped TiO2 . We can find that the lattice parameters of doped TiO2 are bigger than pure TiO2 . This is due to the lager radius of N and Ce than those of O and Ti atoms, respectively. In N doped TiO2, the Ti-N (2.040 Å) bond lengths are similar with Ti-O (2.005 Å) in pure TiO2. However, in Ce doped TiO2, the Ce-O (2.164 Å) is slightly longer than Ti-O (2.076 Å) ones. The more powerful ionicity of Ce than Ti is due to the Mulliken charges of Ce (1.80) is larger than Ti (1.26). In Ce+N doped TiO2, the bond length of Ce-N (2.193 Å)and Ti-N (2.020 Å)are shorter than Ce-O (2.205 Å)and Ti-O (2.535 Å). These show strong covalent interaction for the Mulliken charges of Ce(1.74) is larger than

Ti (1.24), meanwhile, N (-0.66) and O (-0.65) are basically the same. These can explain the situation that the lattice parameters became bigger after doping. These Ti-O bonds are close the doped ions.

Electronic Properties. In order to analyze the electronic properties of co-doped anatase TiO2, the calculated band structures of the pure TiO2 and different doped models are presented in Fig. 2. From Fig.2(a), we could know the band gap of the pure anatase TiO2 is about 2.2eV, which is less than the experimental data of 3.20eV due to the limitation of GGA. But the results is close to the calculation of Shi and his workers[6] using the generalized gradient approximation (GGA) function (2.18eV). Although the drawback in DFT, the calculation results are reasonable for a comparison. The top of valence band maximum (VBM) and the bottom of conduction band minimum (CMB) are located at same points, indicating that pure anatase TiO2 is a direct-gap semiconductor material.

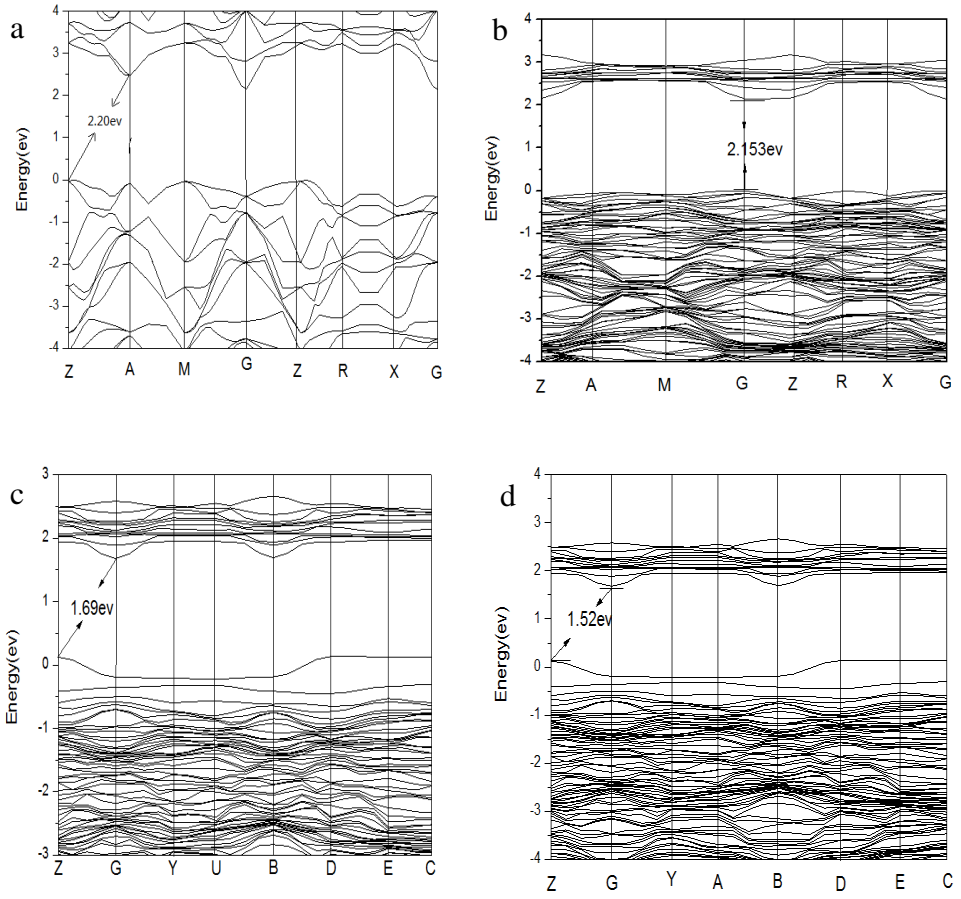

Fig. 2. Band structures plots of (a) pure anatase TiO2, (b) Ce-doped TiO2, (c) N-doped TiO2 and (d) Ce/N.

For Ce doped TiO2 Fig.2(b), The valence band and the conduction band became dense and the band gap is effectively narrowed by introducing impurity states below the conduction band. In this case, the band gap is about 2.153eV, which is less than the band gap of pure TiO2 (2.2eV). For N doped TiO2 Fig.2(c), an unoccupied acceptor state is introduced above the valence band which reduced band gap of TiO2 from 2.20eV to 1.69eV. This narrowed band gap may lead to the reduction of photoelectron transition energy, which shift the optical absorption edge to the visible light region. For Ce/N co-doped TiO2 Fig.2(d), the CBM is located at the G point, and VBM is at the Z point. The calculated indirect band gap is about 1.52eV. The band gap is get narrower and the unoccupied acceptor state is also introduced. Consequently, the probability of electrons being excited from the valence band to the conduction band increases, which may contribute significantly to the visible-light optical absorption.

To further study the modifications in band structure, the density of states (DOS) of different doped models have been calculated as indicated in Fig. 3. Total density of states (TDOS) of the pure TiO2 as well as of the different doped models (Fig.3a) shows that the valence band maximum (VBM) of all the doped models has no obvious shift from that of pure TiO2 , however, the conduction band

minimum (CBM) of Ce doped (Fig.3b) model declines about 0.48eV and N (Fig.3c) doped/Ce+N co-doped models(Fig.3d) declines about 1.0eV. Obviously, the smaller band gap of doped models may results in red-shift of the optical absorption. In pure anatase TiO2, the valence band which is close to the zero point energy is main composed of O 2p states and has a large bandwidth of about 4.93eV. Meanwhile, the conduction is mainly composed of Ti 3d states and has a bandwidth about 5.41eV. Ti^{4+} is surrounded by six O^{2-} which consisted octahedral structure. According to the crystal field theory, Ti 3d states split into t2g and eg states, and thereby the conduction band is divided into two parts, of which part of higher energy consists of O2p states and eg states of Ti atoms, and lower part consists of O2p states and t2g states of Ti atoms.

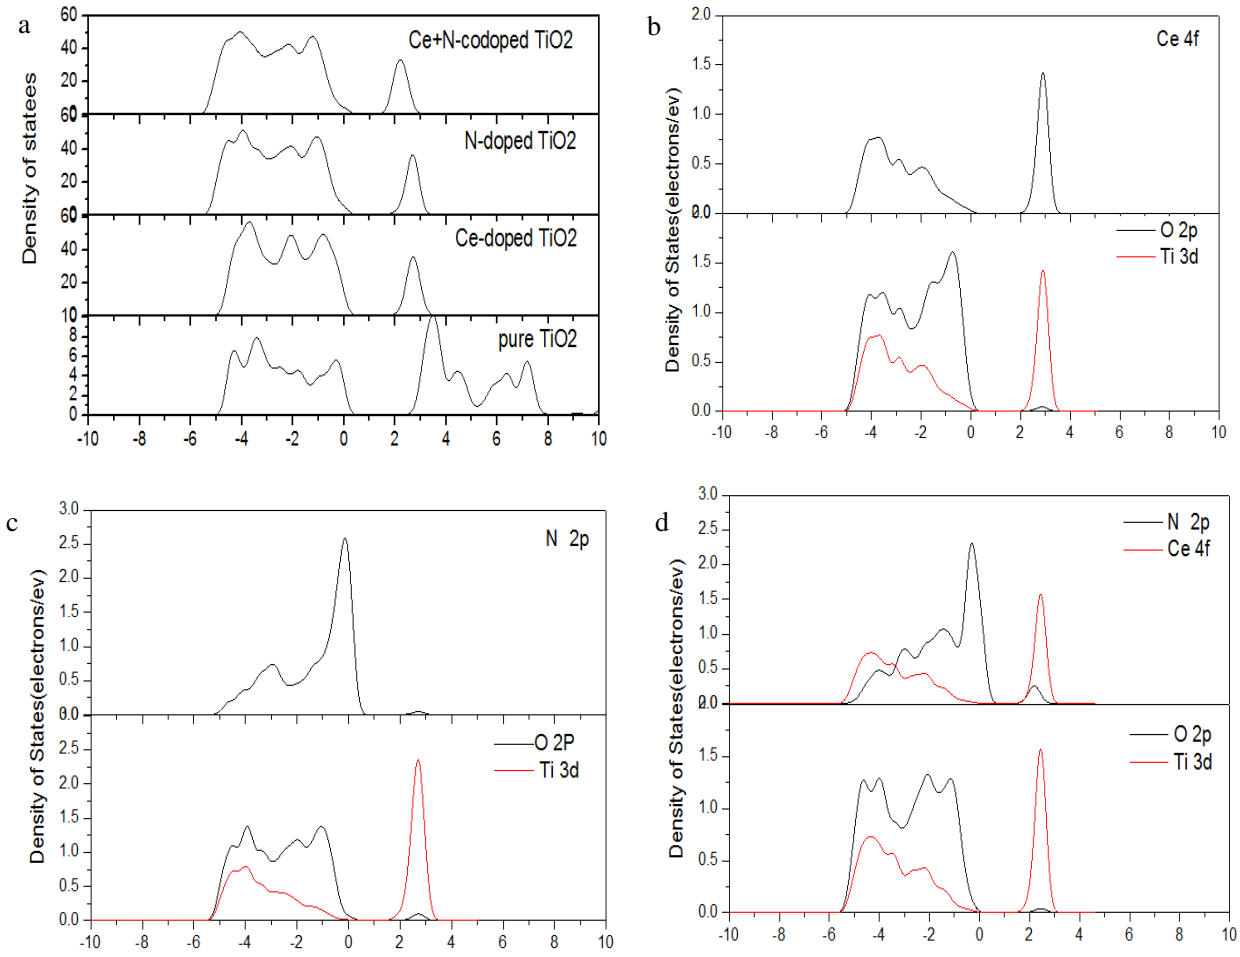

Fig. 3. (a) The calculated and comparison TDOS of different ions doped TiO2, calculated PDOS of (b) Ce-doped TiO2, (c) N-doped TiO2, (d) Ce/N.

As to Ce-doped TiO2, an Ti atom was replaced by a Ce atom which introduced 4f states. (Fig.3b) shows that the valence band is main composed of O 2p states and Ce 4f states and conduction band is predominantly composed of Ti 3d and Ce 4f. It is found that the conduction band moved left(about 0.583eV), improves the mobility of photo-generated electrons. The higher mobility of the photo-generated carriers, the better performance of the photocatalyst. This is same with the situation we found from the band structures of pure anatase TiO2 and Ce-doped anatase TiO2.

With respect to N-doped TiO2, N atom substitute one O atom. The N atom can obtain two electrons and its 2p states are not fully occupied (seen from Fig.3c), leading to the creation of acceptor N 2p states located at above the valence band maximum of TiO2. The bottom of the conduction band is mainly consisted of Ti 3d states. However, the topmost part of the valence band is mainly occupied by N 2p states which is higher than that of the O 2p states. This N 2p states are

responsible for the band gap narrowing. Unfortunately, unoccupied N 2p states may act as recombinations, which promote the electron-hole recombination rates.

For Ce/N-co-doped TiO2, the top of the valence band is mainly occupied by the N 2p states and the bottom of the conduction band is predominantly occupied by an admixture of Ce 4f and Ti 3d. The N impurity level appears above the VBM similar to the N-doped. In this case, the band gap is narrowed because of the decline of the conduction band. All the doped models have narrowed band gap, and thus they may induce a red shift of the optical absorption edge.

Conclusions

In summary, the crystal structures, band structures, density of states of pure anatase TiO2 , N-TiO2, Ce-TiO2 and (Ce,N) co-doped anatase TiO2 have been calculated and analyzed. We came to the conclusion that: N doping will effectively reduce the gap of anatase TiO2, but unoccupied N 2p states promote the recombination rates. Ce doping will introduce 5d states which are involved in the valence band and conduction band. These formed hybrid orbitals narrowed the band gap of anatase TiO2. For Ce and N doped, the top of the valence band is mainly occupied by an admixture N 2p, O 2p and the bottom of the conduction band is predominantly occupied by an admixture of Ce 4f , Ti 3d. The strong interaction between the dopants and the ions in anatase TiO2 is the main reason for its band gap narrowing. Maybe Ce and N doping is the best method which can effectively improve the photocatalytic activity.

Keywords: Nuclear field, Quantum well, Spin dephasing, Time-resolved Kerr rotation

Abstract: Effective magnetic field of nuclear spin polarization (NSP) under circularly polarized pumps excitation and the dephasing time of resident electron spin polarization under pump and control excitation has been detected in a single CdTe quantum well (QW) by a time-resolved Kerr rotation (TRKR) technique. We deduced that the experimental method is verified with the effect, to a certain extent, through confirming the external magnetic field results. In addition, the nuclear field is revealed to be increased with the increasing electron spin component due to the enhanced electron-nuclear hyperfine interaction. Significant nuclear field is observed as 1.85 mT with the applied magnetic field tilted by about 15 degree. What is more, we found the spin dephasing time (SDT) has little relation with the created NSP field, but it decreases largely with the increasing spin polarization magnitude under pump excitation and the spin vector dispersions induced by control pulses.

Introduction

Optically injected spin-polarized electrons polarize and depolarize nuclear spins through dynamic nuclear polarization (DNP) by the contact hyperfine interaction between electron and nuclear spins. The hyperfine interaction between the electron and the ensemble nuclear spins recently has attracted considerable attentions due to the potential applications in spin-based quantum information processing (QIP) [1,2]. Nuclear spins, as ideal quantum bits, play important roles in utilizing spin degree of freedom of semiconductor spintronic devices. Thus, the dynamical nuclear spin polarization created by optically injected spin-polarized electrons via hyperfine interaction has been largely observed in the past in bulk semiconductors [3] and quantum wells (QWs) [4-6], and quantum dots (QDs) [7-9]. However, the contact hyperfine interaction will modify their spin Hamiltonians, such that the spin splitting. This inherent feedback in the Hamiltonian leads to the bistability and hysteresis in the electron-nuclear spin system [8,9]. Therefore we have great interests on the manipulation and detection of effective nuclear field from NSP with keeping the long electron coherence at the same time.

For the applications by using an electron spin, its decoherence via NSP fluctuation becomes a large obstacle, especially for the QIP devices using QDs or QWs. NSP fluctuation limits the number of quantum operations and reduces the potential performance [7]. From this viewpoint, II-VI compound semiconductors such as CdTe [6] are preferable since those generally have a smaller hyperfine constant compared to III-V compound materials such as GaAs [5], and could expect smaller influence for electron spins coherence. However, precise measurements of the NSP amount with this order of magnitude hold several experimental challenges and additional difficulties in the valuation of nuclear field effects. For example, it is difficult to study nuclear spins by creating equilibrium nuclear polarization directly due to the small value of nuclear magnetic moment. Therefore, we try to measure the small NSP in a single CdTe QW by a TRKR method accurately.

Also, the SDT in turn would be influenced by NSP field reaction and the electron spin behaviours. In particular, resident electron spins have a long dephasing time in a QW [10] . Now that we know recent studies have revealed that SDT can be affected by magnetic field, temperature and spin density [11]. Therefore, it is necessary to discuss the dependence of ensemble electron SDT on controllable spin polarization and spin vector distribution, since the comprehensive researches of SDT related to spin polarization and spin dispersion have been a few so far.

In this study, we first have measured the dynamical nuclear-spin field in a single CdTe QW with negative charged excitons (X^-). We will show that the optically-polarized electron can effectively polarize nuclear spins, which is found to produce a few mT of effective nuclear field. The value depends drastically on the applied external magnetic field and photoinjected electron spin polarization. Afterwards, we investigated the SDTs derived from Kerr rotation signals using double circularly (σ^+/σ^+) laser pulses excitation. Which demonstrated that the electron SDT can be changed largely by the spin polarization magnitude modification in each independent subensemble of electrons and the dispersions of inhomo-geneous spin vectors.

Experiments and Analysis of Results

Effective Nuclear Field Under Tilted Magnetic Field.

The sample used here is a single CdTe/$Cd_{1-x}Mg_xTe$ (x=0.15) QW with the thickness of 100 Å. The resident electrons in a QW show the formation of the negative trions, consisting of spin-paired electrons and a hole [12]. Under the excitation of trion resonance, the photocreated electron-hole pair captures one of the resident electrons with a certain spin, leaving the polarizing residual electron ensemble to the opposite spin polarization since the initial polarization of resident electron emsemble is zero. The hole-in-trion spin relaxation time is rather smaller compared with the trion recombination time. Therefore, the effect of the remaining depolarized excited electrons can be ignored and never affect the temporal evolution of the ensemble resident electrons polarization.

The sample was excited by σ^+ (σ^-) circularly polarized picosecond pulses (duration~5 ps) with 769.6 nm near normal incidence and the generated spin polarization was measured by the linearly polarized probe pulse with the controlled delay time. The external magnetic field B up to ~170 mT was applied in Voigt configuration. The sample was mounted in a cryostat and was kept at 10 K through the measurements.

The linearly polarized probe beam was modulated by a photo-elastic modulator set as half wave retard at 50 kHz for a lock-in detection. And circularly polarized pump beam which was created by a quarter-wave plate (QWP) was modulated by a mechanical chopper at 120 Hz. In addition to the laser pump beam modulation, a combination of a half wave plate and a wollaston prism was set in front of a balanced photo-detector in order to cancel the static Kerr rotation with no pump pulses and reduce the influence of the scattered pump beam on the measured signal.

Fig. 1 shows the temporal evolution of the electron spins, which were generated by the circularly polarized pump pulses, was recorded by measuring Kerr rotation angle $\theta_K(\Delta t)$ of the linearly polarized probe pulse with delay time Δt**.** The observed signal can be fitted by exponentially damped oscillations function containing the beating frequency ω_L and a single decay time T^*:

$$\Delta\theta_K = A * \exp\left(\frac{-\Delta t}{T^*}\right)\cos\left(\omega_L \Delta t + \phi\right) \tag{1}$$

where the coefficient A is the initial amplitude of electron spin polarization, T^* is the transverse spin-relaxation time, ω_L is the electron Larmor frequency. Φ is an apparent initial phases for spin precession.

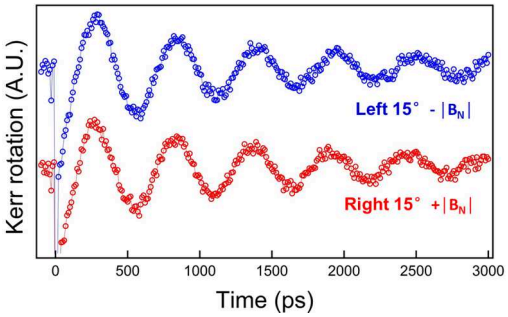

Fig. 1. TRKR signals for σ- pumps excitation in +15°/-15° geometry at T=10 K under 86.6 mT external field.

The Larmor frequency ω_L is shown in the following function:

$$\omega_L = g'_e \mu_B (B_e \pm B_N) / \hbar \tag{2}$$

where anisotropic $g`_e$ is the electron g factor in the magnetic field direction, B is an oblique applied magnetic field , and B_N is a created nuclear field. The direction of B_N depends on the direction of the excited electron spin polarization. Therefore, the nuclear field influences the electron spins precession, as is shown in Fig. 1.

As we mentioned before, this NSP effect only occurs if an applied magnetic field is used at an oblique angle and does not occur in the true Voigt geometry (i.e. right angle case). A longitudinal component of electron spin polarization is necessary to observe an spin precession frequency shift via B_N. Spins are, in principle, injected perpendicular to the field in the Voigt geometry and DNP should not be observed since the longitudinal spin polarization averages to zero. In a word, a direct longitudinal component of spin-injection can be created by simply tilting the applied magnetic field. From this process, we also calculated the exact external magnetic field (shown in Eq. 3) by TRKR measurement. For this technique, the magnitude of the effective field $|B_N|$ should be produced as the equal value at an equal angle of external field tilted to left and to right. Therefore, the measured total effective field B_{left} (B_e+B_N) and B_{right} (B_e-B_N) acting the electron spins can conclude the precise external field.

$$B_e = (B_{left} + B_{right}) / 2 \tag{3}$$

The tilted angle dependence of the applied magnetic field deduced from TRKR experiments is displayed in Fig. 2. As shown by the blue curve derived from σ^- pumps excited experiments and the red curve from σ^+ pumps excited measurements. At the same angle, the nuclear field could vary with different pump pulses, yet the applied magnetic field is a certain mount. Thus we deduced a series of applied magnetic field with the titled angle. As a result, the average measuring error of the detected external magnetic field for equal tilted angle from σ^+ experiments and from σ^- experiments is 0.0406 roughly, which verifies that this measurement method is also quite accurate to nuclear field at some degree.

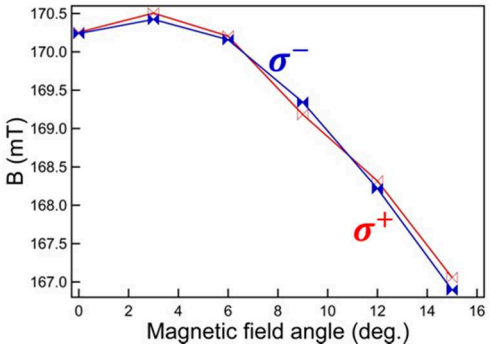

Fig. 2. External magnetic field B_e deduced from TRKR measurement.

In consequence, $B_{N\text{-}total}$ value can be obtained for any angle of external field inclination, which is indicated by Eq. 4:

$$B_{N\text{-}total} = B_{left} - B_{right} \tag{4}$$

Nuclear field absolute value tends to increase as the external magnetic field angle increases, as shown in Fig. 3. This is because the spin components that paralleled to external field increase with the increasing inclination of applied magnetic field. And we can notice that the nuclear field value B_N changed in the way that is almost proportional to the slant angle. Moreover, the largest nuclear field turned out to be 1.85 mT at the angle of 15° under σ^- pumps excitation. In the same way, nuclear field is also increased with the increasing of electron spin polarization, which is shown in Fig. 4. In all of the above experiments, the average electron spin transverse time is about 1400 ps, which is influenced a little by NSP effective magnetic field for this QW, in contrast to other influences, even the spin precession frequency spread causing spin dephasing [13].

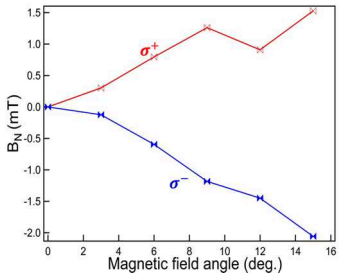

Fig. 3. Effective nuclei field under varied external field slope angle.

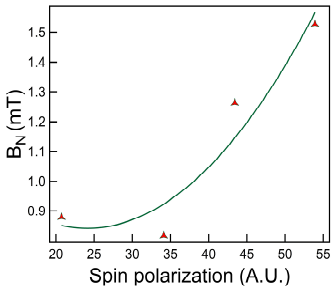

Fig. 4. Effective nuclei field under σ^+ pump excitation with different power around the external field slope angle of 15°.

Electron Spin Dephasing Under an Un-tilted Magnetic Field

The residual electron SDT could be affected by the magnitude and distribution of electron spins polarizations. Therefore, this electron SDT study was carried out by σ^+ pump around the normal external magnetic field B up to 205 mT applied in the same Voigt configuration. Moreover, a control pulse circular polarization was injected at a given controlled timing in the different Larmor period stages. That is because the distribution and magnitude of the resident electron spin polarizations can be varied by control pulse with the same phase and different phase relative to pump, as shown in Fig. 5. The total spin polarization generated by the pump and control excitations in the same phase has a higher polarization. However, the total spin polarization in 1/4 phase difference displays the nearly equal polarization magnitude as that of pump excitation and also shows up a phase shift. Otherwise, the dispersion (φ) increases with the increasing phase difference. For the same phase difference, φ rises with reducing relative magnitude difference of spin polarization excited by pump and control pulses.

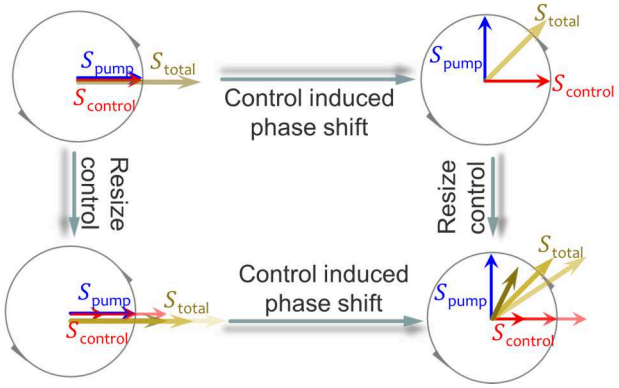

Fig. 5. Combined spin vector superposition (yellow arrow) of pump and control excitation (spin polarizations are presented by blue and red arrows, respectively) precess around normal applied magnetic field.

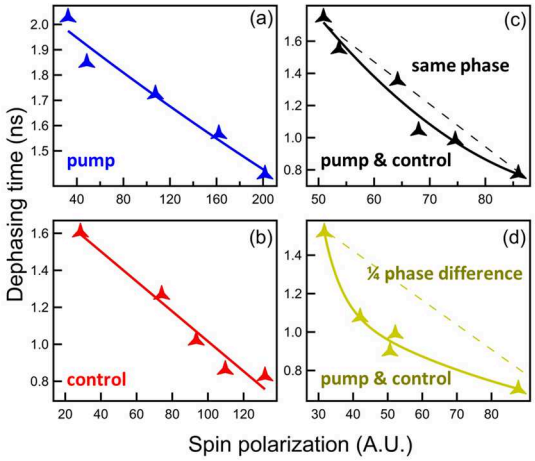
The SDTs were obtained from fitting the measured Kerr rotation signals on the control-probe delay Δt, and were plotted in Fig. 6. Figure shows the clear dependences of electron SDTs on the spin polarization magnitude under different excitation powers: (a) σ^+ pump; (b) σ^+ control; (c) σ^+ pump fixed at 5 mW and σ^+ control from 1 mW to 9 mW with same phase; (d) σ^+ pump fixed at 5 mW and σ^+ control from 1 mW to 9 mW with a quarter phase difference. There is a directly inverse linear relationship between the transverse electron SDT and the spin polarization (P) for an individual ensemble spin polarization under pump or control pulse excitation seen from Fig. 6(a) or Fig. 6(b).

However, the spin dephasing is slowed down by the spin phase dispersion of electron spins formed in different phase shown by Fig. 6(d), in which the dispersion of spin vectors is considered to firstly increase in the region of control < pump, and then decrease with increasing the spins excited by control pulse. Also, the plot of Fig. 6(c) shows a little deviation from linear correlation, which can be explained by the potential spin heating and a little spin vectors diffusion due to some experimental errors.



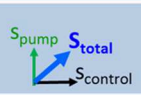


Fig. 6. Electron SDT versus spin polarization under different excitation intensities: (a) σ^+ pump; (b) σ^+ control; (c) σ^+ pump and σ^+ control with the same phase; (d) σ^+ pump and σ^+ control with a quarter phase difference.

Table 1 exhibits the main relationship of the spin vectors of pump-excited spins (green arrow), control-excited spins (black arrow) and the total spins (blue arrow). The measured electron spin polarization ratio derived from Kerr signal amplitudes and the fitted dephasing times (1550 ps: 2018 ps: 1519 ps ≈ 1: 1.3 :1) from Kerr rotation signals by pump and control with a quarter phase difference, pump alone, pump and control with the same phase, respectively, are summarized.

TABLE 1. SPIN VECTOR AND SDT.

Experiment excitation	Only pump	Pump and control with same phase	Pump and control with ¼ phase difference
Spin vector			
Total Polarization	1	1.8	1
Dephasing time [ps]	2018	1550	1519

From the spin polarization analysis above, it can be inferred that the electron spin dephasing is induced by two main aspects: the P magnitude of individual spin vector and the spin distribution φ of more than one spin vectors. According to Fig. 6(a) and Fig. 6(b) along with the left two columns of Table 1, the SDT decreases with the increasing P. Also, as seen in Fig. 6(d) and the right two columns of Table 1, the SDT is reduced by the diffused spin vectors dispersion φ, compared to a concentrated spin for the equal spin polarization value. In addition, from the left and right columns of Table 1 for the pump and control with different phases, the following is concluded: the sum of spin vector modules seemingly largely determines the dephasing time rather than the measurable total spin polarization.

From the above analysis, we can easily reach a conclusion that:

$$\mathrm{SDT} \propto 1/(\varphi * P) \tag{5}$$

Eq. 5 indicates that SDT and spin polarization has a directly negative linear relation as the spins vector dispersions are identical. While the spin polarizations are equal, SDT is supposed to decrease with the increase of ensemble spins dispersion.

Summary

In conclusion, it was shown experimentally that the nuclear field was obtained accurately by TRKR measurements through verifying the acquired precise external magnetic field value in a single QW. In the present of external magnetic field at 15 degree inclination to the sample, the nuclear field was about 1.85 mT when a small magnetic field of 170 mT is applied, being mainly determined by the electron-nuclear interaction. In addition, its value went up with the increasing external magnetic field slant angle and electron spin polarization respectively. However, the residual electron SDT reduced with the increasing spin polarization and dispersion of spin vectors.

Abstract: Fluoroalkylsilanes are a kind of important carbofunctionalized silanes and applied in many fields. while the rearrangement and decomposition reactions could easily occur for these compounds under a certain high temperature or catalysis. In this work, we selected $CH_3H_2SiCH_2F$ as the molecular sample and investigated the mechanism of rearrangement reaction by using quantum chemical DFT methods. The results showed the rearrangement occurred via a transition state, in which the fluorine atom migrated from carbon to silicon and the hydrogen atom migrated from silicon to carbon. To understant the the process details the atomic charge distribution and electronic transfer were analyzed. And atomic vibrations spectra was discussed as well.

Introduction

Organosilicon materials have been widely applied in all fields of national economy because of their many unique and notable properties [1]. For example, the methylsiloxane-based materials are main representatives and possess many prominent advantages, such as high and low temperature resistance, weather resistance, ozone resistance, electrical characteristics, physiological inert [2]. Thus these materials have extensive and important applications, including aerospace, electric, medicine, construction, machinery [3]. Carbofunctionalized polysiloxanes are functional organosilicon materials and have been widely utilized in coating industry, textile industry, daily-use chemical industry, polymer modifications [4]. Meanwhile, carbofunctionalized silanes ($\equiv Si(CH_2)_nX$, X = halogen) are a kind of important organosilicon products and the appearance of these products especially promote the development of polymer composites [5]. However, the rearrangement and decomposition reactions could easily occur for these compounds under a certain high temperature or catalysis, because silicon atom owns empty *3d* orbits and can accept the electron from adjacent electron-rich carbon-containing functional groups. These drawbacks limit their applications [6]. Therefore, it is significant for their applications and developments to investigate the mechanisms of thermal rearrangement and decomposition reactions.

Fluoroalkylsilanes ($\equiv Si(CH_2)_nF$) are a kind of carbofunctionalized silanes and have important applications [7-12]. However, these compounds can also rearrange and decompose under a certain high temperature or catalysis. It is beneficial to find out the mechanisms of rearrangement and decomposition reactions and guide the reasonable utilization. Thus based on the mechanisms, avoid, control or use these reactions. It is facile and efficient to investigate theoretically and the theoretical results can provide the basis for the experimental research. Therefore, herein we selected $CH_3H_2SiCH_2F$ as the model and related information was obtained by using density functional theory (DFT) method. To understand details of the mechanism we will discuss the rearrangement in three aspects as described below.

Theoretical methods

The molecular sample of CH_3SiCH_2F was selected to investigate in this work. To understand the process of thermal arrangement reaction, all molecular structures for reactant, product, as well as its transition state were optimized by using quantum chemical DFT methods at the 6-311G(d, p) level. And the harmonic vibrational frequencies were calculated for these structures at the same level. The result shown there is only one imaginary frequency for the transition state, confirming the certainty of transition state. The intrinsic reaction coordinate (IRC) calculation was further more used to demonstrate the rationality of the reaction pathway. Gaussian 03 software was used for all calculations in this work.

Results and discussion

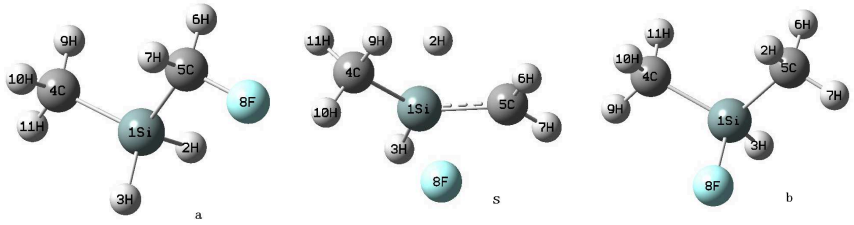

Fig.1 Geometries of the reactant(a), transition state(s), and product(b) of fluoroalkylsilane.

According to the principal of minimum energy, geometries of reactant ($CH_3H_2SiCH_2F$), its rearrangement product ($CH_3HSiFCH_3$), as well as the corresponding transition state were determined through all structures optimized. The structures were schemed the figure 1. Molecular energies for three structures with partial bond-lengths were listed in table 1. Table 2 gave the distribution of atomic charges and electronic transfer among atoms.

Stationary points and energies.

As shown in figure 1, rearrangement occurred from reactant of $CH_3SiH_2CH_2F$, via transition state, to product of $CH_3SiHFCH_3$. In this process, the fluorine atom deviated from the carbon atom step by step, and the hydrogen atom deviated from the silicon atom at the same time, forming the transition state of higher energy. The state possessed energy value of -469.68 a.u and was 205.05 kJ mol^{-1} more than the reactant. That means the reactant should overcome 205.05 kJ mol^{-1} energy barrier to form the transition state. After the fluorine atom migrated from carbon to silicon and the hydrogen atom migrated from silicon to carbon, the transition state transited to its rearrangement product. Compared with reactant, the product was in lower energy level, with energy value of -469.85 a.u and 238.92 kJ mol^{-1} less than the reactant, suggesting the stability of the product.

In the process of rearrangement, some atomic bonds changed obviously. As seen in table 1, when forming transition state the bonds of 1Si-2H and 5C-8F were weakened gradually. The lengths of 1Si-2H and 5C-8F increased 0.12 $\mathring{A}$ and 0.70 $\mathring{A}$ respectively in transition state. Meanwhile, 8F approached 1Si greatly, forming a 1Si-8F bond of 1.83 $\mathring{A}$. Another notable change was the bond of 1Si-5C. From reactant, via transition state to product the length slightly shortened 0.059 $\mathring{A}$ and then enlarged 0.022 $\mathring{A}$.

Table 1. Zero-point energies, absolute energies, relative energies, partial lengths ($\mathring{A}$) of reactant, transition state, and product, calculated at the B3LYP/6-311(d, p) level

species	E_{ZP} (kJ mol^{-1})	E (a.u)	E_R (kJ mol^{-1})	1Si-5C	1Si-2H	1Si-8F	5C-8F
a ($CH_3H_2SiCH_2F$)	218.3397	-469.7549	0.0	1.8857	1.4860	2.7181	1.4087
S	205.6793	-469.6768	205.0499	1.8264	1.6066	1.8315	2.1121
b ($CH_3HSiFCH_3$)	223.1026	-469.8459	-238.9186	1.8686	2.4743	1.6345	2.8402

Atom electronic transfer.

Mulliken atomic charges calculated with above method were listed in table 2. In the rearrangement reaction, those of electronic charges transferred obviously were atoms of 1Si, 2H, 5C and 8F. Due to the interaction of the empty 3d orbit of the silicon atom and the lone pair of electrons of the fluorine atom, partial valence electrons of the silicon atom transferred to the fluorine atom. In the process, the interaction of 5C with 8F weakened gradually, while the interaction of 1Si with 8F enhanced gradually, benefiting formation the transition state. Another active atom of 2H, migrated from 1Si with negative charge to 5C with positive charge, total 0.27 electronic charge transferred. The atom 5C obtained negative charge mainly from 1Si and 2H.

Table 2. Atomic charges in reactant, transition state, and product calculated at the B3LYP/6-311(d, p) level

species	1Si	2H	3H	4C	5C	6H	7H	8F	9H	10H	11H
a ($CH_3H_2SiCH_2F$)	0.735	-0.131	-0.131	-0.631	-0.187	0.115	0.115	-0.289	0.132	0.132	0.140
S	0.939	-0.212	-0.125	-0.598	-0.294	0.177	0.173	-0.446	0.119	0.128	0.140
b ($CH_3HSiFCH_3$)	1.096	0.140	-0.189	-0.640	-0.640	0.125	0.136	-0.430	0.125	0.136	0.140

Vibration frequencies.

Infrared spectra of atomic vibrations were shown in figure 2. Some of the vibrational peaks changed in position and intensity obviously. In figure 2 (a), two strong peaks were located in 906cm-1 and 2225cm-1, one represented the bending vibration of CH_3-SiH_2 group, the other correlated the stretching vibration of two hydrogen atoms relative to the silicon atom. Another major peak located in 1019cm-1, its strength was weaker than the formers, and was caused by the stretching vibration of the C-F bond. When the molecule reached its transition state, obvious changes had taken place in the infrared spectrum. Firstly, the noticeable fact, there was a imaginary frequency at -587cm-1, which was representation of transition state flag. Besides, there appeared many new peaks which were different from that of the reactant. Among them, the strongest one, located at 1669cm-1, was due to the stretching vibration of active H atom relative Si atom, which would weaken the Si-H bond until the disconnect. In 422cm-1 there was a new stronger peak, this was because in the process of forming transition state, fluorine atom migrated to silicon atom to form F-Si bond and the stretching vibration of F-Si bond contributed the infrared spectrum. For the

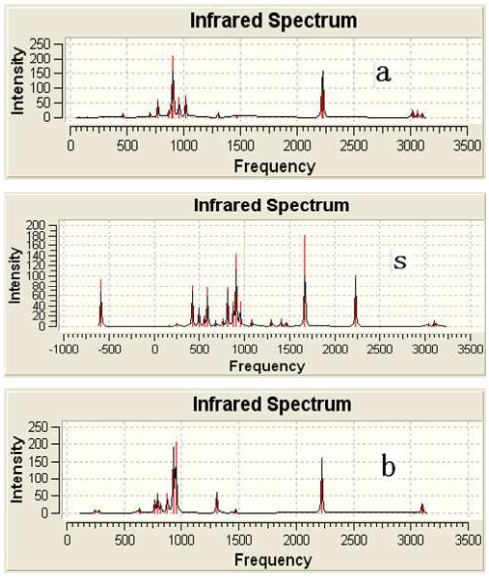

Fig.2 Infrared spectra reactant(a), transition state(s), and product(b) of fluoroalkylsilane.

infrared spectrum of the product, seen figure 2 (b), there were some obvious differences compared with the reactant. In the vicinity of 900cm-1 the original single line in reactant changed to double lines in product. One line at 819cm-1 was the F-Si-H stretching vibration. The additional spectral lines were also observed in the range of 700-800cm-1. And the line of 765cm-1 corresponded to the bending vibration of H-Si-F.

Conclousion

The discussion about rearrangement mechanism of the fluoroalkylsilane showed the reactant would occur rearrangement through a transition state to the product. In the process of rearrangement the fluorine atom migrated from carbon to silicon and the hydrogen atom migrated from silicon to carbon. Part of the electronic charge transferred between atoms, making certain bonds fractured and others formed. The difference of molecular vibrational spectra further confirmed adjustment of the structure as well as the bonding property.

Keywords: fcc Fe; impurity diffusion; atomic mobility; CALPHAD; DICTRA

Abstract: The atomic mobilities for impurity diffusion of Al, Au, Co, Cu, Mn, Mo, Nb, Ni, Pt, Sn and Zn in fcc Fe have been critically assessed based on the experimental diffusion coefficient data available in the literature. The impurity diffusion coefficients calculated from the atomic mobilities agree reasonably well with the reliable experimental data. This work provides a helpful guidance for the establishment of a general Fe-based mobility database to design new Fe-based alloys for practical purposes.

Introduction

There are many phenomena associated with diffusion in metallic materials during production and service, such as smelting, crystallization, segregation, equalization, heat treatment, welding. Diffusion is a basic and important factor that should be considered in design of metallic materials. Impurity diffusion refers to the diffusion of impurity atoms (or ions) A in pure metal B at an extremely small concentration. It is not only of practical importance, but also of theoretical interest to describe the diffusion behavior [1].

In the framework of computational thermodynamics and kinetics (also known as CALPHAD), all kinds of diffusion coefficients contribute to assess the atomic mobilities of species in multicomponent materials. When the atomic mobility and thermodynamic data are available, various diffusion coefficients can be readily calculated [1–7] which is especially significant for multicomponent materials. To realize the goal, a software tool, DICTRA (DIffusion-Controlled TRAnsformations) is developed [4, 8]. It is capable of simulating diffusion-controlled phase transformations in multicomponent materials by coupling thermodynamic data with mobility data stored in databases.

The aim of the present work is to use DICTRA to critically assess the atomic mobilities for impurity diffusion of Al, Au, Co, Cu, Mn, Mo, Nb, Ni, Pt, Sn and Zn in fcc Fe based on the experimental diffusion data available in the literature. The evaluated parameters are validated by comparing the calculated diffusion coefficients with measured data and can be easily incorporated into a general Fe-based mobility database for practical purposes.

Modelling of the Atomic Mobility

Almost 20 years ago, Andersson and Ågren [9] and Jönsson [10] modeled the temperature, pressure and composition dependencies of atomic mobility in multi-component solution phases. According to the absolute rate theory, the atomic mobility of element B, denoted by M_B, can be divided into a frequency factor M_B, and an activation enthalpy Q_B, as follows [9-13]:

$$M_B = M_B^0 \exp\left(\frac{-Q_B}{RT}\right)\frac{1}{RT}\Omega^{mag}, \quad (1)$$

where R is the gas constant; T is the temperature; Ω^{mag} is a factor taking into account the effect of the ferromagnetic transition. For the fcc phase, Ω^{mag} can be regarded as 1 [14, 15]. So for the fcc phase, the atomic mobility M_B can be further modified to:

$$M_B = \frac{1}{RT}\exp\left(\frac{-Q_B + RT\ln\left(M_B^0\right)}{RT}\right) = \frac{1}{RT}\exp\left(\frac{\Phi_B}{RT}\right), \quad (2)$$

where Φ_B is a temperature-dependent parameter. Since the impurity diffusion coefficient is directly related to the atomic mobility by the Einstein relation:

$$D_B^* = RTM_B \quad (3)$$

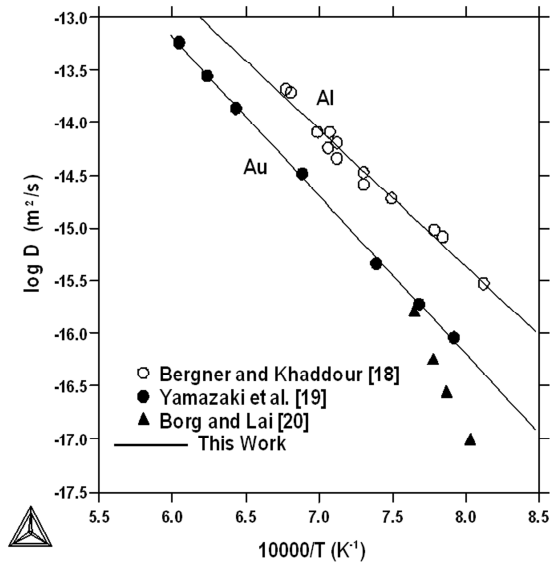
Therefore Φ_B can be easily evaluated from the impurity diffusion coefficient.

Results and Discussion

To assess the atomic mobility parameters, the experimental data are collected and the optimization is performed in the PARROT module in DICTRA, which is based on the minimization of the residual between the calculated and measured diffusion coefficients.

Table 1 summarizes the experimental data utilized in the assessment, together with the temperature range and experimental methods. The work uses the book by Neumann and Tuijn[16] as the main reference from which most of the literature are incorporated and critically classified Additional experimental data are collected by literature research. In the following, these experimental impurity diffusion data are critically evaluated.

Table 1 Experimental information for impurity diffusion in fcc Fe utilized in this work.



Diffusion data	Temperature [K]	Method	References
Al in Fe	1003-1673	Polycrystals, 99.9%; XRD; diffraction method	[17]
	1230-1473	Fe (1.5%Al)/Fe/Fe(1.5% Al); diffusion couple; EPMA	[18]
Au in Fe	1263-1653	diffusion couple ; EPMA	[19]
	1245-1307	^{195}Au; polycrystals; 99.999 %; residual activity	[20]
Co in Fe	1478–1535	^{60}Co; electroplated; lathe	[21]
	1409–1633	Co, polycrystals, 99.999 %; diffusion couple and thin film; EPMA	[22]
	1223-1593	Co, polycrystals, 99.99 %; diffusion couple; EPMA	[23]
	1233-1493	^{60}Co, polycrystals, 99.9 %; residual activity	[24]
Cu in Fe	1202–1293	Cu, polycrystals; EPMA	[25]
	1558–1641	Cu, single crystals, 99.91%; 64Cu; vapour deposition; grinder	[26]

		sectioning

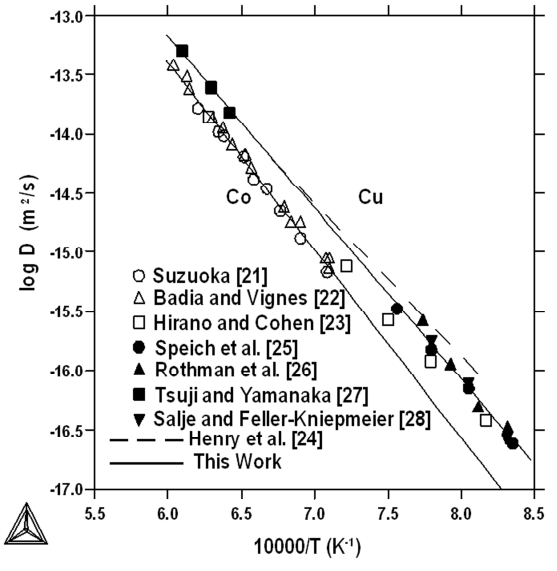
	1409–1633	Ni, polycrystals, 99.999%; diffusion couple and thin film; EPMA	[22]
Pt in Fe	1183–1533	Pt, polycrystals;^{193}Pt; electroplated; residual activity	[35]
Sn in Fe	1197–1653	Sn, polycrystals, >99.97%; ^{113}Sn; dried-on from salt solution; serial sectioning	[36]
Zn in Fe	1273–1425	Zn; Fe/Fe (3% Zn) diffusion couple; EPMA	[37]



Note: EPMA= electron probe microanalysis.

For the impurity diffusivities of Al in fcc Fe, the data reported by Akimova et al. [17] are nearly ten times larger than those measured by Bergner and Khaddour [18]. In addition, no influence of bcc/fcc transition were observed by Akimova et al. In the present work, only Bergner and Khaddour's data were used in the assessment. In the case of Au, more recent data by Yamazaki et al. [19] were adopted in the assessment. The impurity diffusion coefficients of Co measured by Henry et al. [24] are larger than those of Suzuoka [21], Badia and Vignes [22], their data are not consistent with the interdiffusion coefficients measured for fcc Fe-Co alloys and not selected in the assessment. Hirano and Cohen's[23] data were also not used, because the data are larger in the low-temperature region. For the impurity diffusivities of Mn, Mo, Pt, Sn and Zn in fcc Fe, only one set of experimental data was found and used to assess the corresponding atomic mobilities.

Table 2 lists the assessed mobility parameters for impurity diffusion of eleven elements. The calculated diffusion coefficients are shown in Fig. 1. As can be seen, the calculated values agree well with the measured values for the eleven elements.

Table 2 Assessed atomic mobilities for the impurity diffusion in fcc Fe

Phase	Mobility	Parameters
fcc	Al	$\Phi_{Al}^{Fe} = -249274 + R*T*\ln(1.1222E-5)$
	Au	$\Phi_{Au}^{Fe} = -287984 + R*T*\ln(6.8076E-5)$
	Co	$\Phi_{Co}^{Fe} = -303256 + R*T*\ln(1.2749E-4)$
	Cu	$\Phi_{Cu}^{Fe} = -276942 + R*T*\ln(3.1610E-5)$

Mn	$\Phi_{Mn}^{Fe} = -240863 + R*T*\ln(1.9202E-6)$
Nb	$\Phi_{Nb}^{Fe} = -284913 + R*T*\ln(4.4564E-4)$
Mo	$\Phi_{Mo}^{Fe} = -329743 + R*T*\ln(4.5296E-3)$
Ni	$\Phi_{Ni}^{Fe} = -318009 + R*T*\ln(4.2063E-4)$
Pt	$\Phi_{Pt}^{Fe} = -283464 + R*T*\ln(1.0428E-4)$
Sn	$\Phi_{Sn}^{Fe} = -262349 + R*T*\ln(8.4284E-5)$
Zn	$\Phi_{Zn}^{Fe} = -261602 + R*T*\ln(2.6024E-5)$

Summary

Based on the PARROT module in DICTRA and various diffusion data available in the literature, the impurity diffusion coefficients for Al, Au, Co, Cu, Mn, Mo, Nb, Ni, Pt, Sn and Zn in fcc Fe have been critically evaluated. The computed impurity diffusion coefficients resulting from the assessed diffusion parameters agree reasonably with the reliable experimental data. The presently obtained impurity diffusion coefficients are of both technological and theoretical importance.

Keyword: Zn_2GeO_4 afterglow traps Mn^{2+}

Abstract: $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ long afterglow phosphors were synthesized by the high temperature solid state reaction. The X-Ray diffraction (XRD), emission spectra, afterglow spectra, decay curve and thermoluminescence curve were utilized to characterize the sample. The X-Ray diffraction phases indicate that the sample have a crystal structure of Zn_2GeO_4 and was not influenced by co-doped Mn^{2+}, Pr^{3+} no influence for crystal structure. According to the emission spectra, we found that the $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ exhibit a narrow band emission with the peak at 532nm, which could be ascribed to Mn^{2+} transition between $^4T_1$ and $^6A_1$ electron configurations. The green long afterglow of $Zn_2GeO_4:Mn^{2+}_{0.01}$,$Pr^{3+}_{0.01}$ could be observed for three hours by naked eyes at room temperature under 254 nm UV excitation. The thermoluminescence (TL) curve is employed for the discussion of the origin of the traps and the mechanism of the persistent luminescence. The results indicate that $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ may be an excellent green long afterglow material and the Pr^{3+} ions behave as the electron trapping centers to be associated with the occurrence of the ultra-long afterglow.

Introduction

Persistent luminescence is a phenomenon whereby luminescence can last for hours after the stop of the excitation. Phosphors with persistent luminescence have been rapidly developed in the past decade, largely stimulated by the widely used in many areas such as the traffic signs, emergency signage, display, optical memory, imaging storage and high energy ray detection [1]. Therefore, many efforts have been made to discover long afterglow host material as well as activators with high performance. In recent years, germanates has attracted considerable attention and have been widely investigated as new host materials for light emitting devices [2]. Among germanates, zinc germanate (Zn_2GeO_4) is an excellent candidate due to its reasonable conductivity and high stability. As is reported, Zn_2GeO_4 has been discovered to be a self-activated white-blue phosphor, whose emission may be due to a radiative transition from a donor of oxygen vacancy ($V^{\bullet}_{O}$) or Zn interstitial ($Zn^{\bullet}_{i}$) to an acceptor of germanium vacancy (V_{Ge}) or zinc vacancy ($V^{''}_{Zn}$) [3,4]. Especially, the Mn^{2+} activated Zn_2GeO_4 phosphors exhibit more saturated green emission than the commercial FEDs phosphor ZnO:Zn, and it expected that these phosphors are promising for application in field-emission displays [5]. By our knowledge, Zn_2GeO_4 have played an important

role as new host material for field emission displays but few literatures focus on its potential as long afterglow host material. Zinc germanate can acts as long afterglow host material for high luminance and long persistence of phosphorescence phosphors when doped with appropriate active center. As the previous reported [4], transition metal Mn^{2+} ions can serve as luminescence center and exhibit high luminescent output in inorganic oxide compounds, the rare earth Pr^{3+} ions could act as the electron trapping centers to enhance the long afterglow time. Therefore, the $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ phosphor with high luminescence intensity and saturated color have been investigated in the present study. Mn^{2+} ions are centers capable of emitting radiation after being excited, Pr^{3+} store excitation energy and release it gradually to emitters (Mn^{2+}) owing to thermal stimulations. This new persistent material has potential application in optical memory, traffic signs, display, emergency signage and so on. As far as the author's knowledge, the long afterglow property and mechanism of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ are first reported by the present work and a new member of green long afterglow phosphors based on zinc germinates is added. Up to now, the $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ may be the longest and the brightest green long afterglow materials base on Mn^{2+} as luminescence center. The luminescent properties of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ as a long afterglow phosphor have been investigated in detail by measuring the emission spectra, afterglow spectra, the decay curve and the thermoluminescence curve. According to the TL curves, the mechanism of afterglow decay is analyzed in depth based on electron transfer between the traps and energy bands.

Experimental

The sample $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ was synthesized via high temperature solid-state reaction of constituent oxides, namely, ZnO, GeO_2, Pr_2O_3. Manganese was added in the form of manganous carbonate. The raw powders were weighed according to the nominally compositions and the mixture was milled for about 1h in an agate mortar. Subsequently, the mixed powders were moved into a corundum crucible and sintered at 1300℃ for 5h in an air ambient. Meanwhile, we synthesized $Zn_2GeO_4:Mn^{2+}_{0.01}$ for comparing.

The crystal structure of the powder phosphor was analyzed by X-ray powder diffraction (XRD) using Cu Kα (λ=0.15418 Å) irradiation operating at 36 kV and 20 mA. The emission, excite spectra and afterglow spectra were performed by means of a Hitachi F-700 fluorescence spectrophotometer. Prior to the afterglow spectra measurements, the sample was exposed to radiation from a UV lamp with 254nm wavelength for 3 minutes. The afterglow decay curves were detected via GFZF-2A single-photon counter system after the samples were irradiated with a conventional tricolor fluorescence tube. A FJ27A1 thermoluminescent dosimeter was used to record thermoluminescence curve with the heating rate of 1℃/s, the measurement started after switching off the light source 5 minutes.

Results and discussion

phase structure

Structure of the $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ powder was studied by means of the XRD power diffraction technique. As shown in Fig.1, all the diffraction peaks are consistent with the standard JCPDS card NO.11-0687, which indicates that the co-doped Mn^{2+}, Pr^{3+} have little influence on the crystal structure of Zn_2GeO_4, and all of the peaks are assigned to the phase of Zn_2GeO_4. The Zn_2GeO_4, whose structure is constructed by corner-shared ZnO_4 tetrahedral and GeO4 tetrahedral, has a rhombohedra until cell with space group $R\bar{3}$ [5] and has a phenacite structure with lattice constants of a=b=14.231Å and c=9.53Å. The coordination number of Zn, Ge, O atoms is 4, 4, 3,

respectively [6]. Considering the ionic radii of Zn^{2+} (0.60Å), Mn^{2+}(0.66Å), Pr^{3+}(0.99Å) and Ge^{4+}(0.39Å) ions in the site of CN(coordination number)=4, it is expected that the Pr^{3+} ions substitute the Zn^{2+} ions. Meanwhile, it is also expected that the Mn^{2+} ions substitute the Zn^{2+} ions due to the close radius in $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}{}_{0.01}$ phosphor.

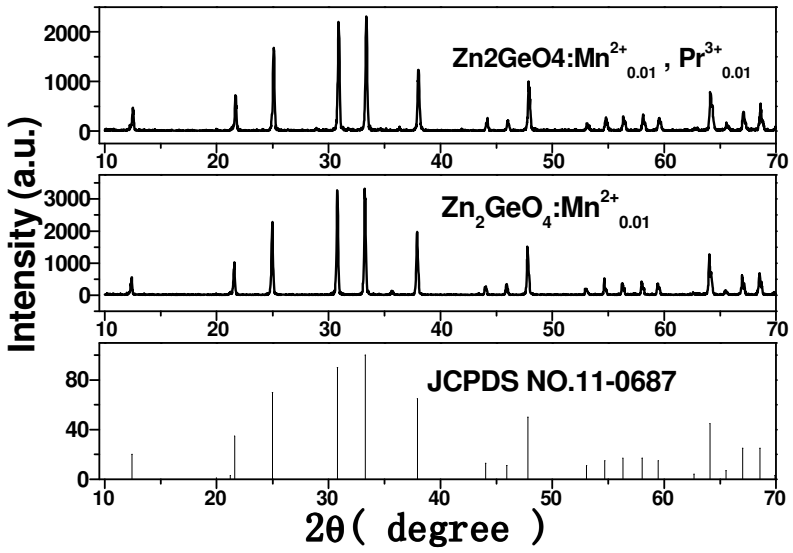

Fig.1. XRD patterns of the as-prepared sample and the pattern of JCPDS NO.11-0687 for Zn_2GeO_4

Luminescence properties

In order to study the photoluminescence properties of the phosphor, the PL emission spectrum of a $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}{}_{0.01}$ at room temperature is shown in Fig.3. As we know, the Mn^{2+} ions activated phosphors can give green or red emission, which depends on the crystal field condition. The Mn^{2+} ion yields green luminescence when it is tetrahedrally coordinated (CN=4) in the lattice whereas it emits red luminescence in octahedral coordination (CN=6) [5]. As mentioned earlier, there are only the tetrahedral Zn^{2+} sites available for Mn^{2+} ions in the rhombohedral Zn_2GeO_4 host. Therefore, Mn^{2+} gives green emission, which is consistent with the spectral result. Just as Fig.3 shows, we can observe that photoluminescence spectrum of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}{}_{0.01}$ exhibits symmetric emission band at about 532nm could be attributed to the $^4T_1$（^4G）$\rightarrow{}^6A_1$（^6S）transition of Mn^{2+} ions which occupy the tetrahedral coordination. Additional, we can infer from the emission spectrum that the Pr^{3+} ions act as electron trap center instead of luminescence center in our research. And the Pr^{3+} ions behave as the electron trapping center to be associated with the occurrence of the long afterglow will be discuss in detail later.

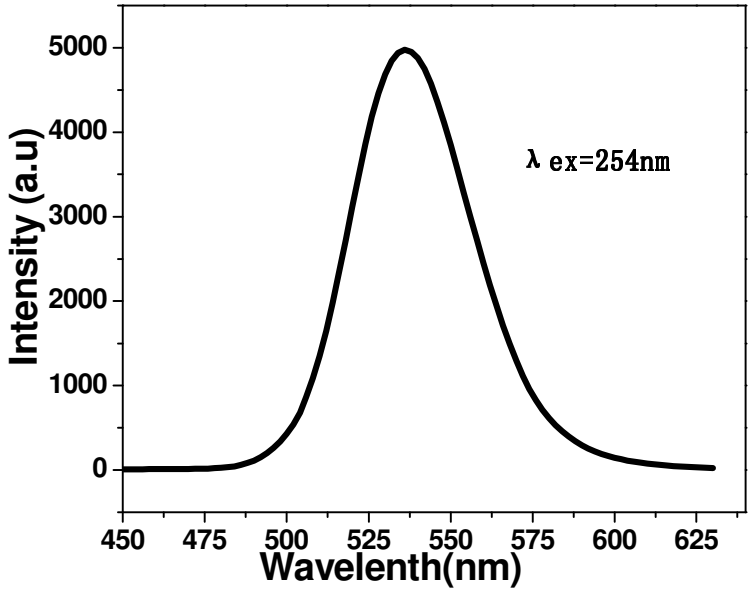

Fig.3 The emission spectrum of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ under the excitation of 254nm at room temperature

Long afterglow properties

Afterglow spectra

Besides the intense photoluminescence, the excitation of UV light can also induce long-lasting persistent luminescence in $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ phosphor with a persistent times ＞3h (here the persistent times is defined as the duration for which the naked eyes can see). Fig.3a displays typical time-resolved photoluminescence spectra of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ phosphor. The emission peak at about 532nm in the afterglow photoluminescence remain the same without any change, indicating that the afterglow characteristics of the as-prepared sample can be considered coming from the $^4T_1$ to $^6A_1$ transition of Mn^{2+} ions, it has also indicated that the Pr^{3+} ions only serve as the trap center, not as the luminescent center. As can be seen in the Fig.3a, the afterglow intensity of 0min is remarkably stronger than that of 2 min, while the intensity is no significant difference of 4 min, 6 min, and 8 min. The long-lasting persistent luminescence of the $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ phosphor discs were also visually evaluated using a fluorescence microscopy in the dark room. Fig.3b-f show the changes of green emission “brightness” with a decay time up to 3h for three $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ discs after exposure to a 4w 254nm lamp for 30s, 3min, 5min. Fig.3b-f clearly shows that the $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ discs can be effectively activated by a 254nm UV lamp and seconds to minutes of irradiation can result in 3h of persistent green emission.

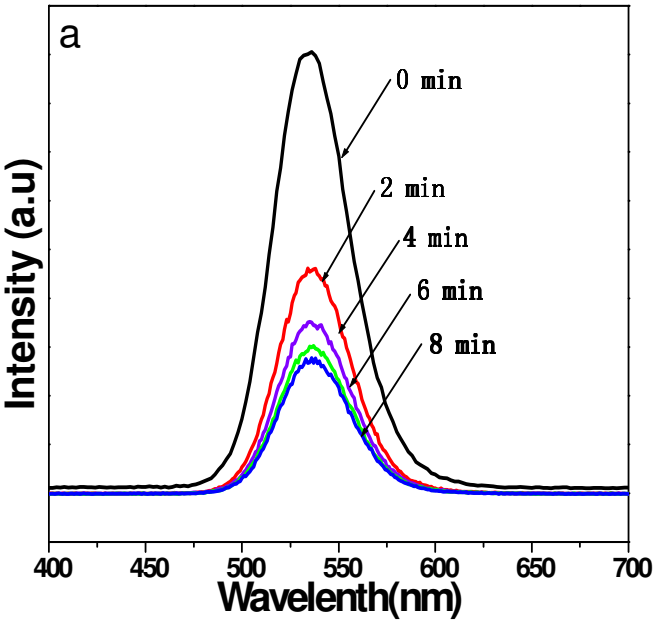

Fig.3a. Long afterglow spectra of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$.

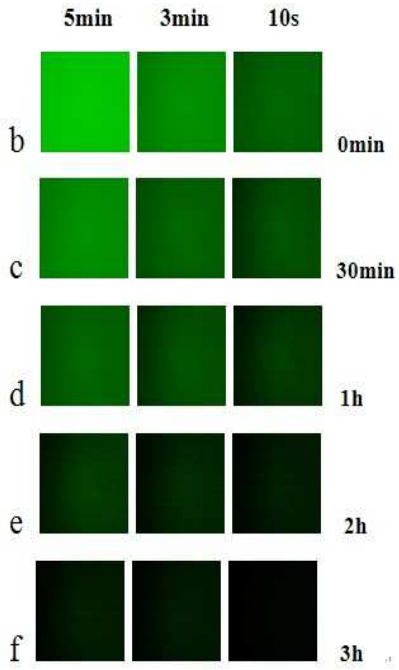

Fig.4b. Time-resolved photoluminescence spectra of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ phosphor which were examined in 0,2,4,6,8min after the 254nm ultraviolet lamp excitation for 5min at room temperature. Fig.4b-f. images of three discs taken at different persistence luminescence times after irradiated by a 254nm lamp for 10s, 3min, 5min, respectively.

Decay characteristics

In order to investigate the decay characteristics, Fig.4 shows the persistent luminescence decay curve of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ phosphor disc monitored at 532nm after irradiation by 254nm UV light for 5min. The recording lasted for 1h. As can be seen, the persistence luminescence intensity drops quickly in the first several minutes and then decays slow. After an hour of persistent emission, the persistence luminescence intensity is still significantly high, indicating that the persistent luminescence should last much longer than 1h. After switch off the exciting resource for 3h, we can see the emission still by the naked eyes. The upper inset of Fig.4 shows a persistence luminescence emission spectrum recorded at 1h after the stop of 254nm UV light irradiation. The profile of the persistence luminescence emission spectrum is almost identical to that of photoluminescence emission spectrum, indicating that the persistence luminescence originates from Mn^{2+} emitting center. The afterglow characteristics are evaluated using the curve fitting, since the decay process of the phosphor contains the rapid–decaying process and the slow-decaying process which has mentioned in the previous study [13,14]. In our work, the double exponential function is utilized to fit into the decay curves. The formation of the function is as follows:

$$I = I_1 \exp(\frac{-t}{\tau_1}) + I_2 \exp(\frac{-t}{\tau_2}) \quad (1)$$

Where t is the decay time; I (t) represent the phosphorescent intensity at the t time; I_1 and I_2 are constants which depend on the rapid and slow initial luminescent intensity at t=0; τ_1 and τ_2 time of $Zn_2GeO_4:Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ phosphor is up to 843s. And we discover that the $Zn_2GeO_4:Mn^{2+}_{0.01}$,

$Pr^{3+}_{0.01}$ phosphor exhibits a much longer slow-decaying time than that of $Zn_2GeO_4:Mn^{2+}_{0.01}$ phosphor. It indicates that the co-doping with Pr^{3+} ions can strongly prolong the afterglow duration of the $Zn_2GeO_4:Mn^{2+}_{0.01}$ phosphor. The main reason why co-doping Pr^{3+} could enhance the decay characteristics will discuss in detail latter.

Table 1 Simulated results for the afterglow curves of $Zn_2GeO_4:Mn_{0.01}^{2+}$, Pr^{3+} and $Zn_2GeO_4:Mn_{0.01}^{2+}$

Phosphor composition	τ_1(s)	τ_2(s)
Zn2GeO4:Mn2+，Pr3+	58	843
Zn2GeO4:Mn2+	24	144

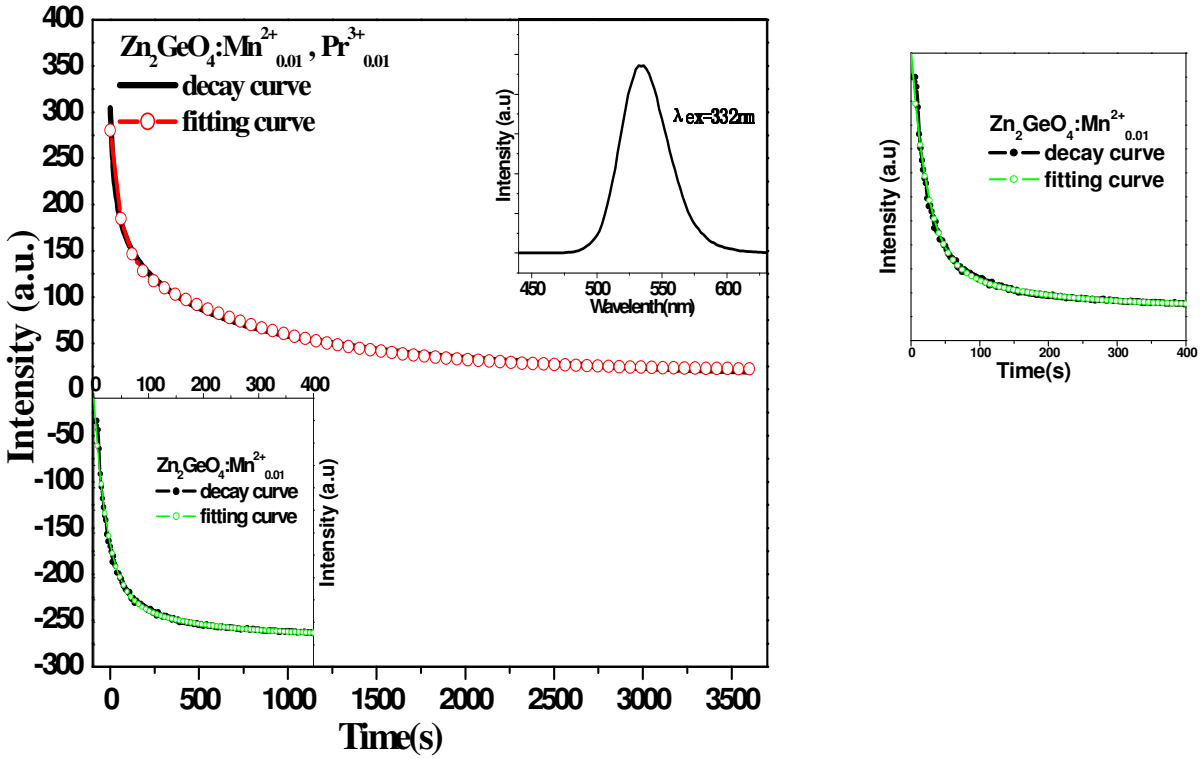

Fig.4 Afterglow decay curve of $Zn_2GeO_4:Mn_{0.02}^{2+}$, Pr^{3+} excited by a 254nm ultraviolet lamp at room temperature. The bottom inset is the afterglow decay curve of $Zn_2GeO_4:Mn_{0.02}^{2+}$ excited by a 254nm ultraviolet lamp at room temperature. Long afterglow intensity (I) monitored at 532nm as a function of time (t). The phosphors were irradiated for 5 minutes. The fitting curves are shown as green line and red line with empty circle. The upper inset shows the persistent luminescence emission spectrum recorded at 1h after the stop of the irradiation.

Thermoluminesecence characteristics

As already known, the afterglow of the phosphors is considered to be generated by the detrapped carriers which recombine in the luminescent centers accompanied by the decay emission, hence the traps which induced by the lattice defects in the phosphor play an important role on the afterglow. In order to investigate the relationship between the long afterglow and the trap energy level, the thermoluminescence curve which reflect the trapping property of defects were recorded and shown in Fig.4. As can be seen in Fig.4, only one peak is observed above room temperature which resides around 68℃, indicating that the sample only have one trap in the range from 25℃ to 250℃. The

TL parameters of the thermal activation energy E which is associated with the trap depth can be obtained by fitting experimental data to the general order kinetics formula. The TL intensity I as a function of the temperature T is described as follows [13,14]

$$I(T) = S\, n_0 \exp(-\frac{E_t}{k_B T}) \times [\frac{(l-1)s}{\beta} \times \int_{T_0}^{T} \exp(-\frac{E_t}{k_B T})\ dT + 1]^{-l/(l-1)} \quad (3)$$

Where I(T) is the TL intensity; E is the activation energy (trap depth); n_0 is the concentration of trap carries(electrons or holes) at t=0; s is the frequency factor; k_B is the Boltzmann's constant; β is heating rate (1℃/s in this study), and l is the order of kinetics. In this research, as the effect of s on T_m (the temperature of glow peak) is neglected and the frequency of an electron escaping from the trap is 1/s, then the thermal activation energy E(eV) could be estimated by the formula of E=T_m(K)/500 [15]. Where T_m is the temperature of the glow peak in the thermoluminesecence curve. Therefore, we can calculate the trap depth of Zn_2GeO_4:$Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ is 0.69eV. Generally, for phosphor, in order to exhibit long afterglow at room temperature, it is crucial to have a suitable trap level and trap density. If the depth of the trap level is too low, the electron in the trap can return to the energy level of the excited state easily, thus resulting in poor afterglow property. On the other hand, if the trap depth is too deep, the energy necessary for the electron to return to the excited state level is so difficult to obtain at room temperature, also resulting in short afterglow time. As previous reported, the trap energy(0.65eV-0.75eV) whose TL peaks located at 50~110℃ can generate optimal long afterglow at room temperature [16]. According to the calculated trap depth and the position of TL peak, we believe that the Zn_2GeO_4:$Mn^{2+}_{0.01}$, $Pr^{3+}_{0.01}$ phosphor have an opportune trap depth so that the sample could exhibit excellent afterglow at room temperature.

In the previous research, we know that Zn_2GeO_4 was a native defect material whose lattice defects have already existed even without (co-)doping other ions [15]. When Pr^{3+} ions were doped into Zn_2GeO_4, they would substitute the divalent cation Zn^{2+}, which have mentioned in the part of phase structure. As the introduction of Pr^{3+} ions, the periodic structure is distorted and the disturbances in the crystal planes are generated since the radius of Pr^{3+} is much bigger than that of Zn^{2+} [20]. It means that the addition of Pr^{3+} ions in the Zn_2GeO_4 lattice results in cationic distortion and new defects. Meanwhile, the addition of Pr^{3+} ions in the lattice also results of the charge compensation. As two Pr^{3+} ions substitute two Zn^{2+} sites, in order to keep the charge balance, one cation vacancy, which possesses two negative charges, is created in the vicinity. So the depth of traps formed by the lattice defects would modify by the clustering of the Pr^{3+} ions which lead to the disturbances and cation vacancies. Those increase lattice defects may have contribution on the modification of the trap depth and the new depth of trap is suitable for generating afterglow. Additional, since the Pr^{3+} is difficult to be reduced to Pr^{2+}. When two Pr^{3+} ions substitute two Zn^{2+} sites, two positive defects of $Pr^{\bullet}_{Zn}$ and one vacancy defect represented as $V^{''}_{Zn}$ with two negative charges would be created by each substitution of every two Pr^{3+} ions in the compound of Zn_2GeO_4:$Eu^{3+}_{0.01}$. From the previous knowledge about the long afterglow, the energy transfer from Pr^{3+} or various vacancies to Mn^{2+} in long-lasting afterglow may be possible. So the $Pr^{\bullet}_{Zn}$ defects may act as electron traps which are connected by $V^{''}_{Zn}$ and the part of the electrons trapped by oxygen vacancies transfer to the Pr^{3+}, forming Pr^{3+} reduce to Pr^{2+}or $Pr^{3+} + e^{-}$. The detrapping of electrons delays the emission then could prolong the persistent luminescence.

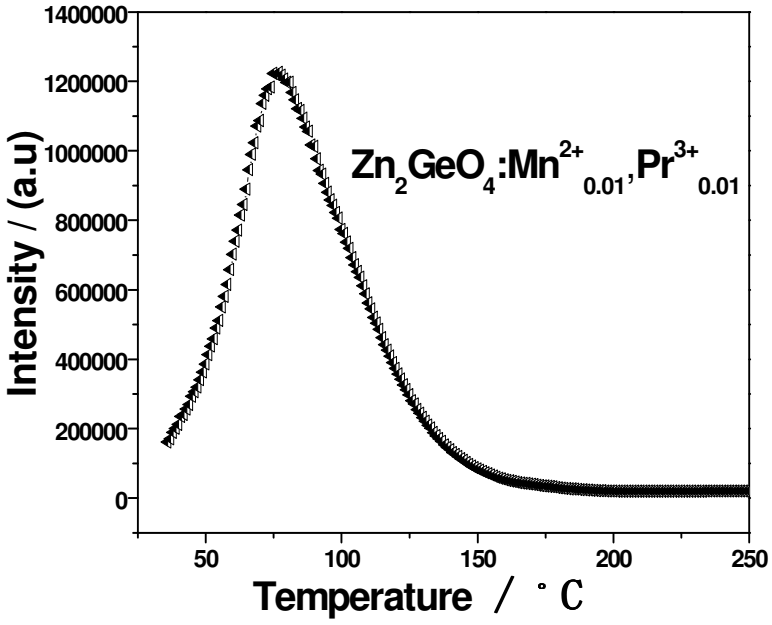

Fig.4. Thermoluminescence curve of $Zn_2GeO_4:Mn^{2+},Pr^{3+}$phosphor at region of 30℃～250℃. The sample was irradiated for 5 minutes before the measurement, with the excitation of a UV (about 254nm) lamp for 3 minutes first.

Previous studies [20] and the above results lead to a possible mechanism of long-lasting afterglow of Mn^{2+} and Pr^{3+} co-doped Zn_2GeO_4. A general schematic of the afterglow process in $Zn_2GeO_4:Mn_{0.01}{}^{2+}$, Pr^{3+} is illustrated in Fig.5. As the oxygen vacancy ($V^{\bullet}_O$) or Zn interstitial ($Zn^{\bullet}_i$) is positive charged, it will act as electron traps. The germanium vacancy (V_{Ge}) or zinc vacancy ($V^{''}_{Zn}$) is negative charged and it can trap holes. Firstly, upon ultraviolet light irradiation, a large number of holes and electrons created(progress①). Then the energy associated with the excited carriers (electrons or holes) will be transferred via the lattice directly to the luminescence centers Mn^{2+}, followed by the Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ emission as the immediate luminescence (progress②). However, part of the excitations trapped by the oxygen vacancies may transfer to the Pr^{3+} and form Pr^{2+}or $Pr^{3+} + e^-$ in the clusters, instead of returning to the ground state (progress③). After stopping UV irradiation, with the thermal disturbance at proper temperature, these electrons trapped by Pr^{3+} will be released from the traps and transferred via the host to the luminescence center then recombine with the opposite charge, followed by the characteristic Mn^{2+} emissions as long afterglow (progress④).

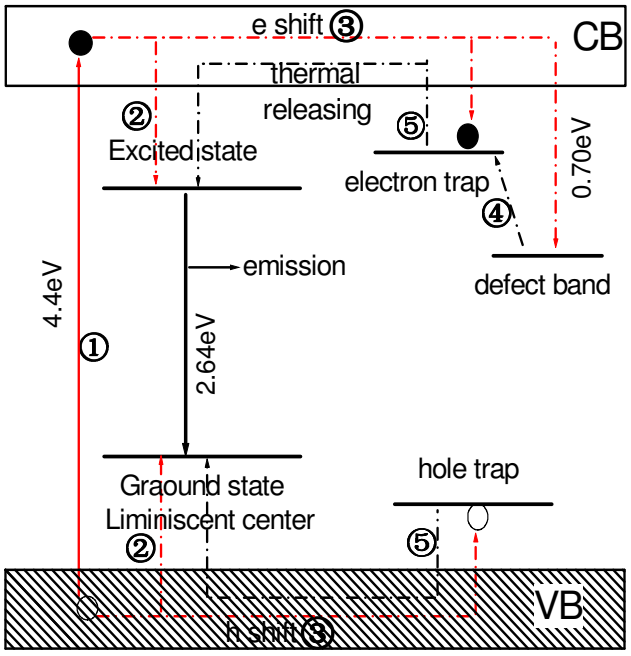

Fig.5 The schematic diagram of the long-lasting luminescence mechanism

Conclusion

In the present study, a novel phosphor $Zn_2GeO_4:Mn^{2+},Pr^{3+}$ were prepared by a high temperature solid state reaction in air atmosphere at 1300℃for 5 h. The investigation of the luminescent properties the $Zn_2GeO_4:Mn^{2+},Pr^{3+}$ phosphor has been carried out. The doped of Mn^{2+} or Pr^{3+} has little influence on the structure of the Zn_2GeO_4 lattice. The results showed that the emission spectra and afterglow spectra of $Zn_2GeO_4:Mn^{2+}$, Pr^{3+} exhibited a narrow emission band at 532 nm due to the $^4T_1 \rightarrow {}^6A_1$ transition of Mn^{2+} ions. With the Pr^{3+} ions co-doping in $Zn_2GeO_4:Mn^{2+}$, the afterglow characteristic was found to be enhanced greatly. It is ascribes to the trap which is created by the disturbances in the crystal planes and the introduction of the cation vacancies. Further analysis showed that the Pr^{3+} ions may behave as the electron trapping centers and the traps induced by Pr^{3+} possess an optimum depth for detrapping, so the Pr^{3+} doping prolonged the persistent luminescence. According to the results in this paper, we may arrive the conclusion that the $Zn_2GeO_4:Mn^{2+},Pr^{3+}$ may be a novel and promising long afterglow phosphor which have a potential application in many areas such as the traffic signs, emergency signage, display, optical memory and imaging storage.

Keywords: long afterglow phosphors; $Sr_4Al_{14}O_{25}:Eu^{2+}$; luminescent properties; luminescent mechanism

Abstract: Dy^{3+} doped blue-green Eu^{2+} doped strontium aluminate ($Sr_4Al_{14}O_{25}:Eu^{2+}$) phosphor was prepared using a high temperature solid state method and the influence of the doped Dy3+ on the luminescent properties was studied using X-ray diffraction, scanning electron microscopy, fluorescence spectroscopy and a series of other characterization methods. It is found that Dy3+ doping can enhance the luminescent intensity and extend the afterglow time. The luminescent mechanism of rare earth ions doped strontium aluminate phosphor was also discussed deeply, the effects of the doping amount on the luminescent properties has been made detailed explanation and description. This work has important theoretical significance for the development of higher brightness and longer afterglow blue-green phosphors.

Intruduction

Despite the long afterglow phosphors and its associated light-emitting products have been gradually realized in industrialization and commercialization, it still needs further research. As a kind of "green" and no pollution cold source, rare earth doped $MAl_2O_4:Eu^{2+}$ (M=Mg, Ca, Sr, Ba) has been called the second generation of long afterglow phosphors, which also has great application prospects in the field of printing, dyeing, ceramics, decorative, military, traffic signs and other aspects. This kind of luminescent materials has excellent afterglow luminescent properties, such as: long afterglow, high luminescent intensity, stable chemical property, etc., which is one of the main developing directions of luminescent materials.

The internal structure and the performance will be different if the crystalline of substances are different. For example, the $SrAl_2O_4:Eu^{2+}$ phosphor issues yellow-green light [1], but $SrAl_4O_7:Eu^{2+}$ phosphor shows blue long afterglow luminescence [2], while $Sr_4Al_{14}O_{25}:Eu^{2+}$ phosphor mainly characterizes blue-green light [3]. The research of strontium aluminate phosphors mainly focuses on $SrAl_2O_4:Eu^{2+}$[4-12], while the study of other strontium aluminate crystallines is relatively less. The common problem of the prepared blue or blue-green long afterglow luminescent materials are that the afterglow is short, and the research of the relationships between the structure of the material, the sintering temperature, the excitation light, the trap depth, and the afterglow time are still not sufficient, the unified and complete theoretical system of the luminescent mechanism is also not formed. So the exploration of the impact of additives on the blue-green long afterglow materials is one of the most urgent problems to be solved for the research field of the rare earth doped strontium aluminate phosphors.

The blue-green strontium aluminate ($Sr_4Al_{14}O_{25}:Eu^{2+}$) phosphor has been studied in this paper, the long afterglow luminescent mechanism has been explored through the research of the influence of assistant activator Dy on the luminescent properties, and combined with external morphology, internal structure, and the relationship between these factor and the luminescent performance. The research of the effect of activators on the performance and mechanism of the phosphors has great significance on the preparation of better blue-green $Sr_4Al_{14}O_{25}:Eu^{2+}$ long afterglow phosphor.

Experimental section

Material preparation

In accordance with the stoichiometry of $Sr_4Al_{14}O_{25}$ chemical formula, the raw materials have been accurately weighed. The strontium carbonate ($SrCO_3$) and alumina (Al_2O_3) were acted as a matrix material. Boric acid (H_3BO_3) was acted as a flux, and its addition amount was set at 10 mol% of Al_2O_3 on the basis of the pre-process optimization. Europium oxide (Eu_2O_3) was an activation agent, its addition amount was Eu / Sr = 2 mol%. The samples were prepared by high temperature solid state method, and the carbon powder (C) was selected as the reductant in order to reduce costs and operate safely. The reductant C was added in sufficient quantities to make the raw materials fully reduced. Dysprosium oxide (Dy_2O_3) was added as an assistant activator, the doping amount of Dy was Dy / Sr = 0 mol% , 0.2 mol%, 0.5 mol% , 1 mol% , 2 mol% , 3 mol% , with the samples labeled as D0 , D1, D2 , D3 , D4, D5, respectively.

The reaction raw materials were sufficiently mixed and grinded in an agate mortar for 20 minutes, then, placed in the corundum boat and heated for 1 hour in the incubator at 90 ℃.

Experimental scheme

After the raw materials being dried, it was pushed into the center of the high-temperature program-controlled atmosphere heat treatment furnace. Then, set the heating-cooling process and sintered the $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphor. The heating rate was set to 4 ℃ / min, the sintering temperature was 1400℃, and the holding time was set to be 2 hours. When the process finished, the sample cooled to room temperature naturally, removed from the furnace, and grinded to powder in the agate mortar.

The chemical reactions occurred in the pipe furnace were as follows:

$$SrCO_3 \xrightarrow{\Delta} SrO+CO_2\uparrow \quad (1)$$

$$C+CO_2 \xrightarrow{\Delta} 2CO \quad (2)$$

$$4SrO+7Al_2O_3 \xrightarrow{\Delta} Sr_4Al_{14}O_{25} \quad (3)$$

$$Eu_2O_3+Dy_2O_3+Sr_4Al_{14}O_{25}+CO \xrightarrow{\Delta} Sr_4Al_{14}O_{25}:Eu^{2+},Dy^{3+}+CO_2 \quad (4)$$

Testing equipments

X-Ray diffractometer

XRD (X-Ray diffractometer system, Dandong Tongda TD-3500 instrument manufacturing) was used to analyze the crystal structure of the luminescent powder. The testing result was compared with the standard JCPDF card. Cu Ka radiation (λ = 1.5406 nm) was used when testing, the tube voltage was 35 kv, tube current was 30 mA, scanning speed was 0.05 degrees/s and the scan area was arranging form 10 degrees to 80 degrees.

Scanning electron microscope

The surface morphology of the samples was examined by scanning electron microscopy (SEM, SU1510, Hitachi, Japan) with the operating voltage of 25 kV. All the samples were evaluated without any pretreatment.

Fluorescence spectrometer

The RF-5301 PC fluorescence spectrometer was used to analyze the fluorescence spectral characteristics of the luminescent materials. The slow scanning speed and low sensitivity were selected.

Results and discussion

The influence of Dy2O3 doping amount on the crystal phase

The matrix structure of materials has great influence on the luminescent performance of phosphors. So, it is necessary to analyze the crystal phase of the samples prepared in the experiments. The XRD pattern of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphors prepared with different Dy_2O_3 doping amount was shown in Figure 1.

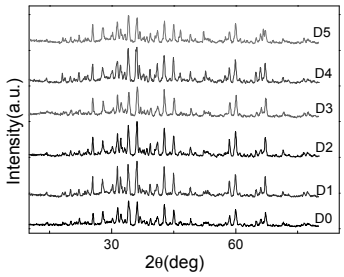

Figure 1 The XRD pattern of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphors with different Dy_2O_3 doping amount.

In this figure, the diffraction peaks displayed are consistent with the standard map JSPDS74-1810, which shows that, the strontium aluminate obtained by the experiment is the monoclinic phase of $Sr_4Al_{14}O_{25}$. It is known from the curve that, the diffraction peaks are basically identical with each other, the crystal structure changes a lot bit, and the crystal type transformation is good. This result proves that, the matrix phase composition not change when the Dy_2O_3 doping amount is different. But the diffraction peak intensity of each sample are different, as the doping concentration of Dy_2O_3 increases, the diffraction peak presents the trend of increases first, then decreases.

The influence of Dy2O3 doping amount on the morphology

According to the microstructure, grain boundary, grain size, agglomeration degree and crystal growth situation, the luminescent performance of the samples could be analyzed. The SEM diagram of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphors with different Dy_2O_3 doping amount was shown in Figure 2.

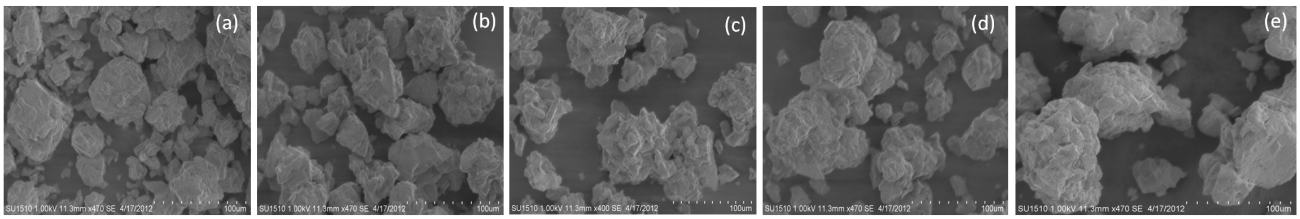

Figure 2 The SEM figure of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphors with different Dy_2O_3 doping amount. (a) Dy/Sr=0%; (b) Dy/Sr=0.2%; (c) Dy/Sr=0.5%; (d) Dy/Sr=1%; (e) Dy/Sr=2%

It is obtained from the figure that, the crystal edge and crystal plane are very clear, and the particle size are quite large for all the samples, which shows that, the crystalline state of the samples are very well, and the impact of Dy_2O_3 doping amount on the particle size of the phosphor is not big. This is consistent with the results of the XRD detection.

The influence of Dy2O3 doping amount on the fluorescence spectrum

The excitation and emission spectrum are important parameters for luminescent materials. The excitation spectrum of the sample was tested firstly to get the optimal excitation wavelength. Then, under the excitation of this wavelength, the emission spectrum was measured to obtain the emission wavelength of sample, which revealed the luminescent color of the sample. The excitation and emission spectrum of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} with different Dy_2O_3 doping amount were shown in Figure 3 and Figure 4, respectively.

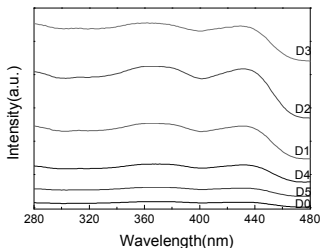

Figure 3 The excitation spectrum of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} with different Dy_2O_3 doping amount. The slit width was 3 nm.

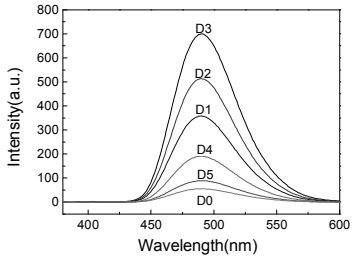

Figure 4 The emission spectrum of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} with different Dy_2O_3 doping amount. The excitation wavelength was 370 nm, the slit width was 3 nm.

It can be seen from the excitation spectrum that, the excitation peaks of each samples are all broadband peak and the peak position is near 370 nm and 430 nm, which mean that, these samples can be stimulated by visible light. The intensity of the excitation peaks changes regularly as the Dy_2O_3 doping amount increasing, the peak intensity increases first, then decreases. It might be relevant with the ability of the electron capturing and hole formation of Dy^{3+}.

From Figure 4, it is clear that, the emission peak is very weak without Dy_2O_3. As the Dy_2O_3 doping concentration increasing from 0 to 1%, the samples has the same emission spectrum shape, the peak position is about 490 nm, and the peak intensity increases gradually. The emission peak intensity reaches the maximum value when the doping content of Dy_2O_3 is 1%, and the values decrease as the doping amount increases continuously.

Because of the radius of Dy^{3+} and Al^{3+} is so different that, Dy^{3+} cannot occupy Al^{3+} in the $Sr_4Al_{14}O_{25}$ matrix. So, when Dy^{3+} is introduced into the lattice, it will take the place of Sr^{2+}. For this is an inequivalent replacement, the electronic trap will be formed. It is known that, the intensity of emission spectrum has great relationship with the density of electronic trap. So, when the doping amount of Dy^{3+} is small, the electronic trap density will be low, and the speed of electronic releasing will be slow. Under this condition, the composition of the electron (which released by electron trap) and the hole (which released by the hole trap) around the Eu^{2+} luminescent center will be slow, then, the releasing speed of photon will be slow too, which resulting the wake emission peak intensity. With the increases of Dy_2O_3 doping amount, the electronic trap goes denser, the electronic release rate become quicker, the composition rate of the electron and the hole become quicker, so, the emission peak intensity gradually increase. When the Dy_2O_3 doping amount increases to a certain extent, the electronic trap density will become too big that the release rate of photons in the luminescent center will be affected, the concentration quenching will be occurred and the emission peak intensity will be decreased. So, in order to obtain the biggest emission intensity, the doping amount of Dy_2O_3 should be controlled at an optimum concentration.

The influence of Dy2O3 doping amount on the afterglow properties

Long afterglow phosphors have an afterglow decay process, that is, after the external excitation stopping, the materials still can shine for a period of time, the luminescent intensity becomes wake and wake until the intensity reduced to 0.32 mcd/m^2, which cannot be seen by naked eyes. The afterglow decay process can be divided to two processes: fast decaying and slow decaying. The afterglow time and persistence brightness are two important parameters to evaluate the light storage performance of long afterglow luminescent materials, which can influence the application prospect and application scope of the luminescent materials to a great extent. The persistence characteristics are different for different materials, which can be expressed by the following formula [13]:

$$I = \alpha_1 \exp(-t/\tau_1) + \alpha_2 \exp(-t/\tau_2) + \alpha_3 \exp(-t/\tau_3) + \cdots \quad (5)$$

where, I is luminescent intensity, t is time, α_1, α_2, α_3 are constant, τ_1, τ_2, τ_3 are index afterglow time.

The luminescent brightness and persistence performance of the samples prepared in our experiment are very well, the afterglow time is more than 24h by visual observation. The equipment detection method of the persistence characteristic is as follows: After located in dark room for 24 h, the $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphor is put into the fluorescence spectrometer, then, set the parameters, open the xenon lamp 20 min to exposure the phosphor and then close the light source, test the afterglow decay curve. The excitation wavelength is set for 370 nm, and emission wavelength is 490 nm when testing. The exponential decay curve of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphor with different Dy_2O_3 doping amount are shown in Figure 5. From this figure, it can clearly see the fast decaying and slow decaying of the afterglow decay process. The relationship between afterglow time and Dy^{3+} doping concentration is shown in Figure 6.

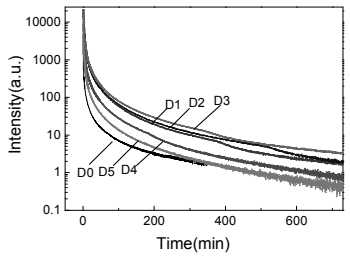

Figure 5 The exponential decay curve of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphor with different Dy_2O_3 doping amount.

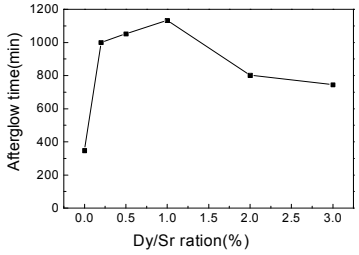

Figure 6 The relationship between Dy_2O_3 doping concentration and long afterglow time.

It can be seen from the afterglow decay curves that, the afterglow time is very short without the doping of Dy_2O_3. As one of the assistant activator, Dy^{3+} do not act as luminescent center [14, 15] in the strontium aluminate matrix, but it has appropriate radius and optical electronegativity, which can slowly release the trapped electrons or holes to the $4f^6 5d^1$ excited state of Eu^{2+}, and produce long afterglow luminescence. For it has been discussed that, the addition of Dy^{3+} can induce inequivalent replacement, and the traps of the $Sr_4Al_{14}O_{25}:Eu^{2+}$ matrix will be increased and the luminescence will be enhanced. So, the initial brightness will be improved accordingly. When the doping concentration of Dy^{3+} is 0, the initial brightness is low, and the composition of electron and hole is less, the afterglow time will be short. As the doping concentration increases, the depth of the electronic trap become deeper and the density of electronic trap increase. So, when the doping concentration increases from 0.2% to 1%, more and more electrons can be captured and then released slowly under the action of thermal disturbance, which resulting the better initial brightness and longer afterglow time. But, when still increase the doping amount, because of the depth of the electronic traps is too deep and the density is too big that the composition of electron and hole will be bounded, which will result low initial brightness and short afterglow time.

The influence of additives on the long afterglow luminescent mechanism

The luminescent mechanism models including hole transfer model, location coordinate model, electronic transfer model, energy transfer model, thermal luminescent model, etc [16-19]. These mechanistic models all give some interpretation and speculation in different extent about the afterglow behavior of rare earth activated strontium aluminate phosphors. However, there are still lack of a complete, accurate, and universal significant theory. The most commonly recognized statement of the previous mechanism is that, the luminescent phenomenon of Eu^{2+} activated strontium aluminate phosphor is caused by the $4f^6 5d^1$- $4f^7$energy level transition of Eu^{2+} in the lattice. When the phosphor is irradiated by the external light, the $4f^7$ ground state electron will be inspired to the excited state. The excited electron can transform to the ground state after the excitation stopped, and emit light. In this section, the long afterglow luminescent mechanism of BO_3^{3-} and Dy^{3+} doped $Sr_4Al_{14}O_{25}:Eu^{2+}$ phosphor was systematically discussed based on the previous research and the results of our experiment.

In the preparation process of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphor, both the doping of rare earth ions and the changing of matrix composition can lead to the point defect. Because the ion radius of Eu^{2+} and Dy^{3+} is close to Sr^{2+}, and much bigger than that of the Al^{3+}, this two doped ions will take place of Sr^{2+}. The radius of B^{3+} is smaller than Al^{3+}, but the electronegativity of B^{3+} is greater than that of Al^{3+}. After doped into the matrix, BO_4^{5-} will partial substitute AlO_4^{5-} to obtain stronger ionicity [20]. The XRD results of this experiment also prove that, the doping of Eu^{2+}, Dy^{3+} and BO_3^{3-} does not change the crystal phase of $Sr_4Al_{14}O_{25}$, only affects the diffraction peak intensity.

When the position of Sr^{2+} is replaced by Eu^{2+}, the point defect (Eu_{Sr}) and (V''_O) will be occurred. Where, (Eu_{Sr}) acts as luminescent center and (V''_O) acts as electronic trap. But the doping of Dy^{3+} is an unequivalent substitution, which will produce three kinds of point defects for once two Dy^{3+} doped into the lattice, one Sr^{2+} vacancy will be formed in order to keep the charge balance. This will form ($Dy^{\cdot}_{Sr}$), (V''_O) and (V''_{Sr}) three point defects [21]. Under the carbon powder reduction atmosphere, Eu^{3+} will be reduced to Eu^{2+}, at the same time, one O atom will be removed from BO_4^{5-} and the (BO_3''') vacancy will be formed. So, the main point defects in the $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} lattice are as follows: ($Dy^{\cdot}_{Sr}$) and (V''_O) are positively charged, which called electronic trap for they can capture electrons, (V''_{Sr}) and (BO_3''') are negatively charged, which called hole trap for they have the ability of capturing holes.

The long afterglow luminescent mechanism of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphor can be explained through the following process, which is displayed in Figure 7:

(1) Under the excitation of ultraviolet visible light, the electron – hole pairs are produced in the conduction band and valence band of $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+}, respectively, as shown in Figure 7, process (1).

(2) These electrons and holes move freely in the band. Through the heat balance, electrons drop to the bottom of conduction band quickly, while holes quickly rise to the top of the valence band. The electrons captured by the electronic trap ($Dy^{\cdot}_{Sr}$) and (V''_O) when diffusing in the conduction band. During this process, the electronic traps can store a lot of electrons and form ($Dy^{\cdot}_{Sr}e'$) and ($V''_O 2e'$), as shown in Figure 7, process (2).

(3) Partial trapped electrons can transit back to the conduction band under the action of thermal disturbance. As shown in Figure 7, process (3).

(4) The similar process also occurred in the valence band. Holes trapped by the hole traps (V''_{Sr}) and (BO_3''') to form ($V''_{Sr}2h^{\bullet}$) and ($BO_3'''3h^{\bullet}$). As shown in Figure 7, process (4).

(5) Partial trapped holes also can transit back to the valence band through the action of thermal disturbance. As shown in Figure 7, process (5).

When ($Dy^{\cdot}_{Sr}e'$), ($V''_{O}2e'$), ($V''_{Sr}2h^{\bullet}$) and ($BO_3'''3h^{\bullet}$) are excited by the thermal disturbance of the environmental temperature, the following reactions can be occurred, electrons and holes will be released.

$$(Dy^{\cdot}_{Sr}e') \longrightarrow Dy^{\cdot}_{Sr} + e' \quad (6)$$

$$(V''_{O}2e') \longrightarrow V''_{O} + 2e' \quad (7)$$

$$(V''_{Sr}2h^{\bullet}) \longrightarrow V''_{Sr} + 2h^{\bullet} \quad (8)$$

$$(BO_3'''3h^{\bullet}) \longrightarrow BO_3''' + 3h^{\bullet} \quad (9)$$

(6) The released electrons and holes can also composite in the (Eu_{sr}) luminescent center, which will release photon and produce long afterglow luminescent phenomenon. As shown in Figure 7, process (6).

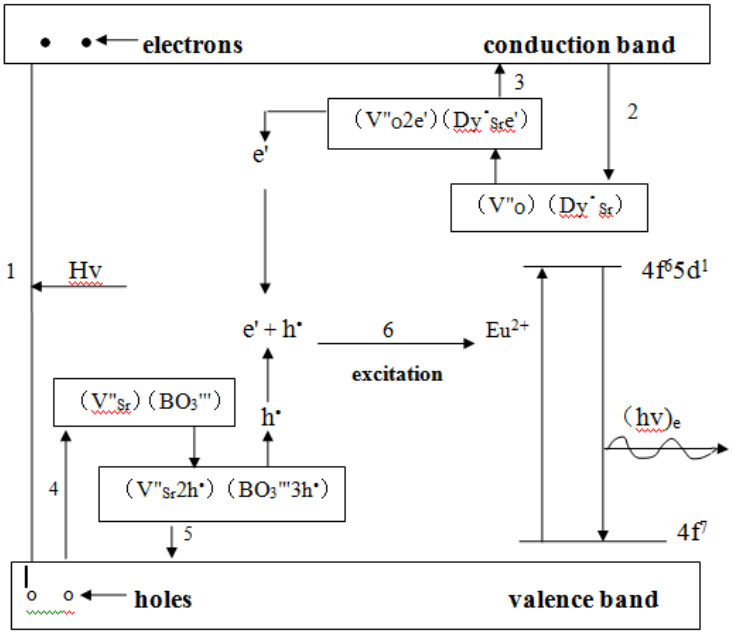

Figure 7 The schematic diagram of the luminescent mechanism for $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphor.

The fast and slow decaying process of afterglow decay phenomenon can be explained by the above process. After the excitation of the external light, the electrons and holes in a shallow trap can quickly get rid of the trap under the thermal disturbance of the environmental temperature, then composite and emit light in the Eu^{2+} luminescent center. This is the fast decay process of the long afterglow luminescence. In the deep traps, the releasing probability of the trapped electrons or holes is small, they can only slowly released to the conduction band or valence band, their composition and emitting is slowly too, which will result slow decay process of the long afterglow luminescence for few minutes or several hours.

Experiments have proved that, the doping amount of the additive has great effect on the luminescent performance of the phosphors. The luminescent performance has the characteristics of enhanced firstly then weakened with the increasing of the doping amount. When the doping concentration of other additive is not changed and the doping amount of Dy^{3+} is low, the formation of (V''_{O}) and ($Dy^{\cdot}_{Sr}$) is less, for Dy^{3+} has little opportunity the doping into the lattice and replace the position of Sr^{2+}. The trapping and releasing of electrons or holes will be less, and the photons released from the composition will be less too, which will result low initial brightness and short afterglow time. As the doping concentration increases, more Dy^{3+} will replace the poison of the Sr^{2+}, and the depth and density of the electronic traps will be increased, which will lead to stronger initial

brightness and longer afterglow time. But when the doping concentration exceed to the critical concentration, the electronic trap is too deep and the density is too large that, the composition of electrons and holes will be bounded, and the releasing speed of the photon also will be slow down, which will result lower initial brightness and shorter afterglow time. That is to say, when the doping amount exceed to the critical concentration, concentration quenching phenomenon will be happened.

The influence of other addictive on the phosphors can be explained similar as the above discussion. In the preparation process of the $Sr_4Al_{14}O_{25}:Eu^{2+}$, Dy^{3+} phosphor, the addition of H_3BO_3 also can increase the electronic traps and the hole traps. As the concentration of H_3BO_3 increase, on the one hand, the formation of $Sr_4Al_{14}O_{25}$ crystal phase will become easy and the preparation temperature could be reduced, on the other hand, the depth of the traps becomes deeper, and the density of the traps increases too. But, if too much H_3BO_3 is added, the glass state borate will be separated out, the formation ratio of the $Sr_4Al_{14}O_{25}$ crystal phase will be decrease, and resulting low luminescent intensity.

Conclusions

The Dy^{3+} doped $Sr_4Al_{14}O_{25}:Eu^{2+}$ phosphor has been prepared by the high temperature solid state method. The afterglow time of the phosphors prepared in our experiments was more than 24 h. A series of characterization means have been used to study the influence of doping amount on the luminescent performance of the phosphor. The results proved that, the doping of Dy^{3+} has little influence on the crystal phase and the morphology, but has great effect on the luminescent performance of the phosphor. The emission peak intensity of the $Sr_4Al_{14}O_{25}:Eu^{2+}$ sample increased as the doping concentration of Dy_2O_3 increasing in the range of 0 to 1%. While, the intensity decreased as the concentration increasing in the range of 1% to 3%. With the increasing of the Dy^{3+} doping concentration, the afterglow time of the samples also expressed the similar tendency. Based on the above results, the important role of additives (Dy^{3+} and BO_3^{3-}) in the luminescent mechanism of phosphor has been further discussed. The reason of why the doping amount can greatly influence the photoluminescent properties also has been explained in detail. This study can provide useful theoretical guidance for the preparation of more excellent long afterglow phosphors.

Keywords: bilayered perovskites; magnetic property; electrical property

Abstract: The nominal compositions of $La_{1.4}Sr_{1.6-x}Mg_xM_{n2}O_7$ (x=0, 0.1, 0.2, 0.3, 0.4) have been synthesized using solid-state reaction method. The XRD analyses show that the x=0 compound is pure I4/mmm tetragonal bilayered perovskites phase, while they are mixture of an orthorhombic ABO_3-type perovskite and tetragonal bilayered perovskites for x=0.1, 0.2 and 0.3). When x is 0.4, the compound is pure orthorhombic ABO3-type perovskite. For lightly doped samples (x=0.1 and 0.2), the Curie and Nair temperature decreases with the increasing Mg^{2+} doping, while the metal-insulation transformation temperature is 90K and 140K, respectively. For heavy doped samples (x=0.3 and 0.4), the magnetic property shows spin-glass state, and the resistance increases nearly 4 order of magnitudes.

Introduction

The magnetoresistance effect of manganites with ABO_3 type perovskite structure can be improved by means of doping in A or B bit, which has attracted quite large attention in recent years [1-2]. The doping for A bit includes the doping of divalent alkaline earth ions and the mutual doping of rare earth ions. The doping practice can change the size of lattices and influence the changes of Mn-O bond length and Mn-O-Mn bond angles, thus further influencing the double-exchange interaction, and it can also indirectly change Mn^{3+}/Mn^{4+} ratio through replacement among icons with various valence states; besides, the changes of average ionic radius after doping can strengthen the distortion of lattices, all of which can influence the magnetoresistance effect of materials.

Many researchers have researched the replacement in La/Sr and Mn bits of double-layer perovskite compound $La_{1.4}Sr_{1.6}Mn_2O_7$ [3-4]. We have also researched the structure, magnetism and magnetic entropy property of $La_{1.4}Sr_{1.6-x}Ca_xMn_2O_7$. The reason why we select Ca^{2+} ion to replace Sr^{2+} ion is that the two ions have the same valence state, thanks to which Mn^{3+}/Mn^{4+} ratio in Mn bit can remain unchanged after their replacement; besides, the radius of Ca^{2+} ion (1.0Å) is lower than that of Sr^{2+} ion (1.26 Å), and great disputes have remained among various research groups in terms of the synthesis of $La_{1.4}Ca_{1.6}Mn_2O_7$ compound. Therefore, the influence of Ca ion replacement on the structure and magnetism of $La_{1.4}Sr_{1.6-x}Ca_xMn_2O_7$ is investigated. Double-layer perovskite structure can still be formed until x=0.8, while the structure is completely disappeared and replaced by ABO_3 type perovskite phase and CaO with x>0.8, which suggest that the mismatching of ionic radiuses can directly influence the phase stability of double-layer perovskite structural $La_{1.4}Sr_{1.6}Mn_2O_7$.

In periodic table of elements, the radius of Mg^{2+} ion is relatively small (0.72 Å) under the same valence state. If we conduct Mg^{2+} ion replacement in Sr bit, will the mismatching between ions with relatively large radius difference still be able to ensure the entry of Mg^{2+} ion into the Sr bit of double-layer perovskite structure, and how will it change the structure of the double-layer perovskite oxide $La_{1.4}Sr_{1.6}Mn_2O_7$ Few reports related to the above issue have been published at present, considering which we synthesized the series of oxides with $La_{1.4}Sr_{1.6-x}Mg_xMn_2O_7$ as the nominal component and researched certain properties related to their structure, magnetism and magnetoresistance.

Sample Preparation

Polycrystalline oxides with $La1.4Sr_{1.6-x}Mg_xMn_2O_7$ (x=0, 0.1, 0.2, 0.3, 0.4) as nominal components were synthesized by a solid state method. Firstly, the raw materials of La_2O_3, $SrCO_3$, MgO and MnO_2 with high purity were mixed according to the stoichiometric ratio, and then calcined for 4 hours at 900 °C after fully grounded. Finally the calcined powder was sintered for another 20 hours at 1,400 °C after another grinding and performing for them.

XRD data related to the series of compounds were collected by means of X'Pert Pro type X-ray diffractometer supplied by PANalytical Company in Netherlands. Cu target Kα rayand Nioptical filter were adopted in the diffraction experiment, during which the voltage and current were 40kV and 40mA respectively. The data were collected by continuous scanning method with a step length of 0.0167°, a rate of 30s/step and the scanning angle ranging from 20°to 120°.

The magnetism and electrical properties of the materials were tested by means of PPMS supplied by American Quantum Company. The Curie temperature (T_C) of samples was determined according to the temperature corresponding to the maximum value of low-field magnetization curve(0.05T)derivative of the temperature.

Experimental Results and Discussions

Figures1 shows the X ray diffraction patterns of $La_{1.4}Sr_{1.6-x}Mg_xMn_2O_7$ compounds with x=0.0, 0.1, 0.2, 0.3, 0.4. When x=0, the compound show a $Sr_3Ti_2O_7$ type (Type 327) tetragonal system perovskite structure with a space group of I4/mmm; crystal face indices of its main diffraction peaks are shown in Figure 3.1 respectively. When x = 0.1, new diffraction peaks appeared at 2θ of 23.02° and 40.39° respectively. The intensity of the two diffraction peaks is also gradually strengthened with the increase of x content; meanwhile, the intensity of diffraction peaks such as (105),(116),(0010) and (2010) belonging to double-layer perovskite structure is gradually reduced with the increase of x content. The new diffraction peaks belong to ABO_3type (Type113) perovskite manganite with rhombohedral structure in $R3\bar{c}$ space group.

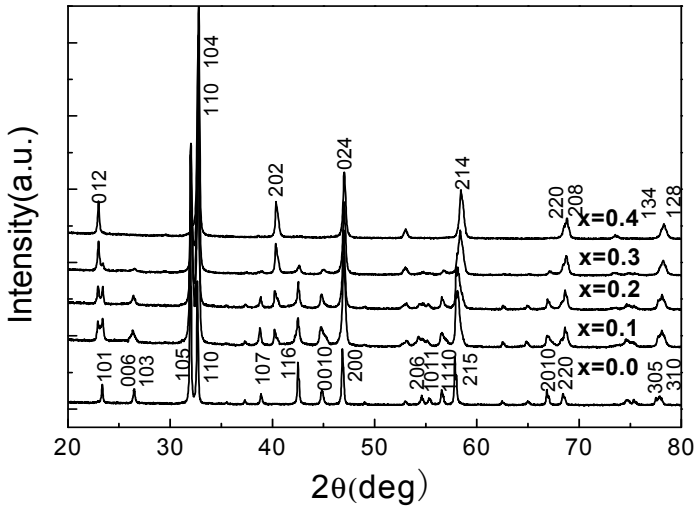

Fig1 The X ray diffraction pattern of $La_{1.4}Sr_{1.6-x}Mg_xMn_2O_7$series of compounds ($x$=0.0,0.1,0.2,0.3,0.4)

We find that Mg^{2+}ion with the radius of 0.72 Å actually enters the Mn bit of perovskite structure owing to the intensified mismatching degree of ionic radius in A bit, thus forming $La_{1.4}Sr_{1.6}Mn_{2-2y}Mg_{2y}O_7/La_{0.67}Sr_{0.33}Mn_{1-y}Mg_yO_3$(327/113) composite. Besides, with the increase of x content, the content of Phase 327 belonging to double-layer perovskite is gradually reduced, while the content of Phase113 belonging to the perovskite with infinite layers is gradually increased.

Figures2 represents variation of magnetization intensity with temperature for $La_{1.4}Sr_{1.6-x}Mg_xMn_2O_7$ under the applied magnetic field of 500Oe. According to our analysis, the sample with x=0 shows antiferromagnetic (ATM) property under 60 K: The magnetization intensity is obviously reduced with the reduction of temperature, and a peak appeared when the temperature reaches Neel temperature T_N (60 K); the magnetization intensity is rapidly reduced when the temperature is above 60 K, accompanied with self-spinning ferromagnetic orderliness and the antiferromagnetic coupling within the double layers of MnO_6[5]; when the temperature ranges from 100 K to 250K, a section of platform approximating the shape of a straight line is formed in M-T curve, which represents two-dimensional ferromagnetic orderliness; when the temperature is above 250K, the material is in the paramagnetic state.

For x=0.1 sample, the component and corresponding content are refined as 72.9(5)% $La_{1.4}Sr_{1.6}Mn_{1.9}Mg_{0.1}O_7$ and 27.0(5)% $La_{0.67}Sr_{0.33}Mn_{0.95}Mg_{0.05}O_3$.Two transformation temperatures are obviously formed in the material: T_N of Phase 327 is reduced to roughly 20K, while *Tc* of Phase 113 is transformed to roughly 320K (the Curie temperature of pure $La_{0.67}Sr_{0.33}MnO_3$is 360K[6]). Two main reasons are suggested for the change in the transition temperature: Firstly, since Mg ion is nonmagnetic, its doping can reduce the total magnetic moment in the system; owing to the random place holding of Mg ion, the original long-range ferromagnetic order of the material is damaged, thus making the double-exchange interaction in Mn^{3+}-O-Mn^{4+} net structure restrained.

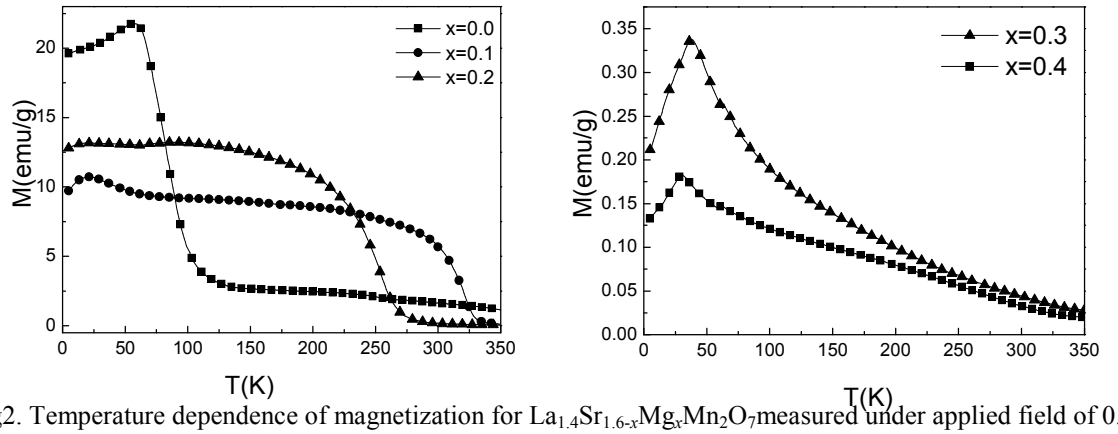

Fig2. Temperature dependence of magnetization for $La_{1.4}Sr_{1.6-x}Mg_xMn_2O_7$measured under applied field of 0.05 T.

When the nominal doping quantity of Mg is increased to such a degree that x=0.2, the component of Phase 327 change into $La_{1.4}Sr_{1.6}Mn_{1.82}Mg_{0.18}O_7$ with the lower content of 58.3(1)%. The reduction of the content and the increase of Mg ion in Mn bit result in the decrease of antiferromagnetic transformation temperature in the low-temperature area of the material; meanwhile, the increase of Phase 113 increases the ferromagnetic component in the low-temperature area, which dominates the higher magnetization intensity of the sample with x = 0.2in the low-temperature area. Similarly, the further increase of Mg content in Mn bit makes the Curie temperature of the material reduced to roughly 250K in high-temperature area.

When the nominal doping quantity of Mg reaches x = 0.3 or 0.4,the magnetization intensity of the material shows obviously different characteristics. Firstly, the numerical value of the magnetization intensity is reduced by nearly 2 orders of magnitude; secondly, the Curie temperature Tc in the high-temperature area disappears, while in the M-T curves, there is an extremely sharp maximum value when the temperature is near 39K for *x*=0.3 and 30K for *x*=0.4 in the low-temperature area, which could be attributed to the high proportion of Phase 113 in the two compositions (70.5(7)% and 100% for x = 0.3 and 0.4, respectively), and the high practical Mg content of 0.13 and 0.17 respectively. Therefore, the magnetic property of $La_{0.67}Sr_{0.33}Mn_{1-x}Mg_xO_3$of Phase 113 is mainly represented in the two materials [7].

Figures3 shows the variation in the specific resistance with temperature. For sample with x=0.0, the specific resistance shows a sharp maximum value at its Curie temperature around 103K, which is corresponding with the insulation-metal transition temperature. When the temperature is higher than the corresponding temperature, the compound shows the semi-conductive property, otherwise, it represents metallicity. Therefore, this temperature is determined as an insulation-metal transformation temperature (Tρ). The sharp reduction of specific resistance below Tρ is closely related to 3D ferromagnetic self-spinning and ordering. The specific resistance of the material represents semi-conductive property when the temperature is further reduced to the Neel temperature T_N (60K). According to researches on neutron scattering[8], when the temperature is lower than T_C, the arrangement of 3D ferromagnetic orderliness will prevail with the ferromagnetic orderliness between two tilting double layers. When the temperature is lower than T_N, the stratiform antiferromagnetic orderliness will prevail. In the antiferromagnetic state, the two layers of ferromagnetic orderliness are coupled along the direction of c axis (perpendicular to the plane) in the antiferromagnetic way. Compared to the mutual ferromagnetic effect in the layer, the mutual antiferromagnetic effect between layers is weaker. Such antiferromagnetic coupling between layers may result from the obstructed tunneling penetration between layers of spin-polarized electrons , which dominates the disappearance of metallicity and the obvious enlargement of the specific resistance.

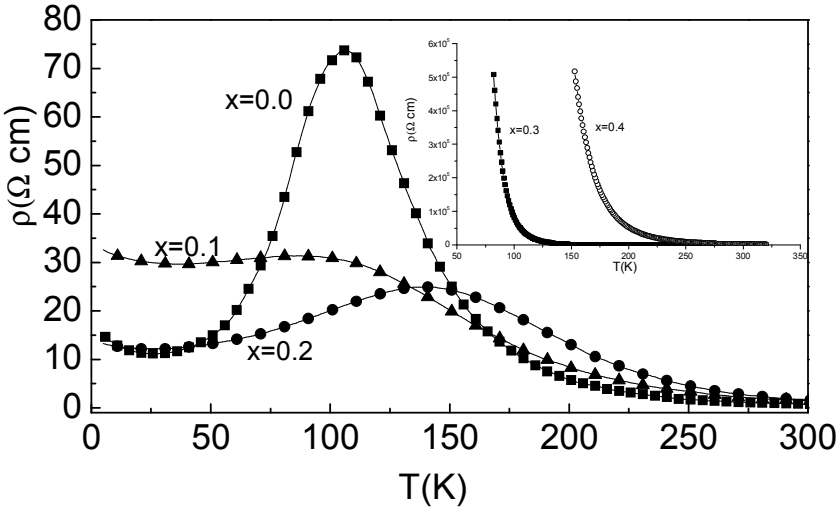

Fig3 The curve showing changes of the specific resistance of sample with $La_{1.4}Sr_{1.6-x}Mg_xMn_2O_7$ as its nominal component with temperature variation

The specific resistance of samples with x=0.1 and x=0.2 is obviously reduced with the increase of Mg content. For sample with x=0.1, its specific resistance has a T_ρ transformation temperature near 90K, while for sample with x=0.2, the T_ρ transformation temperature is near 140 K. Both transformation temperatures are lower than their Curie temperatures in the high-temperature area respectively. As is shown in the illustration of Figure 4, both the specific resistances of samples with x=0.3 and x=0.4 experience a mutation. Firstly, the numerical value of the specific resistance increases by nearly 4 orders of magnitude; secondly, the metal-insulation temperatures disappear, and the temperature zone represents insulativity throughout the measurement. The rules for the changes of the specific resistance are quite approximate to the electrical property of $La_{0.67}Sr_{0.33}Mn_{1-x}Mg_xO_3$series of compounds [9].

Conclusion

We have investigated the structure, magnetic and electrical properties of the nominal compositions $La_{1.4}Sr_{1.6-x}Mg_xMn_2O_7$. The samples are tetragonal bilayered perovskite with space group I4/mmm in the x=0 sample, while they are composed of ABO_3-type perovskite structure with space group Pbnm and tetragonal bilayered perovskite in the $0.1 \leq x \leq 0.3$ dopant regimes. When x is 0.4, the compound is pure orthorhombic ABO_3-type perovskite. For the magnetic properties, the Curie and Nair temperature first decreases with the increasing Mg^{2+} doping in the x=0.1 and 0.2 samples, then shows spin-glass state in the x=0.3 and 0.4 samples. For the electrical properties, the metal-insulation transformation temperature is 90K and 140K in the x=0.1 and 0.2 samples, respectively, and then the resistance increases nearly 4 order of magnitudes in the x=0.3 and 0.4 samples.

Abstract: The current industry needs for new results require current capabilities of computer technology can solve problems on a whole new level. This article briefly describes the algorithms for obtaining the structures and the appearance of discontinuities in the growth of crystals.

Introduction

Solution of some technological issues requires study the internal structure of electron shells. There is a problem of explaining the phenomenon of increasing orders of the electronic resistivity silicon with the introduction of a probe by the diffusion of electrons. To elucidate the structure of the outer electron shells of the 18 copper is an essential knowledge of the inner radius of these shells that is the outer radius of the lower shells. Reference data on X-ray spectra have become an important and reliable source of information on the geometrical dimensions of the inner electron shells of atoms of any chemical element.

Computer simulation of Cu structure

For example, for copper Z=29, R=0.004915 nm. Computer simulation was carried out in the cluster approximation, which consists in the fact that the volume of the crystal was cut limited selection, the initial positions of the atoms which correspond to their positions in the nodes of the real crystal lattice. For copper in Fig. 1 is shown the sphere-rod model third sphere of the fcc lattice with 24 atoms, but the model is rotated 45º around the axis z. In Fig. 2 is shown the sphere-rod model seventh sphere fcc lattice with 48 atoms. The model is rotated 45º about the axis of x. Atoms and bond rods are shown in different colors.

The modeling of properties shows that the crystal structure within a certain distance a gap of uniform growth occurs in the distances from the central atom. For copper, a spatial gap occurs after 321-th atomic node in the cluster. Further, these discontinuities are repeated periodically. And this is a defect associated with impaired growth are not in real crystals and the properties of the ideal lattice. The instability of the first cluster and the introduction of a defect in the corresponding crystal structure is the very first principle on which to conduct a fairly accurate analysis of the growth process of a real crystal and the resulting defects in it.

Copper is a metal, but also for semiconductors, computer simulation provides essential information for subsequent analysis of the process of their growth and ultimate properties. For example, computer simulation was conducted for the GaAs in the cluster approximation, which consists in the fact that the volume of the crystal was cut limited selection, the initial positions of the atoms of which comply with their provisions at the nodes of the real crystal lattice.

The lattice with a radius of 6 in her coverage of the atomic cores is considered. Calculation of the GaAs parameters were performed using the package we have created programs. As a cluster model was chosen 918-atom fragment of the crystal lattice of quantum dots based on GaAs. The properties of clusters depend on their size. Electron spectroscopy gives information averaged over the ensemble non isometric clusters on the surface and in the bulk solid. Therefore, to improve the accuracy and reliability of the information is necessary to create ensembles of clusters with a low dimensional variance.

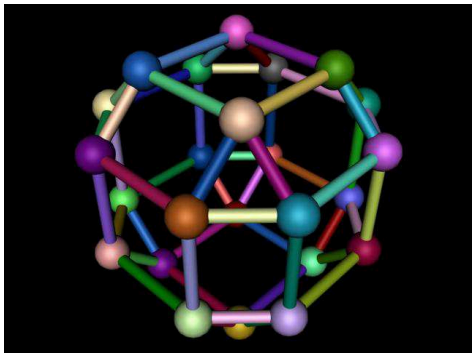

Fig. 1. The sphere-rod model third sphere model of the fcc lattice with 24 atoms. The model is rotated 45º around the axis *z*. Atoms and bond rods are shown in different colors.

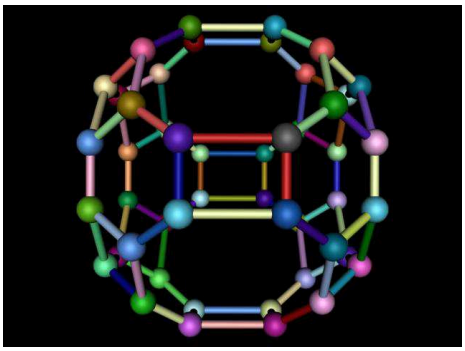

Fig. 2. The sphere-rod model seventh sphere model of the fcc lattice with 48 atoms. The model is rotated 45º about the axis of *x*. Atoms and bond rods are shown in different colors.

Consider the finite crystal with unbroken intervals (except for the crystal boundary violation). For simplicity, we take a large number of cores, when there is a nearly ideal periodicity of the crystal. In this case, the parameters obtained from the mathematical formalism for the analysis of the band spectrum are periodic functions, except for the boundary of the crystal. The crystal potential and wave functions have a period equal to the distance between the cores, depending on the chosen direction.

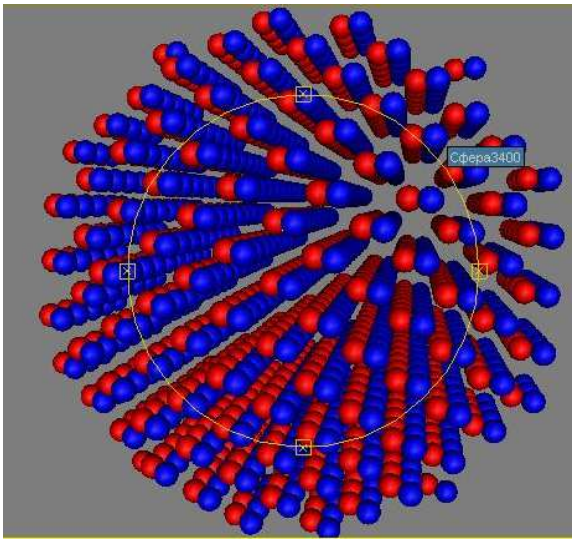

Fig. 3. The As atoms and Ga for the radius of coverage 6. Red marked atoms As, in blue denote atoms Ga. Central atom is As.

The energies have multiple frequency modulus of the wave vector in the quasi-momentum space [1]-[3]. Now turn to the crystal with a very small number of cores. In such a crystal frequency is not as ideal as in the previous case. The simulation of such a crystal is insurmountable difficulties for traditional methods, but this is the case is taken by us as a basic demonstration version. The object in question is distant from a perfect crystal due to its limited size. And despite this, the technique presented by us showed the periodicity of the above parameters. Thus in our problems are not used the condition of periodicity and Bloch's theorem as the necessary initial conditions. The Fig. 3 shows it on the example of GaAs.

Computer modeling of the crystal structure of GaAs

In computer modeling of the crystal structure of GaAs, combined with three-and five-valent elements are observed the following regularities (see Table 1). When the radius of coverage is two in this range there are 38 cores. As the first atomic core in the center of origin, the four Ga atoms are located at a distance of 3 next 12 As atoms at a distance of 8. Nine Ga atoms at a distance there are 11. Six As atoms at a distance of 16, three Ga at a distance of 19 and three Ga at a distance of 27.

Table 1. The Combined lattice GaAs

Total number of cores with zero: 38

We observe quasiperiodic change in the difference. At the border radius of coverage this periodicity is broken. When increasing the radius of coverage this periodicity is restored to the previous radius, but is broken on the new range. Thus, the boundary conditions lead to a violation of the periodicity. Simulated lattice shown in the following figures. The first figure shows the four first neighbors As in the lattice. Neighbors' ions Ga (blue) form a tetrahedron with the center of As (red). The boundary atoms can approximately account for modeling the interface of the quantum dot with the matrix. The Fig. 1 shows the grid with a radius of coverage 6. There are 918 atomic cores in it. There is a periodic step structure. The structure of the previous lattice is preserved. And the structure of the central ion and its neighbors on the tetrahedron is stored and located in the center of this lattice. It can be seen as an increase in the radius of coverage is restored periodicity in the lattice covered by the previous radius and there is a new violation of the periodicity on the boundary spanning lattice. The depth of violation increases with the radius of coverage. This is well observed in the tables you demonstrated for different cores. On the basis of the direct lattice can construct the reciprocal lattice and define the properties of the Fermi surface. And the radius of coverage can be taken arbitrary (millions of skeletons). The calculated structure allows to reach a real-time implementation and to take into account of defects and of real devices based on GaAs, because these are high-speed computing now by our proposed method. On the basis of the direct lattice we can also construct the reciprocal lattice and define the properties of the Fermi surface. And the radius of coverage can be taken arbitrary (millions of skeletons). High-speed computing enables a dynamic computer simulation of the properties of real crystals of the GaAs. Since the GaAs lattice is identical to the lattice of Si, sphalerite and diamond, we can apply the technology provided by and for these substances. In calculating of coordination spheres cells of FCC- and BCC-lattices are presented as superlattice structure to fill own nodes by atoms of cells and additional nodes of the simple cubic lattices (SCL) — interstitial atoms [2]. The completing of coordination spheres with atoms is determined on the basis of a small SC-lattice, taking into account octahedral, tetrahedral internodes. If atoms in the lattice arrange with the dense packing, P-nodes are centers of the inter-body lattices in the methods of presentment of the spatial distribution of atoms and internodes along the coordination spheres in the crystals. Tetrahedral and octahedral internodes in the ion-interionic terminology mean inter-body lattice space surrounded by the atoms in the crystal lattice nodes. Table 1 contains the number of atoms and the distance from the central

atom of the diamond-like structure. The distance is given in units of the lattice constant a. Let us choose the maximum distance based on these conditions, forming a set of atoms contributions on which the calculation of the potential are taken into account.

The crystal potential for crystals with the diamond structure

In this work we consider the crystal potential for crystals with the diamond structure. The Coulomb potential is the sum of the capacity building of the nucleus and the electrons occupied levels:

$$U_c = U_n + U_0, \tag{1}$$

where $U_n = -2Z/r$. Here, Z — number of the element, r — distance from the atom to the specified point.

Potential U_0 is a solution of the Poisson equation:

$$\nabla^2 U_0 = -8\,\pi\rho_0(r), \tag{2}$$

where $\rho_0(r)$ — the density of the electrons of the occupied levels at the distance r from the center of the atom. The density is calculated as follows:

$$\rho_0(r) = \sum_{n,l} r^2 R_{nl}^2(r). \tag{3}$$

Function $R_{nl}(r)$ — the radial part of the electron wave function for a hydrogen atom [4], [5]. Using the principle of superposition of the electronic densities and the additivity of the integral Eq. 3 can solve as follows:

$$U_0(r) = \sum_{i=0}^{I} u(r_i), \tag{4}$$

$$u(r_i) = \sum_{n,l} u_{nl}(r_i), \tag{5}$$

where I — the set of the number of atoms minus one, r_i — the distance from the center of the i-th atom to the specified point

$$\vec{r}_i = \vec{r} - \vec{a}_i. \tag{6}$$

Here a_i — the radius-vector of the i-th atom with respect to the center of origin. Let us obtain the Poisson equation for an electron of i-th atom:

$$\nabla^2 u_{nl}(\vec{r}_i) = -8\,\pi\, r_i^2 R_{nl}^2(\vec{r}_i). \tag{7}$$

Solving (8), we obtain

$$u(\vec{r}_i) = -8\,\pi \sum_{n,l} \iint u_{nl}(\vec{r}_i)\, d\vec{r}_i^{\,2}\ . \tag{8}$$

Directly using the functions (Eq.4, Eq.5, Eq.6, Eq.7, Eq.8) we find the potential U_0(r). This approach allows us to calculate effectively and accurately the electronic potential. We rewrite Eq. 2 accounted for the entire set of atoms:

$$U_c(\vec{r}) = \sum_i U_n(\vec{r}_i) + U_0(\vec{r})\,. \tag{9}$$

Thus, the Coulomb potential is calculated from all the surrounding atoms [1], [6]. This approach allows us to select any line capacity in any direction from the lattice points, and may be any length of line. Moreover, we can specify a curved line capacity. The cell potential near the nucleus has a singularity, and the distance from the nucleus is close to zero in hyperbole. For a single atom inside the Wigner-Seitz sphere the main contribution comes from the nucleus of an atom [6], [7]. Consider

the cell potential obtained at the line potential. In this case, clearly seen the potential frequency, which is created by all the atoms are now set. In passing through the core potential becomes singular. The potential between the atoms is identical and negligible in the magnitude. There is a little effect of the atoms located at the centers of the faces of the two face-centered cubic lattices [8].

The obtained simulation results show the crystal potential, the crystal can be modeled with all its features. In contrast to known methods of calculating of the crystal potential as described in the engineering calculations of the crystal potential is universal. It gives the results without making any correction factors, does not require the use of logarithmic scales, and other non-uniform, allows you to quickly calculate the crystalline potential for all elements of the given crystal structure. There are facilities for the further developments of such technology in the direction of accounting for various disturbances. It will allow a calculating the electronic potential even more precisely. However, even without taking into account the properties of an ideal crystal, this calculation provides sufficiently accurate results. To illustrate the power and versatility of the described technique for the calculating of the potential capabilities it is shown an interaction potential on line drawn along the main diagonals of the two face-centered cubic lattices in Fig. 4.

In determining the energy spectra of quantum-mechanical problems for periodic structures, it often uses methods of the broadcast. In particular, semiconductors have a periodic structure. The crystal potential, having the grating period, usually modeled by the expression [1], [9]:

$$V(\vec{r}) = \left[\sum_{i=0}^{N} V_{\text{n}}(\vec{r}_i)\right] + U_0(\vec{r}) + V_{\text{exh}}(\vec{r}). \tag{10}$$

where $V_{\text{n}}(\mathbf{r}_i)$ — the potential created by the i-th nucleus at the point $\mathbf{r}$; $U_0(\mathbf{r})$ — the electronic potential, formed by the electrons of the core at some point r and is determined from the Poisson equation

$$\nabla^2 U_0(\vec{r}) = -8\pi\rho_0(\vec{r}). \tag{11}$$

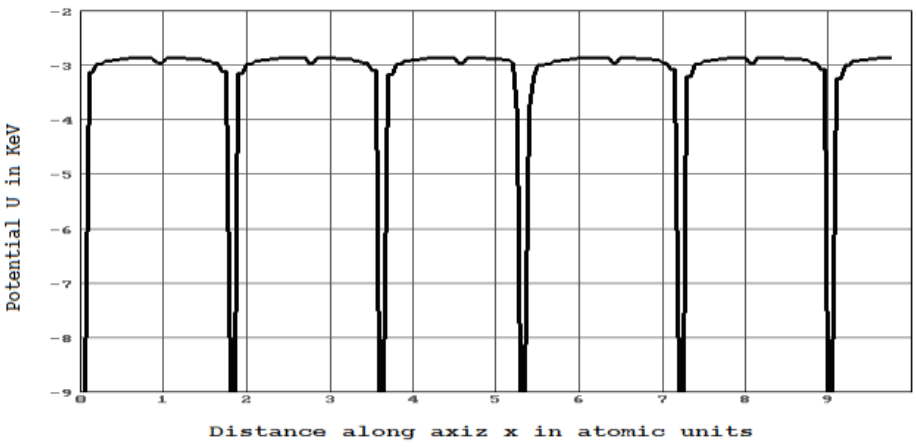

Fig. 4. An interaction potential on line drawn along the main diagonals of the two face-centered cubic lattice

Here $\rho_0(\mathbf{r})$ — the electronic density of the occupied levels at a distance r from the center of the atom; $V_{\text{exh}}(\mathbf{r})$ —the exchange potential at point $\mathbf{r}$; $\mathbf{r}_i = |\mathbf{r}\text{-}\mathbf{a}_i|$ — the distance from the i-th node to the point $\mathbf{r}$; $\mathbf{a}_i$ — the node location; N — the number of neighbors taken into account relatively to the cores. The solution of Schrödinger equation based on the potential (11) is carried out by the Hartree-Fock-Slater. The specificity of a solid compared to other bodies, is the decisive role of spatial-structural properties: a lattice type, a location and an interaction of the defects, a structure of core lattices and inter-ionic space. The period of the inter-ionic lattice coincides with the period of the core lattice. Spatially periodic structure of two weakly coupled and oppositely charged objects is the cause of the stability of rigid body — in this case the semiconductor GaAs — because between these objects appear spatially periodic Coulomb forces. In the geometric structure of each inter-ionic space surrounded on six sides by positive ion cores, and the ionic core in turn — intervals. For a uniform distribution of

electrons in the space of interaction between them becomes energetically unfavorable. There is the possibility of an orderly arrangement of electrons in space, the emergence of the so-called Wigner or “electron crystal”. The geometrical structure of the crystal consists not only of the atomic cores, but inter-ionic space intervals. The valence electrons in inter-ionic space intervals are also elements of the crystal, along with the atomic cores. The inter-ionic space is gap, i.e. the most probable location of the valence electrons. In addition, inter-ionic space intervals are also still a kind of “elements” of the crystal. But then the conclusion is that in the crystal lattice there are two — the well-known lattice consisting of the atomic cores, and another, equally important for the existence of the crystal lattice of the valence electrons are concentrated between the cores. The lattice periodicity of the atomic cores immediately implies the lattice periodicity of the inter-ionic space. Even more natural in such a conclusion, if you do not forget that the atomic cores of the crystal lattice — not a point in space, but the figures, which occupy a significant part of the whole space of the crystal, and inter-ionic space also has a periodic structure, as well as skeletons. The period of this lattice coincides with the usual of the core of the lattice. Fig. 5 shows a two-dimensional lattice with the lattice constant a_0. The coordinate origin of the system Oxy is at the center of one of the cores, and the origin of the coordinate system $O'x'y'$ is located in the center of one of the inter-ionic cells. The coordinate system $O'x'y'$ is formed by the translation of the coordinate system Oxy in $a_0n/2$, where $n = \{0, 1, 2, ...\}$. We assume inter-ionic intervals are the inter-ionic elements of the lattice, which is shifted with respect to a core of the lattice by half a lattice constant in all coordinate axes.

The energies have multiple frequency modulus of the wave vector in the quasi-momentum space [1]-[3]. Now turn to the crystal with a very small number of cores. In such a crystal frequency is not as ideal as in the previous case. The simulation of such a crystal is insurmountable difficulties for traditional methods, but this is the case is taken by us as a basic demonstration version. The object in question is distant from a perfect crystal due to its limited size. And despite this, the technique presented by us showed the periodicity of the above parameters. Thus in our problems are not used the condition of periodicity and Bloch's theorem as the necessary initial conditions. The Fig. 3 shows it on the example of GaAs.

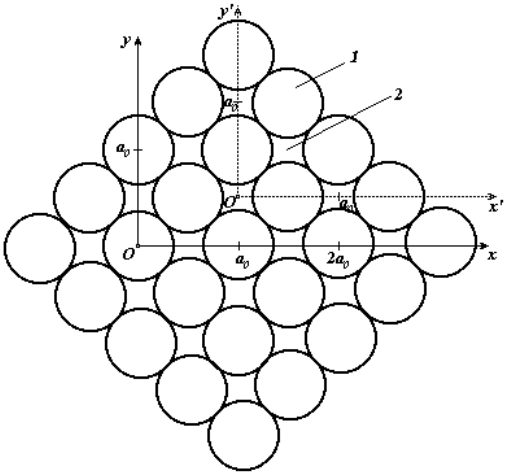

Fig. 5. A two-dimensional lattice with the lattice constant a_0. Cores and inter-ionic space two-dimensional lattice include 1) frame, 2) inter-ionic space.

The determining the location of the centers of the location of the centers of the inter-ionic intervals can be easily receive from the definition of the basis vector for the nodes of the crystal (the core) of the lattice with any structure. But it should be noted that by increasing the radius of inter-ionic volumes (not just their centers) there is a change the number under the consideration inter-ionic space compared to the amount covered by the cores. Since you want to cover all inter-ionic space surrounding covered the skeletons, the radius of coverage inter-ionic space few more skeletons examined. Crystal is in a stable condition thanks to the orderly arrangement of opposite charges. Most of the properties of crystals (eg, electrical conductivity, magnetic susceptibility), are caused not only property of the host lattice, but also the existence of inter-ionic lattice. This inter-ion lattice in addition to the core determines the physical properties of the crystal. Specificity of a solid compared to other bodies is that in them play crucial role spatial structural properties: the lattice type, location and interaction of defects, the structure of the nucleus and inter-ion lattice. The period of the inter-ion lattice coincides with the period of the core lattice. Spatially periodic structure of two weakly coupled and oppositely charged objects is the cause of the stability of rigid body — in this case the GaAs — because between these

objects appear spatially periodic Coulomb forces. In the geometric structure of each inter-ionic cell surrounded on six sides by positive ion cores, and the ionic core in turn — the inter-ionic gaps.

Discussion

Computer simulation of the properties of the crystal lattice gives to use up to 1010 ÷ 1012 atoms. Using the described technique can be obtained from any of these atomic systems, as well as changes in the radii of coordination spheres at various distances. Simultaneously, you can get a number of nearby neighbors, the location of atoms on the coordination sphere.

Thus, algorithms are developed for the FCC, BCC and diamond-like structures for determining the orderly and semiregular Archimedean and Platonic figures, as well as their complexes.

We can develop an algorithm for constructing the structure of compound semiconductor-type A^3B^5, based on this principle. For example, to the type of A^3B^5 of semiconductor compounds it is used compound GaAs. It is crystal lattice of two face-centered cubic lattices shifted relative to each other at *j* spatial diagonal. Each Ga atom has four nearest neighbors located at the tops of a tetrahedron. Each ion is surrounded by four nearest neighboring ions of opposite sign. There are four ions with $q_i\ q_j = -1$ at a distance $a_0 2½/2$, eight ions of opposite sign of $q_i\ q_j = +1$ at the 2 distance $a_0 2½$. The system of links of the GaAs structure establishes the order of the atomic body along tetrahedral combinations [2], [3]. For such compounds of the tetrahedral group of atoms is one-eighth of the basic lattice, so it is convenient to consider as a superstructure. The cell of the GaAs lattice consists of four tetrahedral sublattices.

One of the advantages of the described technique is its application to systems with short-range order, which does not use Bloch's theorem as the initial conditions. This was possible due to the fact that translational invariance follows as a consequence of the calculations, and not postulated initially. Thus, translational invariance in real space and in the quasi-momentum space is not a prerequisite for the determination of the crystal potential, wave functions and energies in wave vector space.

This, in turn, allows you to define these parameters not only for infinite crystals, but also for the real limits on the size of the crystals. Therefore, it is possible to determine the properties of crystals with impaired structure of a single scheme, with no additional idealizations. Individual interest is a violation of the periodicity on the boundary of the crystal. In fact, it is inherent in all real crystals violation of the ideal (i.e. infinite) crystal structure.

The violation of a perfect crystal at the border no doubt affects the theoretical study of the band spectrum. Boundary effects appear in the form of decay phase portraits of the main parameters (the crystal potential, the wave functions and energies in wave vector space) in all directions of the crystal boundaries (in our case spherical).

Summary

In the study of solid-state we considered two sites within the crystal, virtually connected to each other. A theoretical study of solid-state is easily accomplished with the use of these facilities both qualitative and quantitative methods. But the most effective way of investigating solids is to use a direct computer simulation, and that we have done for simple structures.

Thus, the use of techniques discussed in the article allows the calculation of real properties of GaAs crystals with defects and other constraints.

Keywords: cooperative energy transfer, visible quantum cutting, spectral characteristics, $K_2GdZr(PO_4)_3$:Tb^{3+},Er^{3+}.

Abstract. Tb^{3+}, Er^{3+} co-doped $K_2GdZr(PO_4)_3$ samples were prepared by solid-state reaction method and their photoluminescence (PL) properties were investigated in ultra-violet (UV) and vacuum ultra-violet (VUV) region. The results indicate that the energy transfers from Er^{3+} to Gd^{3+} and from Gd^{3+} to Tb^{3+} required for occurring of visible quantum cutting through down-conversion are efficient. In this cooperative energy transfer process, Gd^{3+} is used as an intermediate of energy transfer between Er^{3+} and Tb^{3+}. The optimal quantum efficiency (QE) of this co-doped system $K_2GdZr(PO_4)_3$: Er^{3+}, Tb^{3+} phosphor reached to 110%, suggesting a potential visible quantum cutting phosphor in practical application.

Introduction

In recent several years, the spectral characteristics of phosphors with quantum efficiency higher than 100% have become a new focal point in the field of luminescent materials research.[1-7] This is due to the emerging need for new vacuum ultraviolet (VUV) phosphors in applications such as mercury-free fluorescent tubes and plasma display panels (PDP).[4,8,10] Research on the phenomenon of generating two or more visible photons for each incident VUV photon absorbed by phosphors (quantum cutting) started on Pr^{3+}-doped YF_3 in the early 1970s.[5-7] Up to now, the quantum cutting process and its possibilities in other rare earth ions and host materials have been investigated extensively.[12-19] However, no perfect phosphor for practical applications has been discovered so far. Based on the prediction expected by Van der Kolk et al.[7,8], host materials with weak crystal field, low phonon energies, larger band gap, large cation-anion distance and large coordination number for the substitution site are considered important to exhibit quantum cutting (QC) phenomenon. Besides, as is known to all, fluoride phosphors are unsuitable for lighting and display applications. In contrast, rare-earth phosphates have many advantages over fluorides, such as high VUV absorption efficiency, high physical-chemical and thermal stability, easy fabrication, low solubility, transparent and low cost, which are more useful in practical applications. The particular structure of $K_2GdZr(PO_4)_3$ exhibited in Ref. [11,21] indicates that it could be an ideal host to fulfill the above requirements of QC process. In addition, an efficient visible QC has also been obtained in Er^{3+} - Gd^{3+} - Tb^{3+} system with a maximum quantum efficiency (QE) of 130%.[12] However, to the best of our knowledge, no report has focused on the QC phenomenon in Tb^{3+}, Er^{3+} co-doped $K_2GdZr(PO_4)_3$ phosphor.

Herein, in this paper, the photoluminescence (PL) and spectroscopic characteristics studies of $K_2Gd_{1-x-y}Zr(PO_4)_3$: Tb^{3+}, Er^{3+} (0.5 mol. % $\leq$ x $\leq$ 5 mol. %, 1 mol. % $\leq$ y $\leq$ 5 mol. %) were presented. The cooperative energy transfer (down-conversion) process of Er^{3+} - Gd^{3+} - Tb^{3+} system was also investigated and the quantum efficiency for $K_2GdZr(PO_4)_3$ co-doped with Tb^{3+} and Er^{3+} was evaluated.

Experimental

Sample Preparation.

The samples of $K_2Gd_{1-x-y}Zr(PO_4)_3 : Tb^{3+}$, Er^{3+} (0.5 mol. % ≤ x ≤ 5 mol. %, 1 mol. % ≤ y ≤ 5 mol. %) were prepared by solid-state reaction method. K_2CO_3 (99.0%, AR), ZrO_2 (99.0%, AR), $(NH_4)_2HPO_4$ (98.5%, AR), Gd_2O_3 (99.99%), Tb_4O_7 (99.99%) and Er_2O_3 (99.99%) were used as raw materials. They were thoroughly mixed in stoichiometric proportions. The mixtures were heated at 980 °C (optimal synthesis temperature) for 8 h in reducing atmosphere and finally cooled to room temperature. The phases of as-prepared samples were characterized by monochromatic Cu K_α X-ray powder diffraction (XRD) analysis (Rigaku D/max-2400). During the XRD measurement, the data were obtained by step scanning with an increment of 0.02° (2θ) in the diffraction angles of 10° ~ 80°. The XRD patterns are shown in Fig. 1. All the samples are indexed to the phase of $K_2GdZr(PO_4)_3$ (JCPDF No. 49-0634) with the space group of P_{2_13} and there is no extra peaks corresponding to any other phases. Therefore, the expected compounds were synthesized in this work.

Spectroscopic Properties Analysis.

The UV PL properties were analyzed using an Edinburgh Instruments FLS-920T combined fluorescence lifetime and steady-state spectrophotometer with Xe900 (450W xenon arc lamp) as excitation source. The VUV excitation and emission spectra were measured with FLS-920T and the vacuum monochromator (VM504, Acton Research Corporation, ARC). The VUV light source was a 150W Deuterium lamp (Cathodeon Incorporated). The VUV excitation spectra were corrected by dividing the excitation intensity of sodium salicylate at the same measurement condition. All the spectra were recorded at room temperature.

Results and Discussion

Mechanism of Cooperative Energy Transfer for Er^{3+} - Gd^{3+} - Tb^{3+}.

The possible mechanism for visible quantum cutting through down-conversion in the Gd^{3+}-based host material co-doped with Er^{3+} and Tb^{3+} is illustrated in a schematic energy level diagram[12,16] shown in Fig. 2.

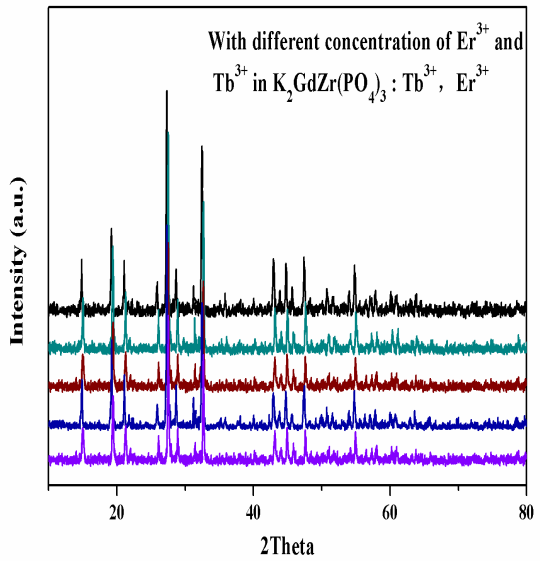

Figure 1 XRD Patterns of $K_2Gd_{1-x-y}Zr(PO_4)_3 : Tb^{3+}$, Er^{3+} (0.5 mol. % ≤ x ≤ 5 mol. %, 1 mol. % ≤ y ≤ 5 mol. %)

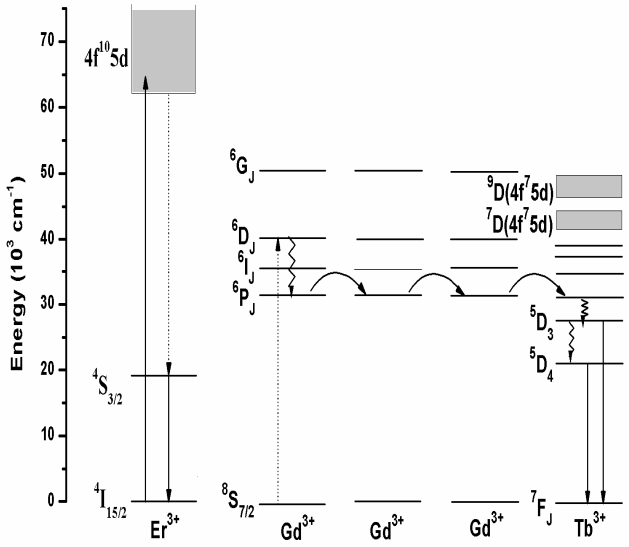

Figure 2 Part of Approximate Energy Level Diagram for Er^{3+}, Gd^{3+} and Tb^{3+}, Showing the Cooperative Energy Transfer Process of the Er-Gd-Tb System and the Possibility for Visible Quantum Cutting Via the Energy Transfer upon Excitation in the $4f^{10}5d$ State of Er^{3+}.[12,16]

According to the energy-matching relationship between Er^{3+}, Gd^{3+} and Tb^{3+}, the quantum cutting process takes place on Er^{3+} upon excitation in its $4f^{10}5d$ levels which are situated in the VUV range. After non-radiative relaxation to the lowest $4f^{10}5d$ state of Er^{3+}, the energy can be transferred to Gd^{3+} by cross-relaxation and excites Gd^{3+} into ^6P_J, ^6I_J or ^6D_J states.[12,13] Then Er^{3+} transfers back to the level in or above the $^4S_{3/2}$ excited state and emits a green photon due to the $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transition of Er^{3+}. Subsequently, the energy transferred to Gd^{3+} migrates over the Gd^{3+} sublattice before reaching to a high-energy state of Tb^{3+}, emitting another green photon corresponding to the Tb^{3+} $^5D_J \rightarrow {}^7F_J$ transition by fast non-radiative relaxation to its ^5D_J states.[14, 17-19] In this process, Gd^{3+} is used as an intermediate of energy transfer between Er^{3+} and Tb^{3+}.[12,20]

PL and Spectroscopic Properties.

In Fig. 3 (a) and (b), the relevant excitation and emission spectra of Er^{3+} single doped $K_2GdZr(PO_4)_3$ under VUV excitation is exhibited. The strong excitation band centered at around 132 nm in the region of 125 ~ 155 nm in Fig. 3(a) is assigned to the spin-allowed transition to low-spin $4f^{10}5d$ state of Er^{3+} as well as the Gd^{3+} f-d transition. The weak band at 163 nm overlapping with the band of transitions originating from the $4f^7$ configuration of Gd^{3+} corresponding to the spin-forbidden transition to Er^{3+}'s high-spin $4f^{10}5d$ level. Besides, the $^8S_{7/2} \rightarrow {}^6D_J$ and $^8S_{7/2} \rightarrow {}^6I_J$ transitions of Gd^{3+} can also been observed. As it shown in Fig. 3 (b), under 147 nm excitation, the emission peaks corresponding to the $^6P_{7/2} \rightarrow {}^8S_{7/2}$ transition at 311 nm of Gd^{3+}, and the $^2P_{3/2} \rightarrow {}^4I_{13/2}$ at 405 nm, $^4F_{5/2} \rightarrow {}^4I_{15/2}$ at 460 nm, $^4S_{3/2} \rightarrow {}^4I_{15/2}$ at 547 nm, $^4F_{9/2} \rightarrow {}^4I_{15/2}$ at 648 nm transitions of Er^{3+}, respectively. The occurring of energy transfer from Er^{3+} to Gd^{3+} plays an important role in the investigation on the probability of quantum cutting. The spectral overlap between Er^{3+} and Gd^{3+} shown in Fig. 3 (a) indicates that the Er^{3+} (f-d) $\rightarrow$ Gd^{3+} (f-f) energy transfer process could be effective, providing a theoretical possibility for the occurrence of visible quantum cutting through the down-conversion process. Fig. 4(a) and (b) exhibit the excitation spectra of Tb^{3+} single doped $K_2GdZr(PO_4)_3$ phosphor in UV and VUV range, monitoring the Tb^{3+}'s 550 nm emission. In the region of 100 ~ 200 nm, the excitation spectra consists of several overlapped excitation bands, which can be ascribed to the Gd^{3+} f-d and $^8S_{7/2} \rightarrow {}^6G_J$ transitions, P-O band covalency, O^{2-} - Tb^{3+} and O^{2-} - Gd^{3+} charge transfer band (CTB), the $4f^8 \rightarrow 4f^75d^1$ transition of Tb^{3+}, respectively. The excitation lines shown in Fig. 4(b) at about 274, 311 and 300 ~ 380 nm range corresponds to the $^8S_{7/2} \rightarrow {}^6I_J$ and $^8S_{7/2} \rightarrow {}^6P_{7/2}$ transitions of Gd^{3+} as well as the f-f transition of Tb^{3+}, respectively. It is clear that there are several cases of good spectral overlap between Gd^{3+} and Tb^{3+}, providing a condition for the energy transfer from Gd^{3+} to Tb^{3+}. The emission spectra of Tb^{3+} single doped sample under 254, 274, 212 and 147 nm excitation in Fig. 5 display that the emission peaks corresponding to the $^5D_3 \rightarrow {}^7F_5$ (416 nm), $^5D_3 \rightarrow {}^7F_4$ (435 nm), $^5D_3 \rightarrow {}^7F_3$ (457 nm), $^5D_4 \rightarrow {}^7F_6$ (490 nm), $^5D_4 \rightarrow {}^7F_5$ (550 nm), $^5D_4 \rightarrow {}^7F_4$ (583 nm) and $^5D_4 \rightarrow {}^7F_3$ (620 nm) transitions of Tb^{3+} are obtained.

As shown in Fig. 5, the emission intensity of the sample excited by 274 nm (Gd^{3+} $^8S_{7/2} \rightarrow {}^6I_J$ transition) is higher than that excited by 254 nm. It suggests that the energy of Gd^{3+} is transferred to Tb^{3+} effectively. Figs. 6, 7(a) and (b) show the excitation and emission spectra of Tb^{3+}, Er^{3+} co-doped $K_2GdZr(PO_4)_3$ under UV and VUV excitation. The excitation bands exhibited in Fig. 6 are due to the f-d, $^8S_{7/2} \rightarrow {}^6G_J$, $^8S_{7/2} \rightarrow {}^6I_J$ and $^8S_{7/2} \rightarrow {}^6P_{7/2}$ transitions of Gd^{3+}, $4f^8 \rightarrow 4f^75d^1$ (low-spin) and f-f transitions of Tb^{3+}, Er^{3+}'s spin-allowed and spin-forbidden f-d transition, respectively. In Fig. 7(a) and (b) the emission spectra in the region of 300 ~ 700 nm under 274 and 147 nm excitations are presented, next to the Er^{3+} and Gd^{3+} emissions, a number of strong emissions which are all assigned to the Tb^{3+} transitions are observed. The most intense $^5D_4$ emission of Tb^{3+}, the $^5D_4 \rightarrow {}^7F_5$ transition (green), overlaps with the Er^{3+} $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transition, emitting two green photons. The results in Fig. 7 prove that a significant part of the Gd^{3+} excitation energy is transferred to Tb^{3+}, resulting in a green photon emission. In addition, the increase of the Er^{3+}'s $^4S_{3/2}$ emission (another green photon)[15] can be seen relative to the other emissions in Fig. 7(a), indicating that the cross-relaxation required for visible quantum cutting via down-conversion occurs.

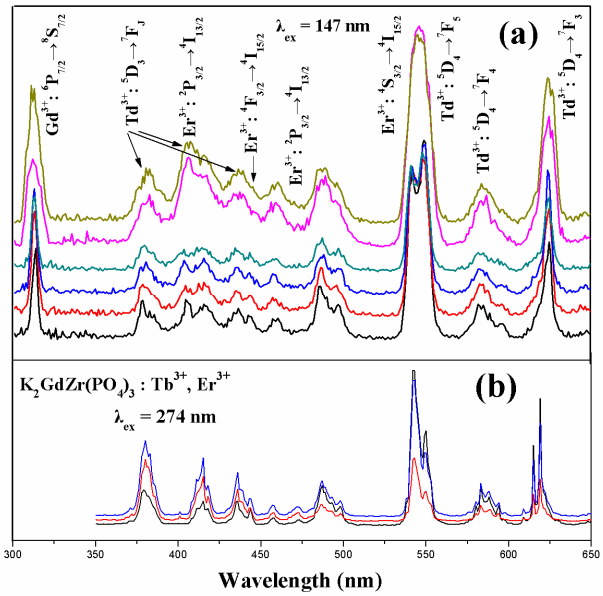

Figure 7 (a) Emission Spectra of $K_2Gd_{1-x-y}Zr(PO_4)_3$: Tb^{3+}, Er^{3+} (0.5 mol. % ≤ x ≤ 5 mol. %, 1 mol. % ≤ y ≤ 5 mol. %) under 147 nm Excitation; (b) Emission Spectra of Tb^{3+}, Er^{3+} Co-doped $K_2Gd_{1-x-y}Zr(PO_4)_3$ Samples under 274 nm Excitation.

Calculation of the Quantum Efficiency

On the basis of the operation explored by Wegh et al., the approximate efficiency of the cross-relaxation needed for visible quantum cutting occurring in $K_2GdZr(PO_4)_3$ co-doped with Tb^{3+} and Er^{3+} can be estimated by comparing the increase in the intensity of Er^{3+} $^4S_{3/2}$ emission with the intensities of other emissions in the emission spectra under UV and VUV excitation. If it is assumed that, in the 300 ~ 700 nm region, all the excited Gd^{3+} result in the emission of one visible photon, either on Er^{3+} or Tb^{3+}. In this process, some emissions of Er^{3+} in the infrared spectral region are so weak that they can be neglected. Thus, the energy transfer efficiency in the Er - Gd -Tb system can be estimated by the following formula[12]:

$$\frac{P_{ET_+}}{P_{ET_+} + P_{ET_-}} = \frac{R(^4S_{3/2} / \text{rest})_{Er^{3+}} - R(^4S_{3/2} / \text{rest})_{Gd^{3+}}}{R(^4S_{3/2} / \text{rest})_{Gd^{3+}} + 1} \quad (1)$$

where P_{ET+} and P_{ET-} are the probabilities of the desired and undesired energy transfer possibilities from the Er^{3+} $4f^{10}5d$ states to Gd^{3+}, respectively. $R(^4S_{3/2} / \text{rest})_{Er^{3+}}$ and $R(^4S_{3/2} / \text{rest})_{Gd^{3+}}$ are the intensity ratios of Er^{3+} $^4S_{3/2}$ emission to all the remaining emissions upon the f-d excitation of Er^{3+} and the ^6I_J excitation of Gd^{3+}, respectively. If the non-radiative losses because of energy transfer at the defects and impurities could be ignored, the quantum efficiency (η) of this Tb^{3+}, Er^{3+} co-doped $K_2GdZr(PO_4)_3$ phosphor can be given by $\eta = (P_{ET+} / P_{ET+} + P_{ET-}) + 1$. From the emission spectra shown in Fig. 5, the optical quantum efficiency was evaluated to be 110 %. That is to say, approximately 10 % of the Er^{3+} exited into the $4f^{10}5d$ levels yields an additional visible photon via cross-relaxation with Gd^{3+}. Although the calculated result of energy transfer efficiency in this phosphor was not very ideal, it was clear that the visible quantum cutting through cooperative energy transfer between Er^{3+}, Gd^{3+} and Tb^{3+} did indeed occur. This could be hopeful for the further development of $K_2GdZr(PO_4)_3$ co-doped with Tb^{3+} and Er^{3+} as a potential VUV phosphor with visible quantum efficiency higher than unity.

Summary

A potential visible quantum cutting phosphor, $K_2GdZr(PO_4)_3$: Tb^{3+}, Er^{3+}, was prepared successfully by solid-state reaction method. Its luminescence excitation and emission properties were

studied at room temperature. Based on the results of experiment in this paper, the visible quantum cutting via energy transfer down-conversion can occur upon the excitation of Er^{3+} in the $4f^{10}5d$ levels followed by the emission of two green photons and the quantum efficiency for this Tb^{3+}, Er^{3+} co-doped $K_2GdZr(PO_4)_3$ phosphor can be calculated to be near 110 %.

Keywords: first-principles calculations, electronic properties, dynamic properties, thermodynamic properties

Abstract: We investigate the electronic, dynamic and thermodynamic properties of α-MnO_2 using first-principles calculations based on density functional theory (DFT) with the GGA+*U* method. The results of electronic structures show that α-MnO_2 is a semiconductor with a direct band gap of 1.4 eV at Γ point. The results of dynamic properties indicate that the structure of α-MnO_2 is dynamically unstable at ground-state. Several important thermodynamic quantities, such as entropy, enthalpy and Gibbs free energy, et al each as a function of temperature were presented.

Introduction

Manganese dioxide (MnO_2) has a huge structural flexibility and appears in a number of crystallgraphic polymorphs, such as α-, β-, γ-, δ-, and ε-MnO_2, which are widely used as catalysts [1], electrode materials in Li/MnO_2 batteries [2,3] and supercapacitors [4-7].

The equilibrium phase of MnO_2 at standard temperature and pressure is β-MnO_2. The electrochemical properties of MnO_2 strongly depend on its particle size, morphology, crystalline structure and bulk density. Gao et al. [8] discussed lattice vibrational properties of β-MnO_2 and α-MnO_2 using Raman scattering spectroscopy. Yang et al. [9] studied the effect of the synthetic condition, morphology and crystallographic structure of MnO_2 on its electrochemical behavior. Lee et al. [10] reported the use of MnO_2 as a positive electrode material in Fuel Cell/Battery systems. They observed that MnO_2 possesses redox capabilities as a positive electrode of a secondary battery when it is subject to charge/discharge cycles.

Sato et al. [11] investigated transport properties and magnetic susceptibility of β-MnO_2. Kim et al. [12] demonstrated the presence of ε-MnO_2 as a major component of electrolytic manganese dioxide. Li et al. [13] successfully synthesized single crystalline α-MnO_2 nanotubes based on the redox reaction of $MnCl_2$ and $KMnO_4$ in the presence of sodium polyacrylate via a soft chemical method for the first time. α-MnO_2 nanotubes may provide novel peoperties, which will offer more application in nanotechnology. Zhang et al. [14] studied reversible Mg insertion and extraction behaviors of α-MnO_2 using discharge-charge cycling.

Franchini et al. [15] have presented a comprehensive study of the ground-state properties of MnO, Mn_3O_4, α-MnO_2 and β-MnO_2 using four different methods to treat exchange and correlation. Cockayne and Li [16] theoretically investigated electronic and magnetic properties of α-MnO_2 using first-principles calculations. The results show that α-MnO_2 is a semiconductor with an indirect band gap of 1.3 eV.

Form the fundamental point of view, manganese oxide material have gained much attention because of the presumably rather strong electron correlation, which leads to interesting phenomena such as colossal magnetoresistance, orbital ordering, and exotic magnetic structure [17,18]. Despite the fact that MnO_2 have been extensively studied for the past several decades, many details of their atomic structures are poorly understood. To our best knowledge, the dynamic property and thermodynamic properties of α-MnO_2 are not even known.

The ability to successfully model and predict the chemical and thermodynamic properties of Mn oxide depends to a large degree on a detailed understanding of their crystal structure [19]. In this work, we systematically investigated the electronic, dynamic and thermodynamic properties of

α-MnO_2 using first-principles calculations to gain a comprehensive understanding of the ground-state properties of α-MnO_2.

Computational details

In this work, the calculations were performed using the plane-wave pseudopotential DFT method as implemented in the CASTEP simulation package [20]. The ultrasoft pseudpotential with GGA+*U* method was employed to model the ion-electron interaction. The GGA+*U* theory is designed to give the self-energy correction to localized states embedded in delocalized states. The localized states have a large Coulomb correlation which is accounted for by the *U*-term whereas the delocalized states are well described by the GGA [21]. The advantage of the GGA+*U* method is the ability to treat simultaneously delocalized conduction band electrons and localized d/f electrons in the same computational scheme. The GGA+*U* method was proved to be very efficient and reliable for the electronic structure calculations of systems where the Coulomb interaction is strong enough to cause the localization of the electrons [22]. The convergence criteria for structure optimization and energy calculation were set to ultrafine quality with a kinetic energy cutoff of 340 eV and *k*-point meshes of 5×5×2. The self-consistent convergence accuracy was set to be 5.0×10^{-6} eV/atom. The convergence criterion for the maximal force between atoms was 0.01 eV/Å. The maximum displacement was 5.0×10^{-4} Å, and the stress was set to be 0.02 GPa.

Results and discussions

Electronic properties

The GGA+*U* method takes into account orbital dependence of the Coulomb and gives a qualitative improvement not only for excited-state properties such as energy gaps but also for ground-state properties such as magnetic moments. In this study, the GGA+*U* method (U = 2.5 eV) is used to correct the strong on-site Coulomb repulsion of Mn 3*d* states.

Because Mn^{4+} is a magnetic ion, it is crucial to include the effects of magnetism in electronic structure studies of manganese oxides. We have carried out spin-polarized electronic band structure calculations of α-MnO_2, as shown in Fig. 1. From Fig. 1, one can see that there is a significant difference between the band structure of majority-spin and minority-spin states. This is because Mn-3*d* electrons quantity of the spin-up state is different from the quantity of the spin-down state.

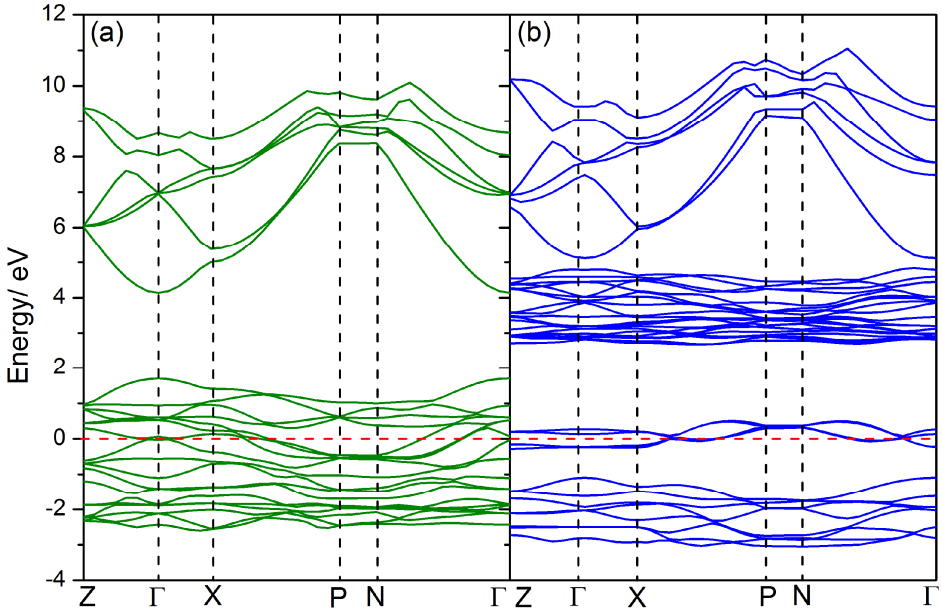

Fig. 1. Calculated band structures of α-MnO_2 at ground-state. (a) the majority- spin state; (b) the minority-spin states

Our result shows that α-MnO_2 is a semiconductor with a direct band gap of 1.4 eV at the high symmetry *Γ* point, which is in good agreement with the previous calculations [16]. The effect of electron-electron correlations is to enhance the hybridization and open the gap around the Fermi

level. It will shift the position of the Fermi level to the lowest conduction states and away from the highest valence states.

Partial density of states of O-*sp* and Mn-*spd* electrons of α-MnO_2 are shown in Fig.s 2 and 3, respectively. Form Fig. 2, it can be seen that around -18 eV are the O 2*s* bands in both of the spin channels with a small exchange splitting. Just below the Fermi energy, the states are predominantly due to the contributions of O 2*p* electrons in both of the spin channels without splitting. This indicates that the contributions of O-*sp* electrons to the magnetic properties are almost zero.

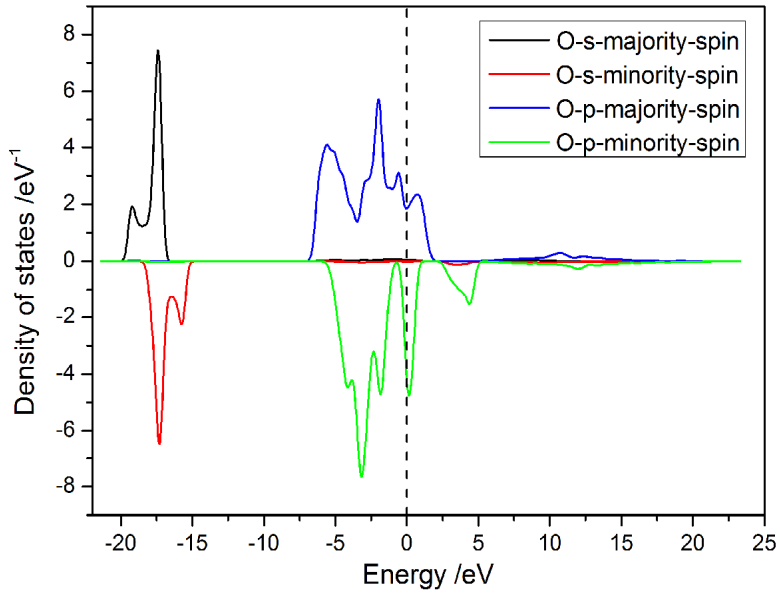

Fig. 2. The partial density of states of α-MnO_2 for O 2*s* and 2*p* states, respectively. The vertical dash line at zero indicates the Fermi energy level.

From Fig. 3, it can be clearly seen that some of the Mn-3*d* bands from the majority-spin crosses the Fermi level (E_f). Above E_f are the contributions of the minority-spin states of Mn-3*d* electrons with some hybridization yielding small contributions from Mn-4*s* and -3*p* electrons. This distribution makes Mn mostly responsible for the magnetism.

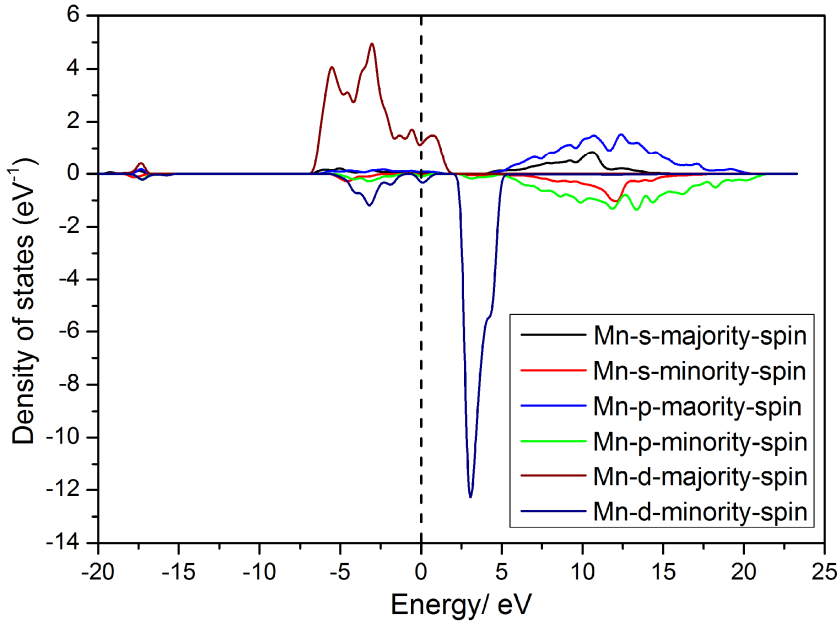

Fig. 3. The partial density of states of α-MnO_2 for Mn 3*p*, 3*d* and 4*s* states, respectively. The vertical dash line at zero indicates the Fermi energy level.

Dynamic properties

Many physical properties of solids depend on their phonon properties, such as specific heat, thermal expansion, heat conduction and electron-phonon interaction. To our knowledge, no

experimental or other theoretical works exist on the lattice dynamics of α-MnO_2. The phonon dispersion curves and density of states of ground-state of α-MnO_2 along the high-symmetry directions are shown in Fig. 4. Form Fig. 4, it can be clearly seen that imaginary frequencies occur at *Z*, *Γ* and *X* high-symmetry points. This indicates that the structure of α-MnO_2 is dynamically unstable at ground-state. As stated above, the equilibrium phase of MnO_2 at standard temperature and pressure is β-MnO_2. This indicates that our result is consistent with experimental result.

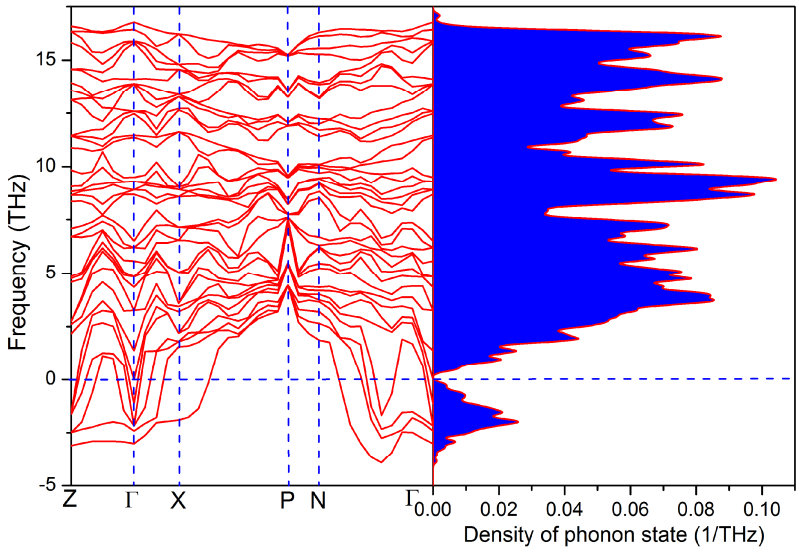

Fig. 4. Calculated phonon dispersion curves of ground-state of α-MnO_2 at zero pressure.

Temperature dependence of thermodynamic quantities

As is known, first-principles phonon calculations are limited to T = 0 K and thermodynamic properties of the crystals are determined in detail by phonons. The quasi-harmonic approximation can describe such properties satisfactorily. In the general Gibbs free energy expression $G(T,P) = F(T,V)+PV$, the free energy $F(T,V)$ of a crystal is the sum of the ground state energy $E(V)$ and the phonon free energy $F_{phon}(T,V)$, the temperature T appears in $F(T,V)$ via the phonon term [23]. The more explicit forms of the internal energy, free energy, entropy, and heat capacity in the harmonic approximation per primitive unit cell are given as follows:

$$E = \frac{1}{2} r \int_0^\infty g(\omega) \hbar\omega \coth\left(\frac{\hbar\omega}{2k_B T}\right) d\omega \tag{1}$$

$$F = r k_B T \int g(\omega) \ln\left[2\sinh\left(\frac{\hbar\omega}{2k_B T}\right)\right] d\omega \tag{2}$$

$$S = r k_B \int_0^\infty g(\omega) \left\{\frac{\hbar\omega}{2k_B T}\left[\coth\left(\frac{\hbar\omega}{2k_B T}\right) - 1\right] - \ln\left[1 - \exp\left(\frac{\hbar\omega}{2k_B T}\right)\right]\right\} d\omega \tag{3}$$

where r is the number of degrees of freedom in the unit cell, h the Plank's constant, and k_B the Boltzmann's constant.

The above formulae were used to plot the temperature dependence of several thermodynamic quantities of α-MnO_2. Figure5 shows the variations of enthalpy, phonon free energy, and entropy with temperature of α-MnO_2. From Fig. 5, it can clearly be seen that enthalpy and product of temperature (T) and entropy increase with increasing temperature. While phonon free energy decreases with increasing temperature.

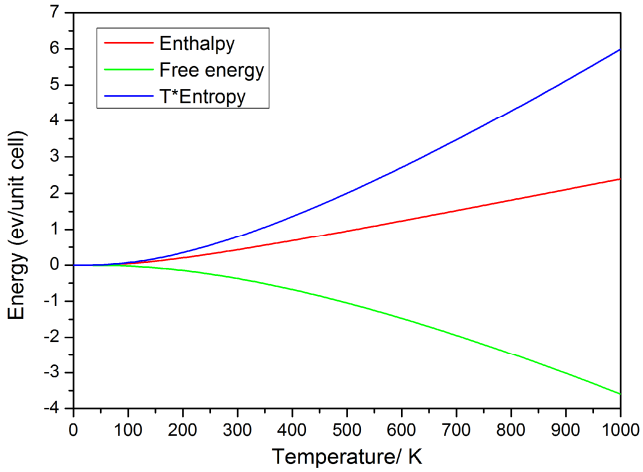

Fig. 5. Temperature dependence of enthalpy, free energy, and entropy of α-MnO_2

Conclusions

First-principles density functional theory calculations were used to investigate the electronic, dynamic and thermodynamic properties. The hybridization of O-2*p* orbitals with Mn-3*p* orbitals is the main contribution to the top of valence bands. α-MnO_2 is a semiconductor with a direct band gap of 1.4 eV at *Γ* point. The dynamic property indicates that the structure of α-MnO_2 is dynamically unstable at ground-state. We presented several import important thermodynamic quantities, such as entropy, enthalpy and Gibbs free energy, et al each as a function of temperature.

Keywords: Phase-change memory, Multilevel Storage, Lateral structures

Abstract. In this study, we investigated ultra-multilevel-storage (UMLS) in lateral phase-change memory (PCM) on the basis of device structure, reliability and programming method. We found that the number of resistance levels was limited strictly by the number of PC layers in multilayer multilevel cell (ML-MLC). A number of distinct levels up to 16 were obtained using a simple single-layer multilevel cell (SL-MLC). And material engineering is expected to greatly improve the reliability of MLS. We believe that fast-freely-achievable (FFA)-MLC by stair-like-pulse programming is a very promising method for future's application.

Introduction

Large capacity is required for memory nowadays. One of the most effective approaches to increase the memory capacity is the multilevel storage (MLS), by which much more information can be stored without increasing memory size. Phase-change memory (PCM) [1-6] based on amorphous-crystalline transition is expected to apply to MLS [7-12] since a lot of intermediate resistance levels are possible by controlling the total crystallinity between electrodes. On the other hand, lateral PCMs have been demonstrated to have many advantages such as low-power consumption over vertical ones [13-14].

In this study, we report two structures of lateral MLS PCM: multilayer multilevel cell (ML-MLC) and single layer (SL-) ultra-MLC (UMLC). And then we discuss how to obtain high reliability for MLC based on material engineering. Staircase-like shaped pulse programming is finally shown for the future's application of fast-freely-achievable (FFA) MLC.

Multilayer MLC and Single-layer UMLC

The phase-change layer of SbTeN (STN) is firstly adopted in these devices. STN shows a gradual resistivity drop and good phase stability with temperature, a characteristic which makes it suitable for MLS applications. [7, 8, 10, 15]

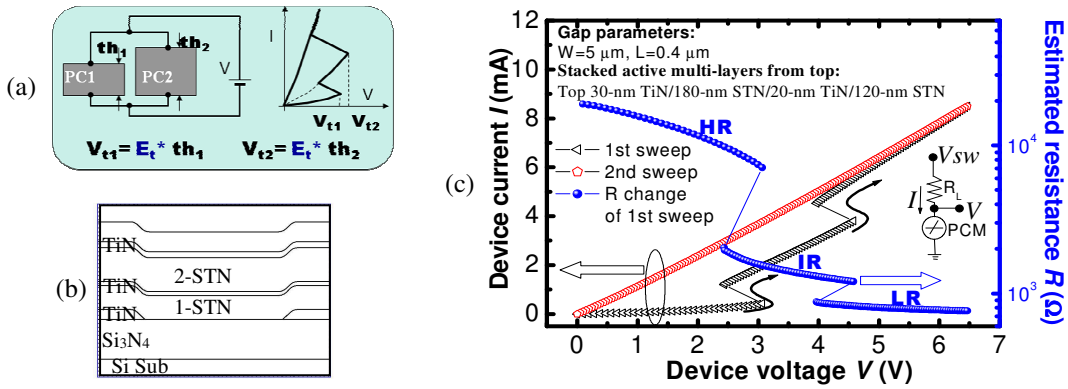

Fig. 1. (a) Principle of Multilevel Storage of ML-MLC With Different Thicknesses of PC layers. (b) Structure of Lateral ML-MLC. (c) I-V Characteristics And Resistance Change With Device Voltage of ML-MLC.

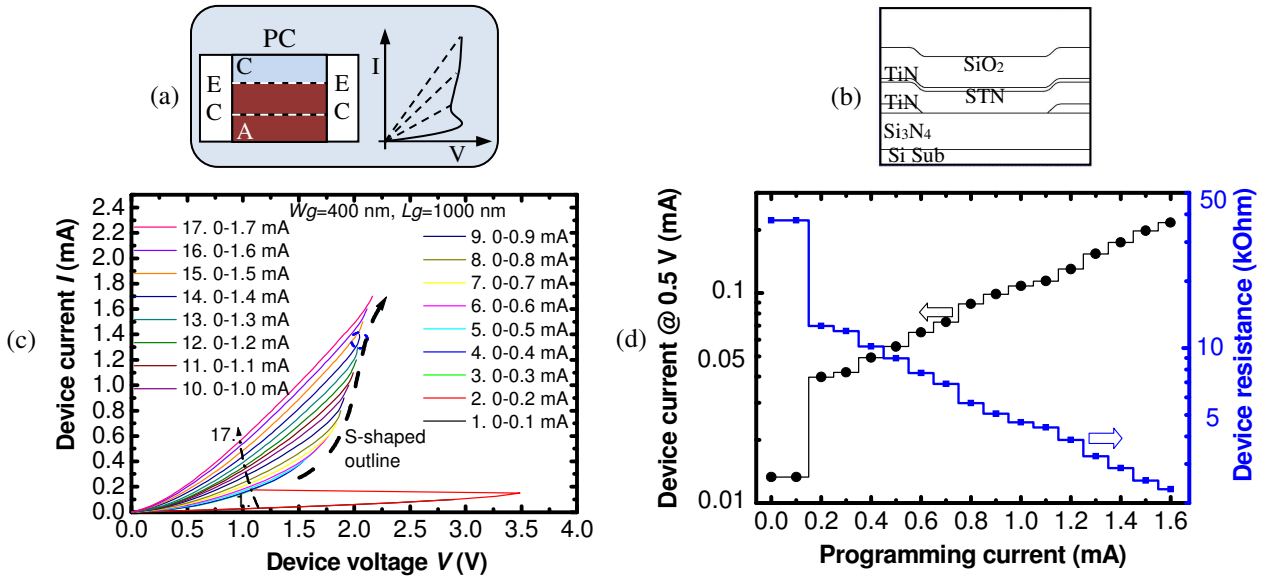

Fig. 2. (a) Principle of Multilevel Storage of SL-MLC with a Single PC layer. (b) Structure of Lateral SL-MLC. (c) I-V Characteristics. (d) Resistance Change with Device Voltage of ML-MLC.

We propose MLS based on multiple phase-change (PC) layers of different thicknesses as shown in Fig. 1(a). For two PC layers, three levels are expected to be obtained due to the two switchings at two threshold voltages. A top 30-nm TiN/180-nm STN/20-nm TiN/bottom 120-nm STN stacked structure is experimentally adopted as the active medium in the multi-layer devices, as shown in Fig. 1(b). Three stable and distinct device resistance levels are demonstrated in switching characteristics, as shown in Fig. 1(c). From the principle and analysis of this ML-MLC, the available number of resistance levels is strictly limited to be n+1 by the number of PC layers n.

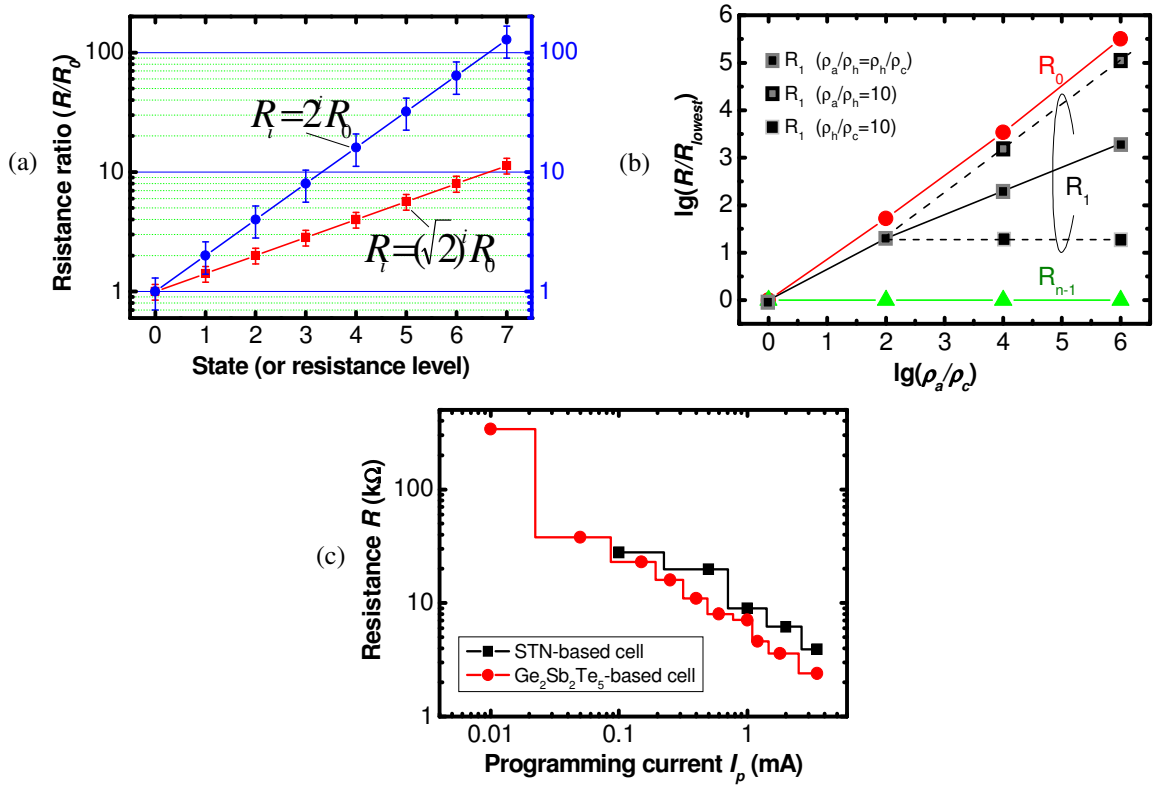

Fig. 3. (a) Larger Resistance Change Implies Higher Reliability. (b) Resistance Change of Lateral SL-MLC Depends Strongly on Material Properties. (c) Lateral GST-based SL-MLC Exhibited Higher Resistance Change than STN-based SL-MLC.

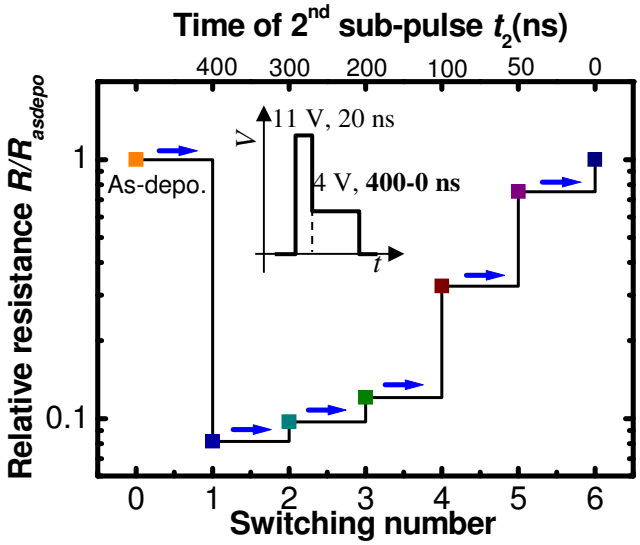

Fig. 4. Fast-freely-achievable MLC by Stair-like-pulse Programming.

To overcome the above limit, we propose SL-UMLC to obtain much more resistance levels as shown in Fig. 2(a). Principally, the MLS results mainly from the gradual enlargement of crystalline (C) region between electrodes (EC) by Joule heating. The active layers of SL-UMLC consist of 150-nm-thick STN layer with an additional top 50-nm-thick TiN layer, as shown in Fig. 2(b). Experimental results, as shown in Fig. 2 (c-d), exhibit a number of levels up to 16 are distinct and stable, which are induced by electric currents.

High-Reliability MLC by Material Engineering

Reliability (or stability) is the critical characteristics for MLC. In order to improve reliability of SL-UMLS, there are two effective approaches, (i) enlargement of the ratio between resistance levels as shown in Figs. 3(a) and (b), and (ii) reduction of scattering of resistance level. On the basis of our experimental results, it is demonstrated that the $Ge_2Sb_2Te_5$ (GST)-based double-layered cell has a high ratio of highest to lowest levels up to two-to-three orders of magnitude, implying high reliability, as shown in Fig. 3(c).

FFA-MLC by Stair-like-pulse Programming

The effect of the staircase-like shaped pulse with two sub-pulses on programming characteristics is investigated in SL-UMLS for fast-freely-achievable MLS. Phase-change material is melt by the first sub-pulse while the second one is used for controlling the total crystallinity after melting by crystallization time. Our finite-element analysis shows that the shorter the second sub-pulse is, the lower the crystallinity is. It is experimentally demonstrated that the device resistance increases with reducing the width of second sub-pulse due to the decreasing crystallinity, as shown in Fig. 4. This implies that any resistance levels are expected to be freely achieved by staircase-like shaped pulse programming.

Summary

MLS in lateral PCM was investigated from device structure, reliability and programming method. The number of resistance levels was limited strictly by the number of PC layers in ML-MLC. Simple SL-UMLC exhibited potential to obtain a number of distinct levels up to 16. And reliability can be expected to be greatly improved by material engineering. FFA-MLC by stair-like-pulse programming is very promising for future's application.

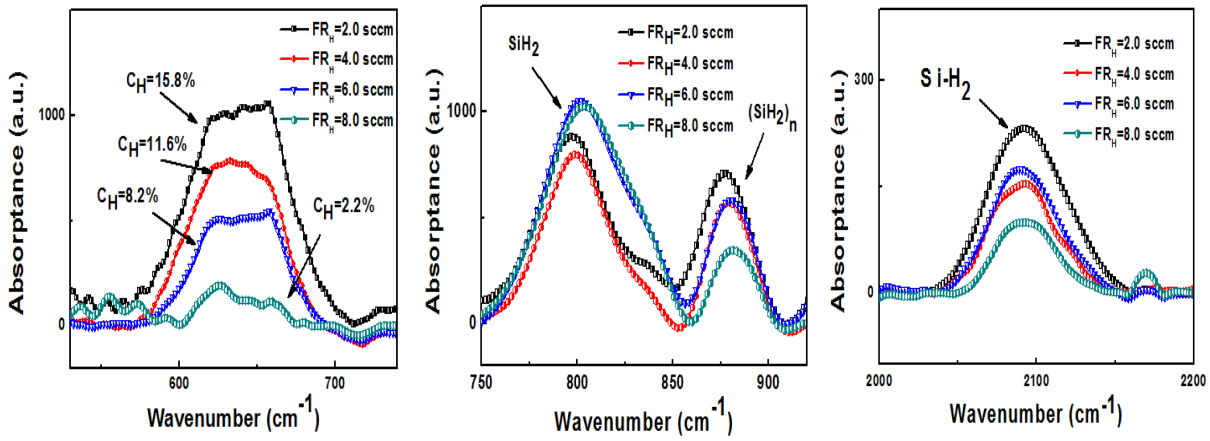
Keywords: surface passivation, the minority carrier lifetime, hydrogen flow rate.

Abstract: Surface passivation of c-Si by a-Si:H thin films has been studied. In this paper, the minority carrier lifetime of 345μs (from 85μs) is obtained at optimal hydrogen flow rate (8.0sccm) by using RF-magnetron sputtering method.



Introduction

With the further promotion of semiconductor applications, crystalline silicon surface passivation for improving the performance of the devices got more and more research, especially the hydrogenated amorphous silicon (a-Si:H) thin films deposited on c-Si surfaces as passivation layers. As in laminated film solar cells, the photoelectric conversion efficiency, the device performance and stability depend on strongly the surface cleanliness and the surface recombination center density related to the passivation effect. In all known strategies, a-Si:H is still the best candidate for many silicon devices compared with the others, it is due to the simple processing without the introduction of any atoms other than silicon and hydrogen and the excellent passivation properties obtained at low deposition temperatures. The a-Si:H on crystalline silicon surface as a passivation layer can achieve the minimization of electronic losses by reducing the semiconductor surface activity and the surface recombination velocity [1-3]. For the termination of dangling bonds on the cysalline silicon surface, the hydrogen in a-Si:H is a key factor, which affects directly the passivation quality. So it is necessary to study the crystalline silicon surface passivation using the a-Si:H with different hydrogen content.

Results and Discussion

The FTIR spectra of the thin films deposited with various FR_H are shown in Fig.1. There are three bands related to Si-H bond within wavenumber range of 500-2300cm^{-1}. The first one located at near 630 cm^{-1} is attributed to Si-H rocking/wagging mode. It is observed from Fig.1.(a) that the intensity of the absorption peak at around 630 cm^{-1} decreases apparently with the increasing FR_H. Combined with the film thickness obtained from SE850, we can figure out the hydrogen contents in varying FR_H from the infrared results. The hydrogen content decreases with the increasing hydrogen flow rate. The hydrogen contents in a-Si:H thin films deposited at hydrogen (H_2) flow rates of 2.0 sccm, 4.0 sccm, 6.0 sccm and 8.0 sccm are 15.8%, 11.6%, 8.2%, 2.2%, respectively. According to the TO peaks mentioned in the above Raman spectra, we can deduce that hydrogen ion etching effect has influence on the hydrogen content. The second one is a doublet at 800-900 cm^{-1} which is associated with the dihydrides SiH_2 scissoring mode and the polysilanes $(SiH_2)_n$ bending mode, respectively. From Fig.1.(b), it is obviously shown that the absorption bands present near 800 cm^{-1} increase with the increasing FR_H, which can be due to the increase of the amount of

SiH_2 in a-Si:H thin films. The opposite phenomenon appears around 870 cm^{-1}, which reflects the reduction of the amount of $(SiH_2)_n$ in a-Si:H thin films. The third one at ~2100 cm^{-1} is recognized as the SiH_x (with x=2 or 3) stretching mode [4]. In Fig.1.(c), we can see that the signals at ~2090cm^{-1}, which mean stretching mode of Si-H_2 bond, become weak with the increasing FR_H.

(a) (b) (c)

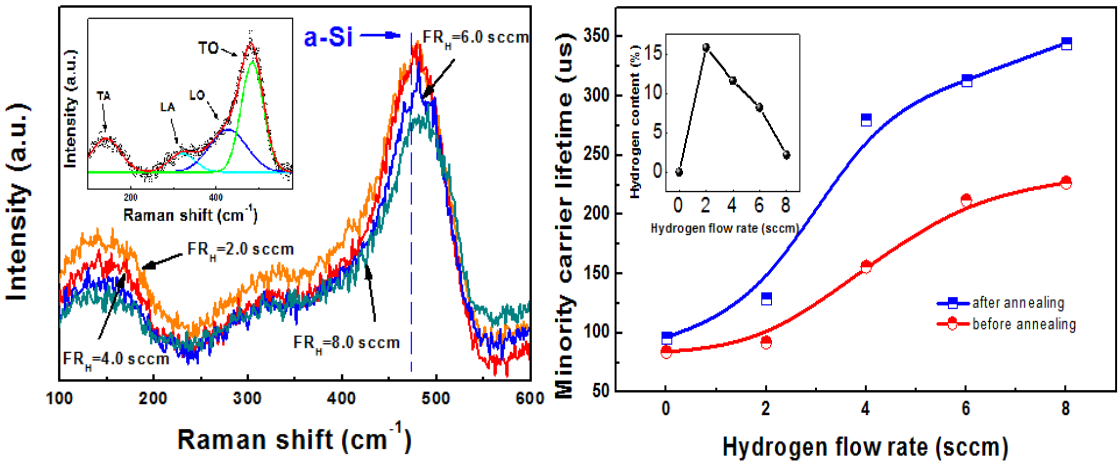


Fig.1 Ir Absorption Spectra Of Thin Films In Various Absorption Regions. (a) A Bending Mode At Near 630 Cm^{-1}; (b) A Doublet At 750-950 Cm^{-1} Which Is Associated With The Dihydrides Sih_2 Scissoring Mode And The Polysilanes $(Sih_2)_N$ Bending Mode, Respectively; (c) A Stretching Mode Centered At Approximately 2090 Cm^{-1}.

The Raman scattering are used to estimate the crystal phase information in the thin films due to its sensitivity to the structural disorder in solids. A typical deconvolution result is shown in the inset of Fig.2.(a), the Raman spectra of a-Si:H film prepared at hydrogen flow rate of 6.0 sccm, where curves (from left to right) denote the TA bond, LA bond, LO bond and TO bond, respectively. The TO phonon band at about ω_{TO}=480 cm^{-1} is sensitive to the short-range order (SRO) of amorphous network. Fig.2.(a) includes the Raman spectra of a-Si:H thin films prepared at various FR_H. The corresponding characteristic parameters are listed in Table 1. It can be seen that the all curves have the broad TO peak at near 480 cm^{-1}, namely Raman features of typical a-Si. The increase in MRO is characterized by the decrease in the ratio I_{TA}/I_{TO} in experiment. As shown in Table 1, there are a decrease in value of I_{TA}/I_{TO} from 0.63 to 0.39, a narrowing of Γ_{TO} by ~2.5 cm^{-1}, a blue-shift by ~3.1 cm^{-1}, and a decrease in the average bond angle deviation $\Delta\theta$ by ~0.41°, indicating that the amorphous network becomes more ordered on both short and intermediate scales. In addition to the structural disorder, the shift of ω_{TO} also depends on the intrinsic stress in the thin film [5]. It is seen from Table 1 that as FR_H increases from 2.0 sccm to 8.0 sccm, the ratios of I_{LA}/I_{TO} and I_{LO}/I_{TO} decrease from 0.3 and 0.64 down to 0.19 and 0.58, respectively. In our present study, the decrease in LA (near 300 cm^{-1}) and LO (near 410 cm^{-1}) strength associated with coordination defects, can be attributed to the reduction of silicon coordination defects and closed rings in the amorphous network due to a higher FR_H. It is verified that the amorphous network of a-Si:H films become more ordered on short and intermediate scales. We find that with the increase of hydrogen flow rate, E_{opt} collapse from 1.78 eV to 1.67 eV by UV-VIS test.

TABLE.1 RAMAN CHARACTERISTIC PARAMETERS OF THIN FILMS. THE AVERAGE BOND ANGLE DEVIATION $\Delta\theta$ IS CALCULATED BY THE EMPIRICAL FORMULA $\Gamma_{TO}=15+6\Delta\theta$

Sample	FR_H (sccm)	ω_{TO} (cm^{-1})	Γ_{TO} (cm^{-1})	$\Delta\theta$ (°)	I_{TA}/I_{TO}	I_{LA}/I_{TO}	I_{LO}/I_{TO}
A	2.0	482.07	54.68	6.61	0.63	0.30	0.64
B	4.0	482.87	53.32	6.39	0.58	0.28	0.61
C	6.0	484.54	52.26	6.21	0.42	0.21	0.59
D	8.0	485.17	52.18	6.20	0.39	0.19	0.58

In our study, the in-situ annealing treatment in vacuum is performed on the prepared samples. The annealing time is kept constant for 2 h, and the annealing temperature is 300 ℃. The FR_H dependent effective lifetime τ_{eff} is shown in Fig.2.(b) Comparing the minority carrier lifetime before and after annealing treatment, while the τ_{eff} increased with increasing FR_H in both cases, but the minority lifetime improved more obviously after annealing. As a result, the maximum value of carrier lifetime ～345 μs was obtained in the annealed sample deposited at a FR_H of 8.0 sccm. Accordingly, it can be concluded that the hydrogen atoms in the films were activated and the weak bonding, Si-H_2mode, were rearranged to Si-H mode by annealing treatment [6].

(a) (b)

Fig.2 (a) Raman Spectra Of A-Si:H Films Prepared At Various Hydrogen Flow Rates And The Inset Shows A Typical Deconvolution Result (Raman Spectra Of A-Si:H Film Prepared At Hydrogen Flow Rate Of 6.0 Sccm); (b) The Minority Carrier Lifetime Before And After Annealing Treatment In A-Si:H Films Deposited At Fr_h Of 2.0, 4.0, 6.0 And 8.0 Sccm And The Inset Shows Variations Of Hydrogen Content (C_H).

Conclusion

In summary, a-Si:H thin films were deposited using radio-frequency magnetron sputtering method at various FR_H. The passivation effects of these thin films on crystalline silicon display the dependence on hydrogen flow rates. Our experiment demonstrated that the variation of the hydrogen content not only affects the nature of the film itself, but also the c-Si surface passivation. The in-situ annealing can also enhance the lifetime value through hydrogen diffusion toward to the interface. These are attributed to the saturation effect of the dangling bond and the stability of Si-H

bond. Optimal hydrogen flow rate as 8.0 sccm was obtained in this experimental conditions. Moreover, the further improvements of effective carrier lifetime in the prepared samples were found after in-situ annealing at 300℃ for 2 h. Base on these results, we realized that the combination of the RF-magnetron sputtering deposition and the thermal annealing of a-Si:H film are essential for improving the surface passivation.

Microwave-assisted Synthesis of Graphene Oxide-MnO_2 Composites for Supercapacitors

Ying Wen Duan[a*], Xun Sun[b], Hong Yu Zhao[c] and Zhi Bo Liu[d]

Institute of Materials Science and Engineering, Lanzhou University, Lanzhou 730000, China

[a]duanyw@lzu.edu.cn, [b]sunx_2010@lzu.edu.cn, [c]zhaohy10@lzu.edu.cn, [d]lzb867266@163.com

Keywords: grapheme oxide-MnO_2 composites; microwave-assisted synthesis; electrochemical property; supercapacitor

Abstract: Graphene oxide-MnO_2 (GO-MnO_2) was successfully synthesized by microwave -assisted method with the substrate of GO covered by MnO_2. MnO_2 contained disordered pore structure and aggregate of random shape. GO exhibited layer-like shape and had a large numbers of functional groups on its surface. The electrochemical measurements were employed by cyclic voltammetry (CV) and galvanostatic charge/discharge (GCD), the results showed that the GO-MnO_2 composite had good capacitive performance, the maximum of specific capacitance was 127 F g^{-1} at the current density of 100 mA g^{-1}.

Introduction

In recent years, tremendous effort has been devoted to the development of new energy storage devices due to their excellent electrochemical property, which can be used in different electric devices to meet the requirement of energy application, ranging from hybrid vehicles to portable electronics and large industrial equipment [1]. Supercapacitors, also named electrochemical capacitors (ECs) or ultracapacitors, have attracted incredible attention with their outstanding chemical and physical properties such as longer cycle life, higher power and energy densities than conventional electrical capacitors and secondary batteries [2]. Two types of supercapacitors, electrical double layer capacitor (EDLC) and pseudocapacitor, have been currently developed. The EDLC stores the electric energy from the electrostatic charges at the interface between the electrode and electrolyte [3], and the pseudocapacitor generally uses active metal oxides as its electrode, transferring their faradic charges by fast and reversible redox through a conducting polymer [4].

Metal oxide-carbon composites have gained extraordinary interest owing to their superior and additional electrochemical functions for pseudocapacitor and EDLC. Graphene oxide (GO), one of the most valuable derivatives of graphene, well-dispersed in aqueous solution due to its electrostatic repulsion [5], is a kind of carbon material that has been intensively employed for EDLC. The material with a two dimensional plane has plenty of oxygen functional groups bearing on the surface and edges [6]. The function groups are capable of immobilizing nanoparticles of metal oxides for charge storage [7]. Transition-metal oxides are fundamental candidates which are used as supercapacitor electrode materials [8]. As for the transition-metal oxides, RuO_2, one of the most popular electrode materials, exhibits prominent capacitive properties [9], but the high cost of Ru limits the commercial acceptance for practical application [10].

Manganese oxides have received considerable attention for supercapacitors due to its high theoretical specific capacitance, low cost, and good eco-friendly properties [11]. Recently, various research groups have worked with the syntheses of MnO_2 and carbon-based materials, including various methods such as thermal decomposition, electrodeposition, physical mixing and redox reaction [12,13]. The synthesis process usually uses hydrazine, sodium borohydride, ethylenediamine or oleic acid as reducing agents [14].

Being widely used in daily life and academic research, microwave irradiation has been a fast growing research field in the materials synthesis due to its dramatic reduction in reaction time and high internal heating rate, which are not possible to achieve by conventional heating methods. Manganese oxides can be prepared via dielectric heating by microwave irradiation [11], meanwhile, graphene oxides are perfect absorbents of microwave energy owing to the electrical conductive properties that can absorb a considerable fraction of irradiation [15]. The rapid and internal heating process has provided a remarkable efficiency to large-scale synthesis of carbon materials and their composites. In our work, we synthesize GO-MnO_2 composites by microwave irradiation, the experimental results reveal that the produced materials via this simple method have a good electrochemical performance for supercapacitor electrodes.

Experimental Method

Synthesis of Graphene Materials

GO was prepared from natural graphite (99.9999%, 200 mesh, Alfa Aesar) by a modified hummer method [16]. The as-prepared GO (0.27 g) was dispersed in deionized (DI) water and subjected to ultrasonic vibration for 2 h. Then 0.81 g $KMnO_4$ powder (99.99% J.T. Baker) was dissolved in DI water. Subsequently, $KMnO_4$ suspension was added dropwise into GO suspension under vigorous stirring. The mass ratio of GO:$KMnO_4$ was 1:3. The solution mixture was placed in a microwave reactor (Discover, CEM, USA) and heated at 150 °C for 10 min under 300 W. The resulting mixture turned to a brownish color. After cooling to room temperature, the deposit was filtered, washed several times with DI water and ethanol, and dried at 60 °C for 12 h in a vacuum oven. For comparison, 1.00 g $KMnO_4$ was dissolved in DI water to prepare pure MnO_2 following the same rest steps directly.

Preparation of Electrodes

The fabrication of working electrodes was carried out as follows. Briefly, the as-prepared composites, carbon black and poly (vinylidene fluoride) (PVDF) were mixed in a mass ratio of 80:10:10 and dispersed in the N-methyl-2-baredpolyvinylpyrrolidone (NMP) solvent. Then the slurry was coated onto the stainless steel substrate (1 cm × 2 cm) with a spatula, which was followed by drying at 100 °C for 12 h in a vacuum oven. Pure MnO_2 also used the same proportion and the step for preparing an electrode.

Characterization

The crystallographic structure of the materials was determined by powder X-ray diffraction (Shimadzu Labx XRD-6000) equipped with Cu K_α radiation (λ=1.5406 Å). Fourier transform infrared (FT-IR) spectrum was recorded on a Nicolet Nexus spectrometer with the standard KBr pellet method. The morphology of the sample was investigated by a scanning electron microscopy (SEM, JEOL JSM 5600).

Electrochemical Measurement

Electrochemical characterization was carried out using a three electrode configuration. A conductive substrate coated with GO-MnO_2 composites served as the working electrode, a platinum sheet and a saturated calomel electrode (SCE) served as the counter and reference

electrodes, respectively. The CV and GCD were employed by a CHI 614D electrochemical workstation in 1 M Na_2SO_4 aqueous solution. CV was applied between -0.1 and 0.9 V (vs. SCE) at different scan rates of 50, 100, 200 and 500 mV s^{-1}. GCD characteristics were measured in the potential range of -0.1–0.9 V (vs. SCE) with different current densities of 100, 200, 500 and 1000 mA g^{-1}. All the electrochemical experiments were carried out at room temperature.

Results and Discussion

Materials Characterization

In Fig. 1, the pure MnO_2 with the broad peaks shows poorly crystallized compound. The XRD pattern of GO shows sharp peaks at 11.5° and 43° corresponding to the diffraction of (002) and (100) planes, respectively. The sharp and strong peaks suggest a high crystalline structure of the GO. Calculated by Bragg's law, the basal spacing of GO (0.81 nm) is larger than that of the origin graphite (0.17 nm), indicating the interlayer distance is greatly expanded after the excellent oxidation of graphite into the GO. Three broad peaks of GO-MnO_2 at 12°, 37° and 66° are corresponding to the diffraction of (002), (006) and (119) planes of birnessite-type MnO_2 (JCPDS 18-0802, a=5.82 Å, c=14.62 Å), respectively. Herein, the diffraction peaks of GO cannot be observed, we think that the surfaces of graphene are covered by loaded MnO_2. The graphene content is estimated to be about 16 wt% by TGA. The broad and weak diffraction peaks of MnO_2 suggest the crystallization of MnO_2 is not complete.

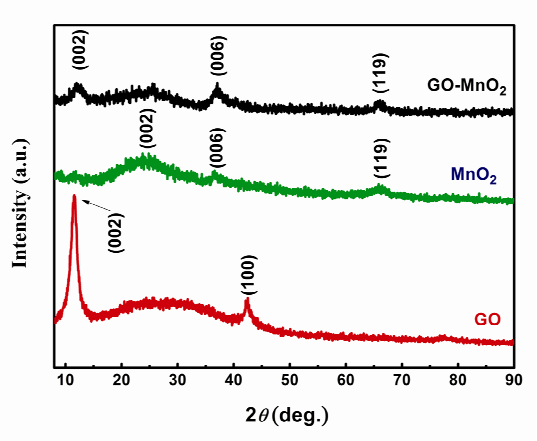

Fig. 1 XRD patterns of the MnO_2, GO and GO-MnO_2 composites.

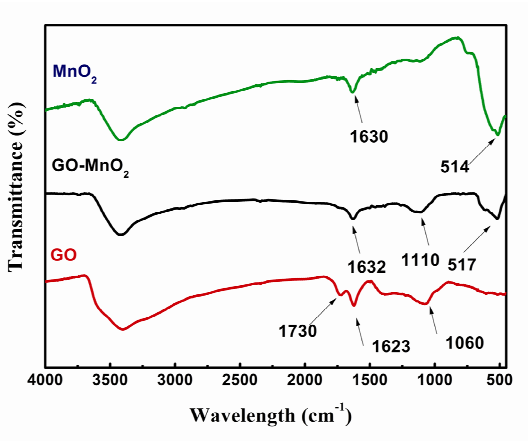

Fig. 2 FT-IR spectra of the MnO_2, GO and GO-MnO_2 composites.

Fig. 2 represents the FT-IR spectrum of the MnO_2, GO and GO-MnO_2 composites. The broad peak at 3250–3500 cm^{-1} is linked to the stretching vibration of water molecule and hydroxyl groups in the lattice. The 1630 cm^{-1} band is assigned to the C=C stretching, and the 1730 cm^{-1} band is usually attributed to the COOH groups of GO. The 1632, 1623 cm^{-1} band and the 1060, 1110 cm^{-1} band are usually attributed to the O-H bending vibration combined with Mn atoms of MnO_2 and composite. The band located at 517 and 514 cm^{-1} can be ascribed to the Mn-O vibrations of MnO_2. The FT-IR studies confirm the successful synthesis of GO-MnO_2 composites with plenty of functional groups on the surface.

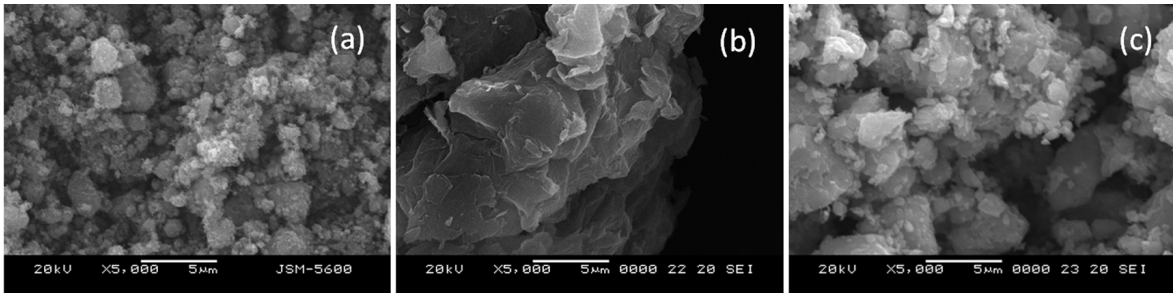

Fig. 3 SEM images of (a) MnO_2; (b) graphene oxide; (c) GO-MnO_2 composites.

The pure MnO_2 with a flower-like structure is not uniform with chunk presence in Fig. 3(a). The graphene oxide exhibits curved and layer-like shape with smooth surface in Fig. 3(b). The GO sheets are formed due to van der Waals interactions between layers [8]. Fig. 3(c) shows that the graphene sheets were coated on all surfaces with MnO_2, which contains disordered pore structure and aggregates of random shapes with different sizes from hundreds of nanometers to a few micrometers. The formation mechanism of as-obtained composite is due to plenty of functional groups on the basal planes and edges of GO, which provides the anchor sites to enable the MnO_2 attaching on these sides, i.e., the graphene oxides with carbonyl, carboxyl, and/or hydroxyl groups are more active and vulnerable to anchor metal oxides than the defect-free graphene surface [13].

Electrochemical Performance

Fig. 4(a) shows the CV curves of GO-MnO_2 and MnO_2 electrodes in 1 M Na_2SO_4 electrolyte at scan rate of 100 mV s^{-1}. The CV curve of GO-MnO_2 shows larger area compared with that of MnO_2. The specific capacitance of material is in proportion to the area of its CV curve, thus the electrochemical capacitance of GO-MnO_2 as electrode is larger than that of MnO_2 in 1 M Na_2SO_4 aqueous solution. The graphene sheet with inter-spacing expanded in the GO-MnO_2 composite electrode facilitates the penetration of the electrolyte into electrode. With additional and abundant micropores, MnO_2 coated on GO sheets shows good capacitive behavior due to the significant reducing of Na^+ diffusion length during the process of charge/discharge.

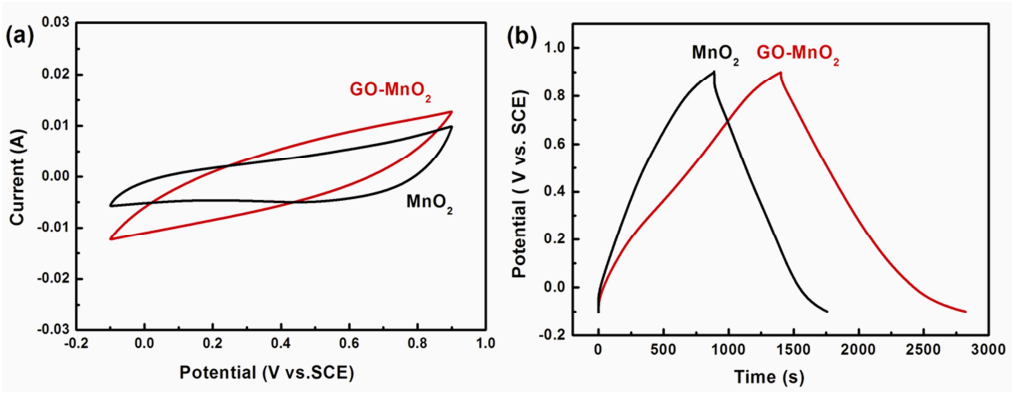

Fig. 4 (a) CV curves of GO-MnO_2 and MnO_2 electrode in 1 M Na_2SO_4 solution at scan rate of 100 mV s^{-1}; (b) GCD curves of GO-MnO_2 and MnO_2 electrode and pure MnO_2 in 1 M Na_2SO_4 solution under a current loading density of 100 mA g^{-1}.

Fig. 4(b) shows the GCD curves of the GO-MnO_2 and MnO_2 electrodes in 1 M Na_2SO_4 aqueous solution at a current density of 100 mA g^{-1}. It is clearly observed that the charge curve is symmetric to its corresponding discharge counterpart with a negligible curvature, which suggests the pseudocapacitive performance along with double layer contribution [6]. The C_s is calculated

according to $C_s=I\times\Delta t/(\Delta V\times m)$ from the discharge curves, where I is the constant discharge current, Δt is the total discharge time, and ΔV is the potential drop during discharge and C_s is the specific capacitance. The C_s is calculated to be about 127 and 50 F g^{-1} for GO-MnO_2 and MnO_2 electrode, respectively. Here, GO is not involved in the comparison due to the poor electrical conductivity and low faradic reaction rate as reported elsewhere [17], the electrochemical performance of GO is generally below 30 F g^{-1}.

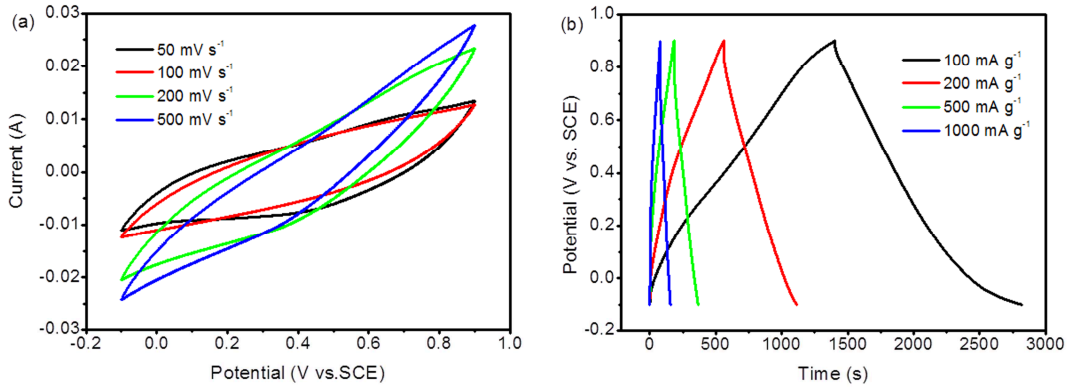

Fig. 5 (a) CV curves of GO-MnO_2 electrode in 1 M Na_2SO_4 solution under different scan rates; (b) GCD curves of GO-MnO_2 electrode in 1 M Na_2SO_4 solution under different current loading density.

To further evaluate the electrochemical performance of the as-synthesized GO-MnO_2 as electrode materials for supercapacitors, changing scan rates and current densities during the CV and GCD measurements are conducted. Fig. 5(a) shows the CV curves of the GO-MnO_2 electrode in 1 M Na_2SO_4 electrolyte under different scanning rates. The CV curves still retain a similar shape without obvious distortion and no redox peaks appear at different scan rates in the CV curves, proving that the electrode is charged and discharged at a pseudo-constant rate over the complete voltammetric cycle. Fig. 5(b) shows the GCD curves of the GO-MnO_2 electrode in 1 M Na_2SO_4 electrolyte under different loading current densities. The charge curve is almost symmetric to its corresponding discharge counterpart with a slight curvature, indicating the pseudocapacitive contribution along with the double layer contribution. The specific capacitances are calculated to be about 127, 116, 102 and 92 F g^{-1} at 100, 200, 500 and 1000 mA g^{-1}, respectively.

Conclusions

We have demonstrated a one-pot method to prepare GO-MnO_2 composites assisted by microwave irradiation without any chemical reductant. Compared with specific capacitance of 50 F g^{-1} for MnO_2, GO-MnO_2 composites exhibit a higher specific capacitance of 127 F g^{-1} at the current density of 100 mA g^{-1}, which derives from the disordered pore structure of the MnO_2 and expands inter-spacing of the GO-MnO_2 composite, i.e., MnO_2 anchored on the GO sheet improves the charge transfer and diffusion rate, and the graphene sheet with expanded layer structure in the GO-MnO_2 composite electrode facilitates the penetration of the electrolyte into electrode.

Abstract. The concentration and size distribution of Te inclusions in CdMnTe (CMT) are key factors in nuclear devices' performance. High-concentration and large-size Te inclusions degrade the performance drastically, especially for electrical properties. In this paper, the Te inclusions along the axial and radial directions in CMT crystal grown by the Traveling Heater Method (THM) were revealed by Infrared Microscopic System. The size of Te inclusions is 5-17 μm and the concentration is (2.5-4.6) $\times 10^5$ cm^{-3}. The Current-Voltage measurements were performed and the resistivity of the CdMnTe crystal with excess Te was in the range of 10^8-10^9 Ω•cm, and the correlation between the Te inclusions and resistivity was investigated. The large size (>17 μm) and high concentration (4.5 of $\times 10^5$ cm^{-3}) Te inclusion decrease the resistivity of the CMT crystal seriously.

Introduction

The $Cd_{1-x}Mn_xTe$ (CMT) crystals belong to group II-VI compound semiconductors and they are the excellent materials for developing X-ray, γ-ray detector and magneto-optical isolator [1-2]. It possesses several opportune properties, such as large band gap (1.53-2.54 eV), high density (5.2-5.9 g/cm^3), and good electronic-transport properties (10^{-3}-10^{-5} cm^2/V), making it a very attractive material to be used as room-temperature nuclear-detectors for homeland security, astronomy, and medical imaging [3]. In addition, because the segregation coefficient of Mn in CdTe is about 1, the distribution of Mn in crystal is uniform along axial-direction, which makes CMT a promising material for nuclear-detectors instead of $Cd_{1-x}Zn_xTe$ (CZT) [4].

The devices usages demand monocrystalline CMT crystals with good compositional homogeneity, free from macroscopic defects, such as grain boundaries, twins, and large Te inclusions. CMT crystals are usually grown by the conventional Bridgman method [5]. However, the high growth temperature (1120 ℃) causes the crystal many kinds of defects which degrade the electrical properties of CMT crystal [6]. The THM has been proven to be a promising method in yielding large-size, uniform single-crystalline CZT and CdTe ingots [7, 8]. By THM, crystals can be grown at relatively low temperatures (900 ℃) compared with the melt growth, and the Te solution absorbs the impurity from the source materials and growth crucibl，therefore, crystals can be grown with less thermal stresses and high purity. However, the THM method has a major disadvantage that the Te solution introduces Te inclusions in the ingots because of the microscopically irregular melt–solid interfaces during growth, which can trap the Te-rich CMT solution forming inclusions [9-11]. It decreases the resistance of CMT and traps electron-hole when exerting bias voltage on CMT wafer. In this study, the CMT crystal was grown by the THM method and Te inclusions along the axial and radial directions of the CMT ingot were revealed by the Infrared microscopic system BX51-IR. Then the resistivity of the CMT wafers was measured by the current-voltage curves using Keithley 4200-SCS electrometer, and the relationship of the Te inclusions and the resistivity was investigated.

Experiments

All the CMT(x=0.1) crystals were grown by the THM technique from a Te-rich solution. The crystal growth was unseeded, carried out in conically tipped quartz ampoules, with a graphite coating on their inner walls. We loaded the required amount of CMT source and excess 6N purity Te, as well as 6N purity indium as a dopant, in the ampoule of 26-mm inner diameter. The ampoule was subsequently sealed under a vacuum of 1 $\times 10^{-4}$ Pa. The sealed ampoule was loaded into a three zone vertical tubular furnace. The temperatures of the three zones were set to achieve the required temperature gradient near the growth interface. A very low-speed DC motor was used for lowering the crucible into the furnace. Lowering rate from 3 to 5 mm/day was used for the growth and the temperature gradient near the growth interface was between 20 and 50 ℃/cm. The crucible was rotated in a speed from 3 r/min to 10 r/min. Finally, ingots were cooled at a rate of 100 ℃/h to room temperature after the growth was completed.

To study the distribution of Te inclusions, the crystal ingots were sliced into wafers with the thickness 2-5 mm perpendicular to axial-direction with inner circle cutting machine, then the wafers were sliced-into pieces with 8×8 mm^2 area using an inside-diamond wire saw machine. The testing samples were from different parts of the ingot, as shown in Fig.1.

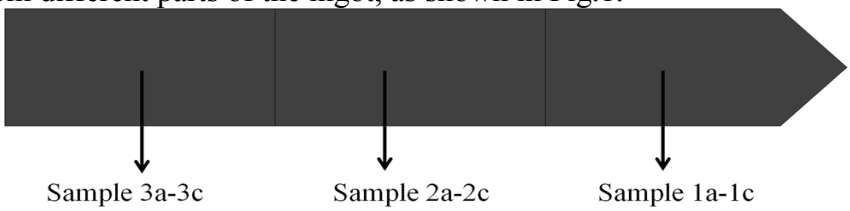

Fig.1 The samples from the different region of the ingot

The samples were mechanically polished with 0.3 mm alumina and 0.05 mm alumina suspensions to obtain mirror-like wafer surfaces. An Infrared Transmission Microscopy was employed to record the concentration and size distribution of Te inclusions in CMT. The current-voltage curves of the samples were measured at room temperature to evaluate the electrical behaviors. The wafer surfaces were passivated using BM (Br_2 and Methanol) and LB (Br_2 + Lactic Acid + Glycol) for 2 minutes, separately. Deposited gold was used for contact metallization.

Results and discussion

The IR transmission microscopy is known to be one of the most effective ways of detecting Te inclusions in CZT and CMT. Fig.2 shows the typical IR microscopic images of Te inclusions with regular triangular or hexagon shapes in the CMT wafers grown by THM. Taking into account the isotropy of melt, the trapped Te-rich droplet will tend to stabilize into a spherical shape due to surface tension. However, Te-rich droplet gradually becomes a polyhedral such as triangular or hexagon because of the deformation of CMT lattice and the anisotropic growth of Te inclusions.

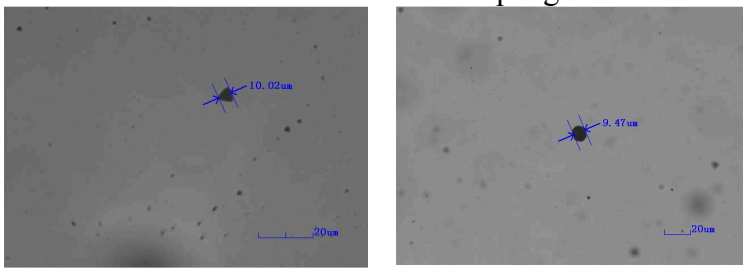

Fig. 2 The typical Infrared microscopic images of Te inclusion

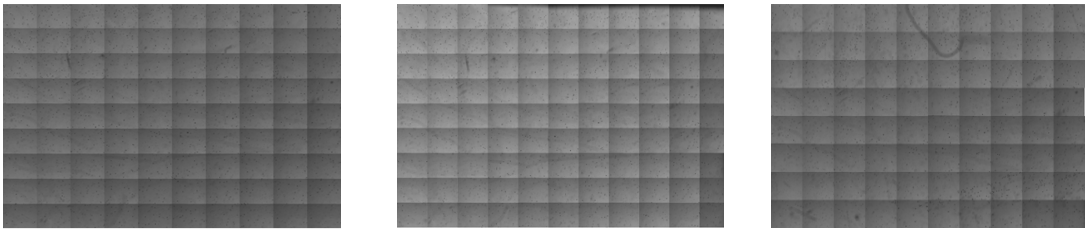

Fig. 3 shows the IR transmission images of Te inclusion in the samples from the first-to-freeze, stable-to-freeze and last-to-freeze parts of the ingot named with (a） CMT1b, (b) CMT2b and (c) CMT3b. It reveals that Te inclusions were randomly distributed throughout the samples. The size of those inclusions is mostly less than 20 μm, and their concentration is about 10^5 cm^{-3}. In order to reveal

the concentration and size distribution of Te inclusions intuitively, we change the actual datum of Te inclusions in Fig. 3 into a column chart, as shown in Fig. 4.

It's found that, in the first-to-freeze region, the size of Te inclusion is small, about 6 μm and the concentration is high, about 4.5×105 cm^{-3}. In the stable-to-freeze region, the size becomes larger, about 10 μm and the concentration decreases to 2.5×10^5 cm^{-3}. In the last-to-freeze region, the size is about 17 μm and the concentration is about 4.2×10^5 cm^{-3}. The size of Te inclusion varies in connection with the annealing time of ingot. From the first-to-freeze to the last-to-freeze part of the ingot, the time becomes less, so the size keeps on growing. The concentration is affected by the stability of interface and the excessive Te. In the first-to-freeze region, the excessive Te is small but the interface is unstable, so the concentration is high. With the stable interface in the stable-to-freeze region, the concentration of Te inclusion decreases. In the last-to-freeze region, the concentration is still high with the large excessive Te.The concentration of Te inclusion is mainly effected by Table 1 gives the Te inclusions in the radial direction of CMT samples. The results shown that the Te inclusions are almost the same in the equal radial direction, which indicate a planar solid-liquid interface during the THM growth.

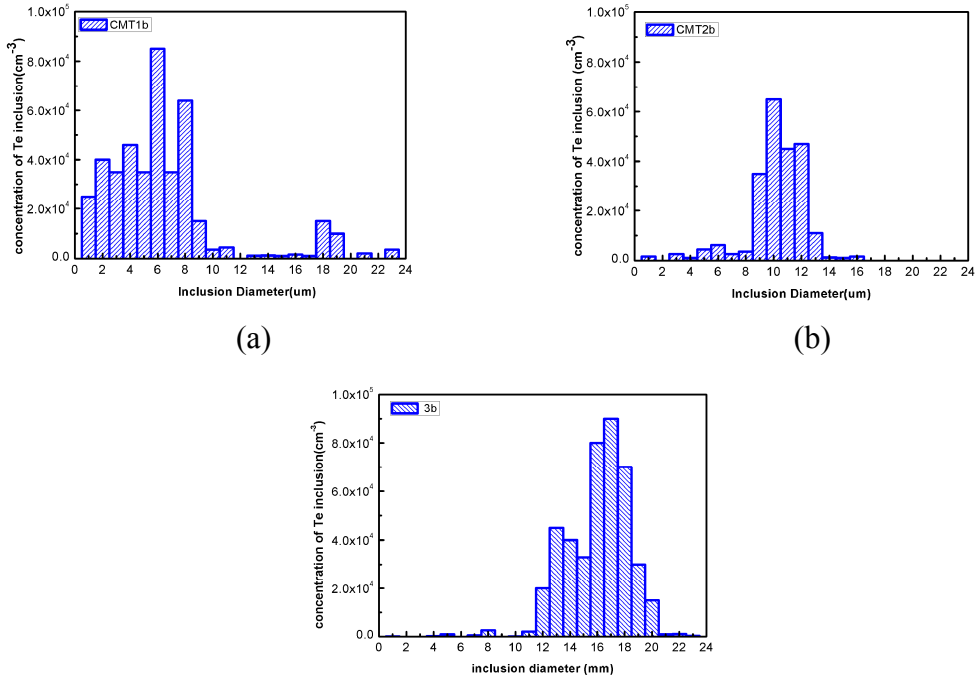

Table 1 The concentration and size of the samples of Te inclusions

Sample	1a	1b	1c	2a	2b	2c	3a	3b	3c
$D_{Te}[10^5cm^{-3}]$	4.6	4.52	4.46	2.45	2.50	2.53	4.3	4.19	4.10
Size[μm]	5.7	6.1	6.4	8.8	10.2	9.6	16.8	17.1	17.2

(a) (b)

(c)

Fig.4 Histogram of the Te inclusions size distribution in CMT samples（a）CMT1b（b）CMT2b（c）CMT3b

The current-voltage (I-V) curves of the samples are measured at room temperature. The typical I-V curves of sample 1b, 2b and 3b are shown in Fig. 5. The corresponding bulk resistivity of the three

wafers were 2.3×10^8 Ω•cm, 4.4×10^9 Ω•cm, 6.6×10^8 Ω•cm respectively. The results were shown in table 2. From CMT1b to CMT3b, with the size of Te inclusion becoming larger and the concentration tardily becoming lower then high, the resistivity of sample first becomes high then becomes low. Te inclusion in the crystal not only reduces the lifetime of electron-hole but also absorbs other impurities. When the size of Te inclusion is small, it is unable to degrade the lifetime, thus the resistivity is low. With the size becoming lager, the shorter the lifetime of electron-hole is, the high resistivity of the samples is. But when the size of Te inclusion increases to 20 μm, it also absorbs other impurity, the resistivity of the samples is low again. Consequently, the resistivity is not only related to the size of Te inclusion but also related to the concentration. The larger the size and the higher the concentration of Te inclusion are, the lower the resistivity of CMT is.

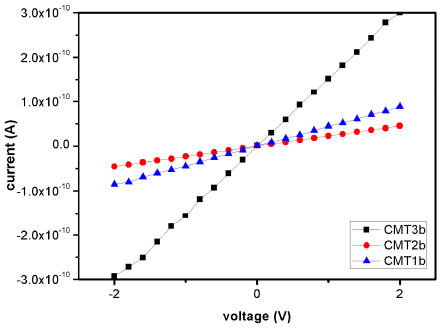

Fig.5 I-V curves of the CMT samples from different parts by THM

Table 2 The size and concentration of Te inclusion and the resistivity of sample

	CMT1b	CMT2b	CMT3b
$D_{Te}[cm^{-3}]$	4.5×10^5	2.5×10^5	4.2×10^5
Size[μm]	6	10	17
ρ [Ω.cm]	2.3×10^9	7.4×10^9	6.6×10^8

Summary

1) Te inclusion with regular triangular or circular shapes is randomly distributed throughout CMT crystal by THM.

2) In the first-to-freeze region, the size of Te inclusion is about 6μm and the concentration is 4.5×10^5 cm^{-3}; In stable-to-freeze region, the size is about 9 μm and the concentration is 2.5×10^5 cm^{-3}; In the last-to-freeze region, the size is about 17 μm and the concentration is about 4.2×10^5 cm^{-3} μm.The rate of the radial directions is almost the same.

3) The resistivity of the CMT is low to high to low from the first-to-freeze to the last-to-freeze region. The large size and high concentration of Te inclusion seriously decrease the resistivity of the CMT crystal.

Keywords: Cu-doped ZnO film, Copper source, Optical properties

Abstract: Cu-doped ZnO (CZO) films have been widely discussed due to its potential applications in semiconductor devices, such as gas sensors or solar cells, but few articles were reported to show the effect on properties of CZO films by using different Cu sources. The article demonstrates that CZO films have been prepared by using different Cu source via a simple ultrasonic spray method, in which copper nitrate and copper acetate were used as copper sources. Optical properties of CZO films prepared by copper nitrate and copper acetate were investigated by transmittance and photoluminescence measurement. The X-ray diffraction analysis and field emission scanning electron microscopy were used to investigate the composition and the morphology of the films. The CZO films prepared by using copper acetate shows better optical properties by comprehensive analysis.

Introduction

It is well known that zinc oxide (ZnO) is a wide direct bandgap (3.36eV) II-VI compound semiconductor, which has a large exciton binding energy of 60mV with a hexagonal wurtzite structure [1]. On the other hand, copper oxide is one kind of semiconductor with a band gap of 1.4eV and absorbs strongly in visible spectrum [2]. The Cu-doped ZnO film (CZO) which is combined by ZnO and CuO has been widely researched due to its potential application in many fields, such as gas sensors, solar cells and so on [3~9]. The common copper source used for CZO film via ultrasonic spray method are copper nitrate and copper acetate [10,11]. There are few papers reported to discuss the physical properties of the CZO films using different copper sources.

In this study, ultrasonic spray method is employed to prepare CZO films with different Cu sources and the structures, morphologies, and properties were measured by various techniques. The ultrasonic spray method was used because it has the advantage of high growth rate, large area uniformity, and inexpensive preparation [12].

Experimental Details

CZO films were deposited by ultrasonic spraying technique at atmospheric pressure on a glass substrate. Before deposition, the glass substrates were first cleaned in Acetone and Methanol. Then the substrates were rinsed in de-ionized water and dried in the flowing Nitrogen. To obtain the precursor solution, three kinds of aqueous solution, zinc acetate, and ammonium acetate were chosen as the sources of zinc and nitrogen, copper acetate or copper nitrate as the source of copper respectively. The molar concentration of zinc acetate and ammonium acetate solution were 0.05M and 0.45M and the copper acetate or copper nitrate is 0.1M. The solutions were stirred at room temperature for 1h and then moved into a commercial ultrasonic nebulizer where makes the solutions be aerosol. The aerosol was transported to the substrate by high-purity nitrogen gas and the substrate was kept at 500°C. The deposition time lasts for 15 minutes.

The crystalline microstructure of the films were determined by a PANalytical X'Pert Pro DY2840 X-ray diffraction with Cu-Kα radiation (λ=0.1541nm) in the scanning range between 2θ=20° and 60°. Surface morphology was studied by a JEOL JSM-5600LV scanning electron microscope. Optical

transmission properties were measured in the range of 300-1000nm using by a Hitachi U-2001 Ultraviolet-Visible spectrophotometer. Photoluminescence (PL) spectra were excited by a He-Cd laser (325nm) and collected by a Dongwoo spectrophotometer at room temperature.

Results and Discussion

Crystalline structure

Fig.1 shows the XRD patterns of CZO films deposited on glass substrates. The CZO film using copper acetate have several peaks, which show that the film has both ZnO and CuO phases. The diffraction peaks marked as "Z" were observed at 2θ=31.86°, 34.57°, 36.39°, 47.66°and 56.71°, which can be corresponded to (1 0 0), (0 0 2), (1 0 1), (0 1 2), and (1 1 0) planes of ZnO phase. This result showed the thin film was polycrystalline and had a hexagonal wurtzite structure of ZnO phase. For the peaks marked as "C" and observed at 2θ= 35.60°, 38.76°, 48.95°, and 58.30° are corresponding to (1 1 -1), (1 1 1), (2 0 -2), and (2 0 2) planes of CuO with monoclinic structure. The peaks observed above are fully matched with the hexagonal wurtzite structure ZnO (JCPDF # 75-0576) and monoclinic structure CuO (JCPDF # 89-5895). On the other hand, the film using copper nitrate only shows two diffraction peaks which are corresponding to (1 1 -1), (1 1 1) planes of CuO with monoclinic structure and the intensity of the peaks are lower than that of the former. From Fig.1 it is evident that the film using copper acetate has both CuO and ZnO phases and the intensity difference between two films implies that the film using copper acetate has better crystalline.

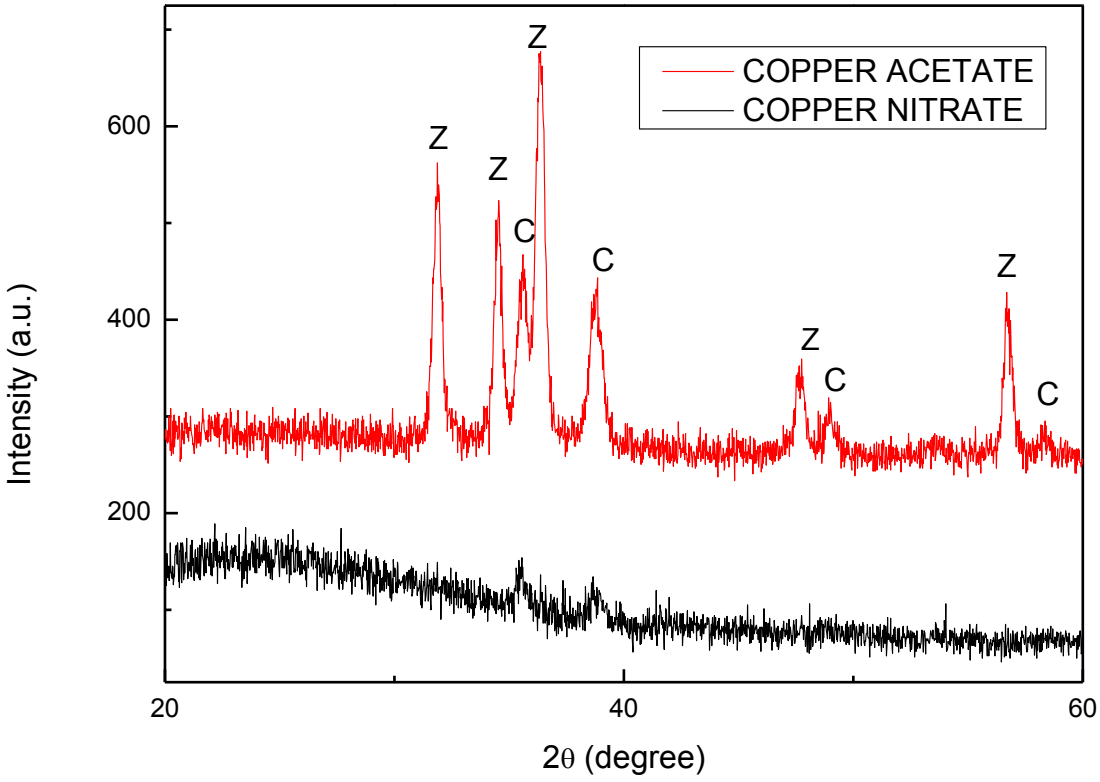

Fig. 1 XRD Patterns of CZO thin Films Using Different Copper Sources.

Fig. 2 depicts the scanning electronic microscopy (SEM) images of the surface morphology of CZO films were observed. As shown in the figure, the morphology of the films using different copper sources are quite different from each other. The film using copper acetate formed small island

structure with about 1 micrometer diameter on the films and the film thickness is about 500nm. The deposited film using copper nitrate failed to cover the whole glass substrate and form uniform and dense layer. The dark background of the SEM image is corresponding to glass substrate and the bright areas is CZO film with sheet morphology structure. The SEM images show that the film using copper nitrate has poor crystalline which is in keeping with the result of XRD analysis and also imply that the film deposition velocity is much slower when using copper nitrate as copper source.

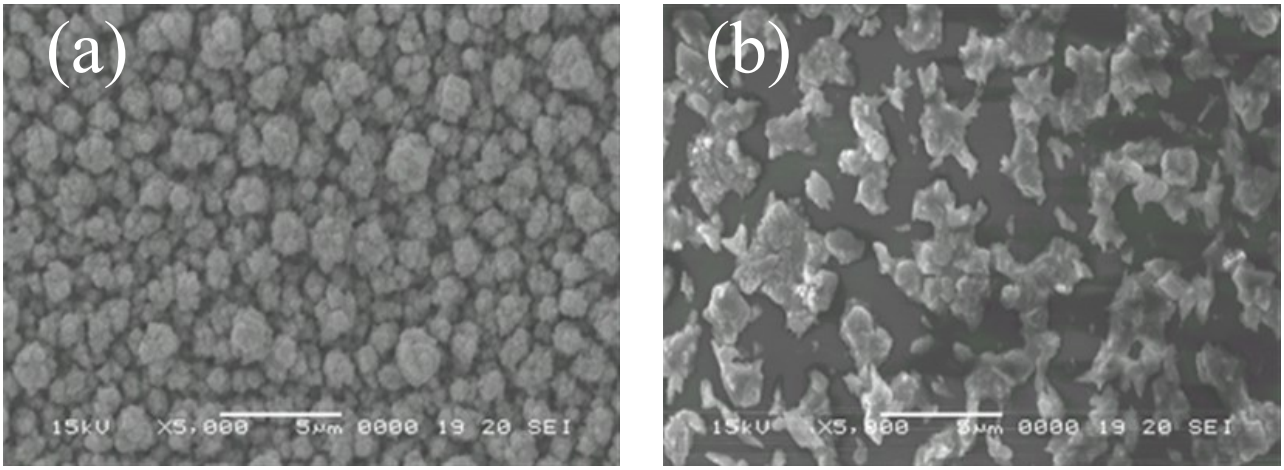

Fig. 2 SEM Images of CZO Films Using Different Copper Sources, (a) Copper Acetate, (b) Copper nitrate.

Optical characteristics

The optical transmittance spectra of CZO films are shown in Fig. 3(a). Due to the film using copper nitrate failed to cover the whole substrate, the lowest value of the transmittance spectrum of the film using copper nitrate isn't zero, and the value of transmittance spectrum is about 19% from 300nm to 700nm which means that about 80% region of the substrate were covered with CZO film. It can be observed from the spectrum that the film using copper acetate has strong absorption in visible region. It's similar to the properties of CuO film.

The direct optical band-gap E_g of the films as shown in Fig. 3(b) was obtained from the transmission spectra using the following relationships:

$$\alpha d = -\ln T \tag{1}$$

$$(\alpha hv)^2 = A\left(hv - E_g\right) \tag{2}$$

Where α is the absorption coefficient values; d is the film thickness; T is the transmittance spectra of thin films; A is a constant; hv is the photon energy and E_g is the optical band-gap of the semiconductor.

The graph of α^2 versus hv plots for the film using copper acetate is shown in Fig. 3 (b). It can be seen that the extrapolation of linear portion of the graph to energy axis at $(\alpha hv)^2=0$ gives the E_g value. The optical band-gap of the film using copper acetate is 1.8eV which is in the interval of the band-gap of CuO (1.4eV) and ZnO (3.36eV). The optical band-gap of the film using copper acetate were failed to be calculated by this way because the film thickness were hard to measure.

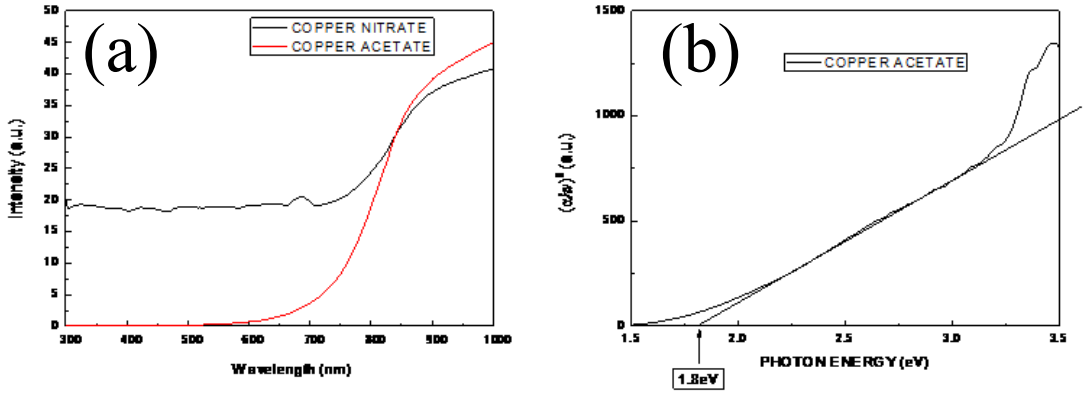

Fig. 3 Transmittance Properties and Variation of the CZO Films: (a) Optical Transmission Spectra of the CZO Films, (b) the Graph of $(\alpha hv)^2$ vs. hv Plots For the Film Using Copper Acetate.

Photoluminescence (PL) measurement of the CZO films was carried out to gather further information of optical properties. Fig. 4 shows the PL spectra of the films. The peaks of the film using copper acetate was indicated at 665nm and 760nm. The peak centered at 665nm is corresponding to the optical band-gap of the CZO film and is close to the band observed in a single ZnO film, which is also attributed to the single and double ionized oxygen vacancies [13,14]. Many groups postulated that the near-IR emission at about 760nm originates from defects similar to those responsible for the red emission in ZnO, i.e. oxygen vacancy [15,16]. It's obvious that the CZO film using copper nitrate shows weak Near-IR emission which is centered at 760nm and mainly caused by oxygen-related defects.

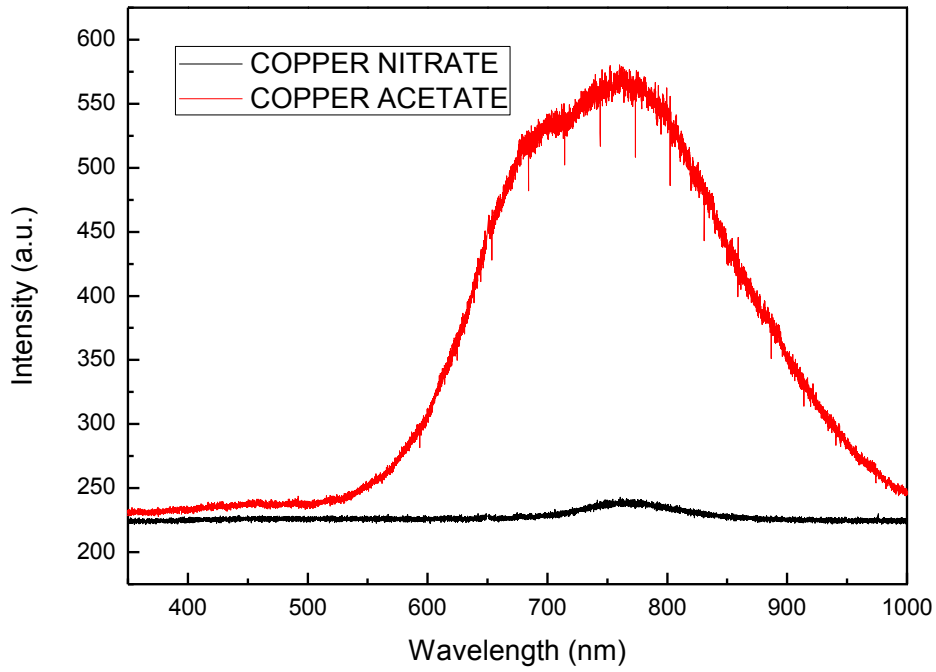

Fig. 4 Room Temperature PL Spectra of CZO Films.

Conclusion

The structural, morphological, and optical properties of the CZO films using different copper sources prepared via ultrasonic spray method were investigated. The XRD patterns showed that the film using copper acetate are polycrystalline with both ZnO and CuO phase and has better crystalline. The transmission measurement related to the optical band-gap of the film using copper acetate showed the film having strong absorption in visible region as expect and the optical band-gap is about 1.8eV. The film using copper acetate showed strong Near-IR emission of photoluminescence features. All these analysis indicates that the prepared CZO films using copper acetate has better crystalline and optical properties than using copper nitrate.

The Model of Nano-scale Cu-particle Removal in CO_2-based Micelle Solutions with Different Surfactants

Yunrun Wang

Department of Physics, Renmin University of China, Beijing, 100872, China

yunrunwang@163.com

Keywords: equilibrium separation distance, net adhesion force, high pressure, carbon dioxide, surfactant

Abstract: This work focused on the analysis of static forces of a Cu particle in CO2-based micelle solutions with different surfactant, including fluorinated surfactants PFPE COO-NH4+, 8FS(EO)2 and hydrocarbon surfactants L31, DiF8-PO4-Na+. Calculations demonstrated that high pressure could impose enough capillary pressure effect beneath a particle to compete with the net adhesion force and increase the particle surface separation distance. The ESD for the micelle solutions had the similar behavior, otherwise, the value of NAF for the micelle solution with surfactant DiF8-PO4-Na+ had the minimum relative to other surfactant micelle solutions, suggesting that Cu particles would be more easily removed in micelle solution with DiF8-PO4-Na+ surfactant.

Introduction

Copper has replaced aluminum for interconnectors in semiconductor industry to satisfy the demand for better performance [1]. During the cleaning units in semiconductor industry, residues on the via sidewall and bottom of the trenches must be removed. As the characteristic dimension in wafers shrink to nano-scale dimension, the ability of cleaning solutions to penetrate small features and contact the residues will become significantly challenging. Generally, external pressure must be exerted on the fluid to penetrate the features. In addition, the cleaning solution will be difficult to remove due to Laplace pressure. Therefore, novel concepts in cleaning processes are required to overcome these challenges.

Water and carbon dioxide constitute two of the most abundant and environmentally benign solvents on earth. Dense CO2, liquid and supercritical, has many desirable properties for cleaning wafers. It is inexpensive, essentially nontoxic, inert, and nonflammable. The surface tension of liquid carbon dioxide is only 1.5 mN/m at 25 ºC and reaches zero at the critical point, where liquid droplets are no longer formed [2]. The beneficial interfacial property promotes the penetration of small features. The formation of water-in-CO2 (W/C) microemulsions has spawned novel applications for CO2. The H2O-CO2 systems with surfactants are being explored for cleaning of wafers in microelectronics processes. The introduction of excess amount of solution into CO2 solvent forms a fluid bridge between microscopic particles and surfaces, which makes the static-force system more susceptible to pressure changes. This second fluid phase forms a well-defined phase interface with the bulk CO2 solvent. Because of the curvature of this phase interface, there is a pressure change within the entrapped fluid bridge, which can be calculated by the Kelvin equation [3]. The entrapped fluid brings two opposing forces on the particle, one adding to the adsorption forces, the other acting to counteract those forces [4].

In this study, the net adhesion forces (NAF) and equilibrium separation distance (ESD) of a copper particle adhering on silicon wafer in CO2-based micelle solution with different surfactants were calculated. The calculated results demonstrated that elevated pressure applied in cleaning system can significantly alter the static force balance on adhered particles.

Model Description and Procedure

In the general way, adsorption forces consist of Van der Waals force, classical Coulombic attraction (electrostatic image force), contact potential force, and fluid bridge force. These forces act as an obstacle for removing particles adhering to the surface. With regard to the fluid bridge entrapped between the particle and the surface, there is an opposing force or the capillary pressure due to the curvature of the interface acting against the adsorption force. We adopted the model and procedure intruduced by the reference [4], and caculated the net adhesion forces (NAF) and equilibrium separation distance (ESD) of a copper particle adhering on silicon wafer in CO2-based micelle solution with different surfactants. In the calculation, we introduced a variable (immersion height d) to represent the depth of the particle beneath the heavy phase of the CO2-based solutions.

Results and Discussion

The NAF is the sum of all of the forces which adheres the particle to the substrate. The ESD is a static particle-substrate separation distance where the all of the downwards forces imposed on the particle and the upwards forces are equal in magnitude. The calculation focused on the copper particles with different radius (50 nm~300 nm) in CO2-based micelle solution with fluorinated surfactant PFPE COO-NH4+, 8FS(EO)2 and hydrocarbon surfactants L31, DiF8-PO4-Na+ under different pressures. In the calculation, the data of surface tension and entrapped fluid dielectric constant of CO2-based solutions at certain pressure and temperature were taken from references [4].

Generally, a particle with larger ESD and smaller NAF would be removed more easily. Chai' research work demonstrated that high pressure could increase the particle-substrate separation distance in the regions of pressures studied and this effect might be coupled with a decrease in NAF for the CO2-H2O system, suggesting that particles would be removed more easily at high pressure.

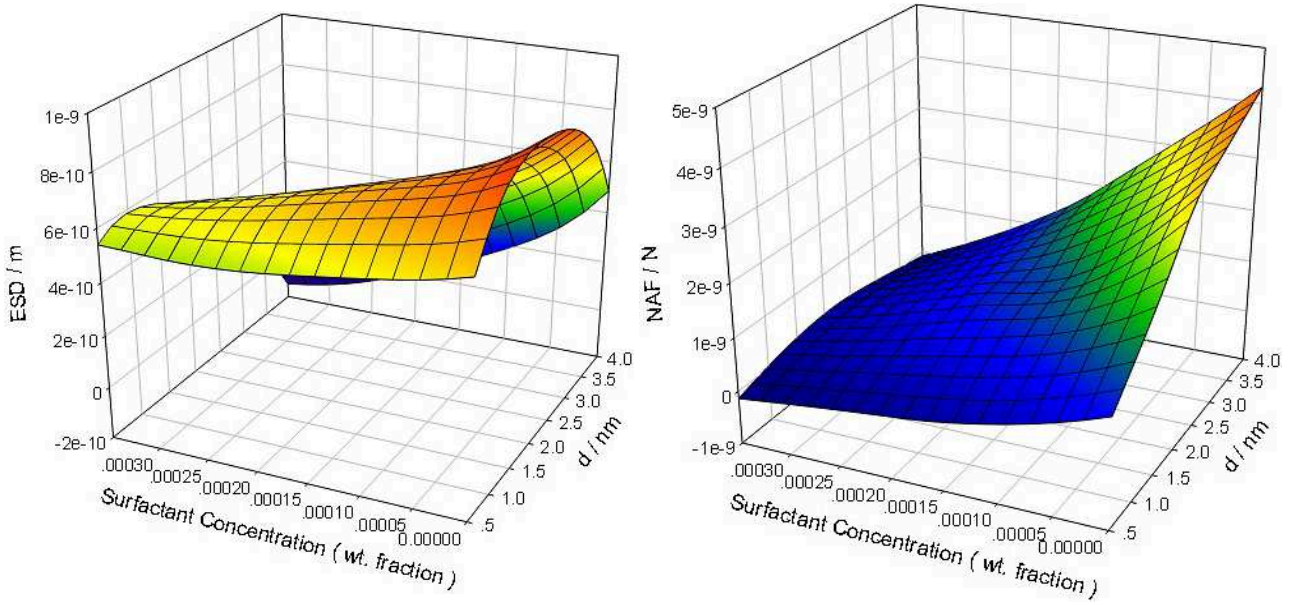

Figure 1. ESD and NAF as a function of the surfactant concentration and submersion height (d) in CO_2-based micelle solution at 313 K and 25 MPa, surfactant: PFPE COO-NH4+, particle radius: 50 nm.

In this work, a copper particle with 50 nm radius in CO2-based micelle solutions with surfactants PFPE COO-NH4+,8FS(EO)2, L31 and DiF8-PO4-Na+ was be given the object of study. Figures 1 to 4 showed the NAF and ESD as a function of surfactant concentration and immersion height in CO2-based micelle solutions. The value of ESD in CO2-based micelle solution was nearly independent of surfactant concentration as the immersion height was fixed, and the value of NAF decreased with increased surfactant concentration. As the surfactant concentration was given, the value of NAF decreased with the decrease of immersion height. Unlike the trends of NAF, the value of ESD had a maximum in the immersion height ranges for both surfactant systems. The ESD for the micelle solutions has the similar behavior, otherwise, the value of NAF for the micelle solution with surfactant DiF8-PO4-Na+ had the minimum relative to other surfactant micelle solutions, suggesting that Cu particles would be more easily removed in micelle solution with DiF8-PO4-Na+ surfactant. From the calculation results, we could see that in order for particles to remove, entrapped fluid layer between the particle and substrate is needed. Holding the certain value of immersion height will be favorable to particle removal.

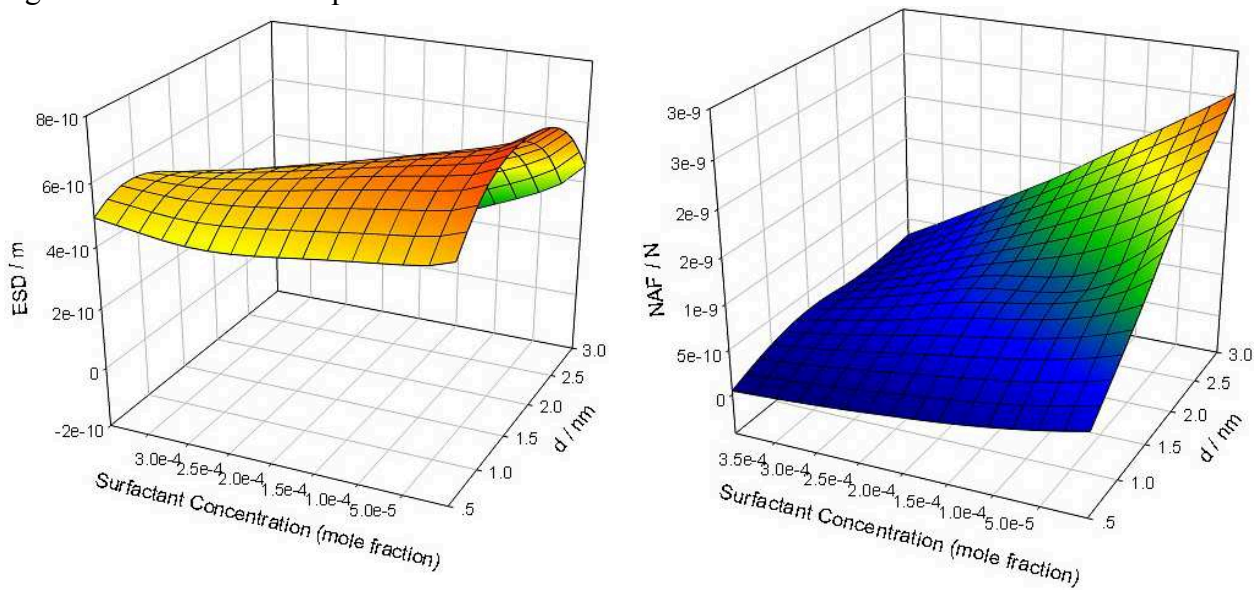

Figure 2. ESD and NAF as a function of the surfactant concentration and submersion height (d) in CO_2-based micelle solution at 313 K and 25 MPa, surfactant: L31, particle radius: 50 nm.

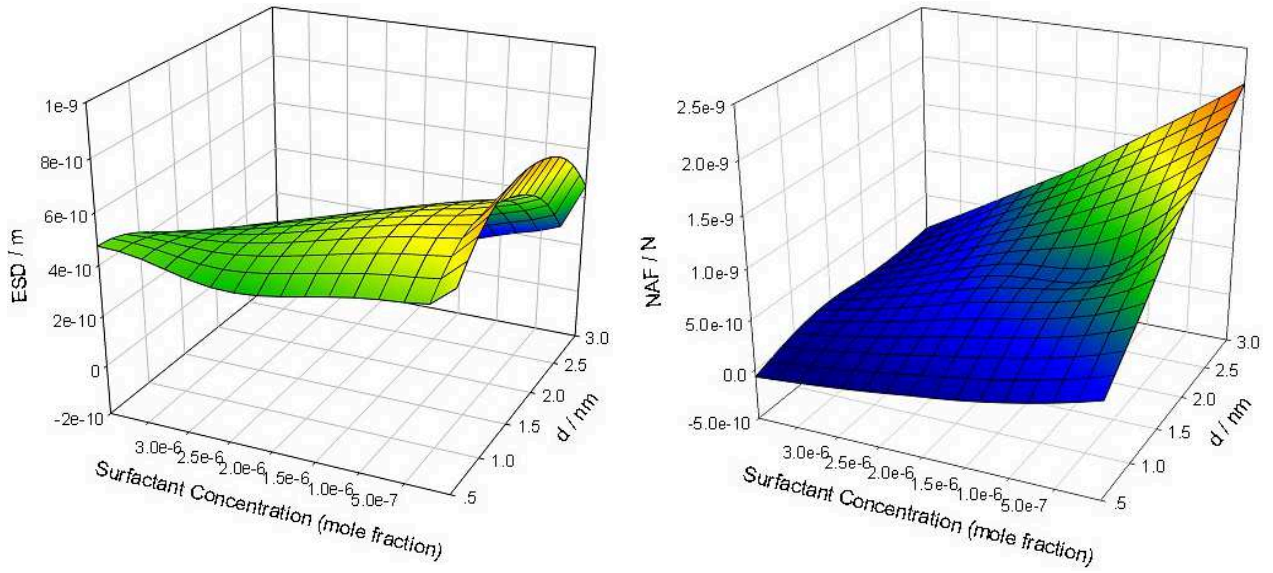

Figure 3. ESD and NAF as a function of the surfactant concentration and submersion height (d) in CO_2-based micelle solution at 313 K and 25 MPa, surfactant: 8FS(EO)2, particle radius: 50 nm.

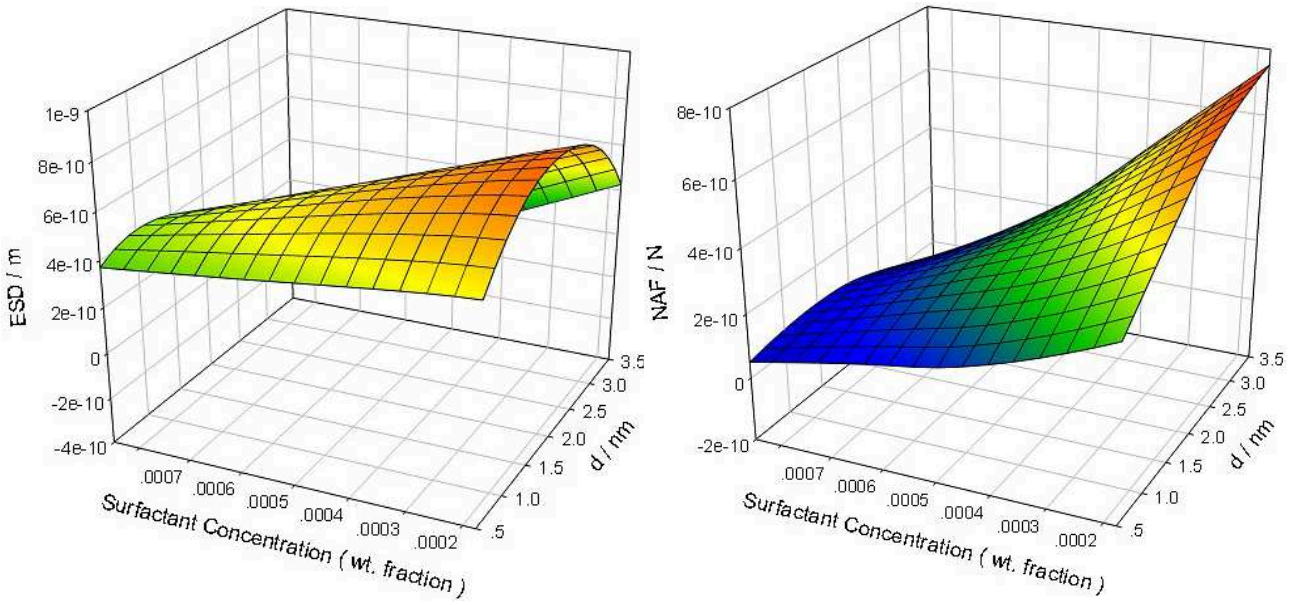

Figure 4. ESD and NAF as a function of the surfactant concentration and submersion height (d) in CO_2-based micelle solution at 313 K and 25 MPa, surfactant: DiF8-PO4-Na+, particle radius: 50 nm.

Summary

A physical model was presented to illustrate the behavior of all kinds of static forces existed in nano-scale Cu particle on flat surface with a fluid layers on the substrate. the values of NAF and ESD in CO2-based micelle solutions with different surfactants were calculated. The results demonstrated that high pressure could impose enough capillary pressure effect beneath a particle to compete with the net adhesion force and increase the particle surface separation distance. The existence of entrapped fluid layer between the particle and substrate favor the particle removal. The ESD for the two micelle solutions had the similar behavior, otherwise, the value of NAF for the micelle solution with surfactant DiF8-PO4-Na+ had the minimum relative to other surfactant micelle solutions, suggesting that Cu particles would be more easily removed in micelle solution with DiF8-PO4-Na+ surfactant. The model is expected to be helpful to design and analysis of high pressure CO2-based micelle cleaning systems.

Key words: free-drop, failure analysis, BGA Packages, drop test

Abstract: The failure of plastic ball grid array under intense dynamic loading was studied in the project. This paper presents the drop test reliability results of SnPb flip-chip on a standard JEDEC drop reliability test board. The failure mode and mechanism of planar array package in the drop test was comprehensively analyzed. High acceleration dropping test method was used to research the reliability of BGA (ball grid array) packages during the free-drop impact process. The model RS-DP-03A drop device was used to simulate the falling behavior of BGA chip packages under the real conditions, The drop condition meets the JEDEC22-B111 standards (pulse peak 1500g, pulse duration 0.5 ms)when dropping from the 650mm height . In the testing, according to the real-time changes of dynamic voltage, the relationship between drop times and different phases of package failure was analyzed. With the dye -penetrated method and optical microscopy, it was easy to observe the internal crack and failure locations. The growth mechanism of the cracks in solder joints under the condition of drop-free was analyzed and discussed.

Introduction

Along with the rapid development of the electronic industry, the electronic products are regenerated more and more quickly. Handheld electronic products are developed to miniaturization and multifunction, such as mobile, camera, DV and tablet computer. These electronic products have been widely used in people's daily life. In using process of customers, sudden falls occur frequently. The drop impacts not only destroy the shell of electronic products, but damage internal encapsulation of components seriously. The drop events may result in failure of solder joints inside these devices.

There has been a significant amount of research which were done in the last few years on drop impact reliability. BGA package solder ball faces such drop impact test. Recently, the research about drop test is more and more subtle. Numbers of boundary bolts can influence the chip's service life greatly[1]. To edge combined the chip package, different combine material have different influence on the service life[2]. Combining with the finite-element simulation, the dynamic performance of the test board can be obtained completely. Qin Fei etc analyze the mechanical behavior of solder ball with the Johnson-Cook model in drop test [3]. Liu Fang etc get the fracture mode of Lead-free solder ball is the brittle fracture of the IMC layer [4]; In abroad, It is one of the hot issues to research the reliability behavior of package drop. They use many methods to analyze the package dynamic mechanics performance, such as using the finite element analysis, improving the experiment instrument, changing weld layer of the internal encapsulation components [5-7].

In this article, the drop tester was different from JEDEC standard. In order to imitate the electronic components free-drop conditions, the drop test of BGA packages was conducted. The plane-hit destruction causes and failure mechanism of the packages are analyzed through the test.

This paper presents the drop test reliability for edge-bonded 0.5mm pitch lead-free chip scale packages on a standard JEDEC drop reliability test board, the failure mode and mechanism of planar array package in the drop test are comprehensively analyzed.

Experiment

Specimen preparation

The chip components in the test are 12 x 12 ball grid array packages, the solder pitch is 1.27 mm, diameter of the solder joints is 0.6 mm, welding plate size is 0.45 mm, solder joints arrangement is shown in figure 1. The solder joints of the BGA package constitute two "Daisy chains", the number of nodes around is used to test the failure position of solder joints. PCB substrate is coated of copper and sinker gold for the surface of FR-4 fiber glass, the size of PCB board is 54 mm x 45 mm x 0.5 mm.

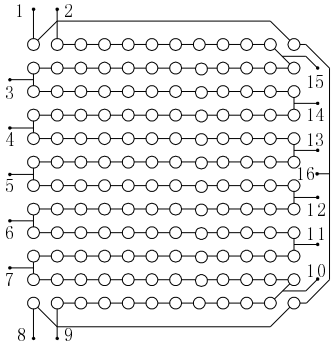

Fig. 1 BGA Solder joint arrangement

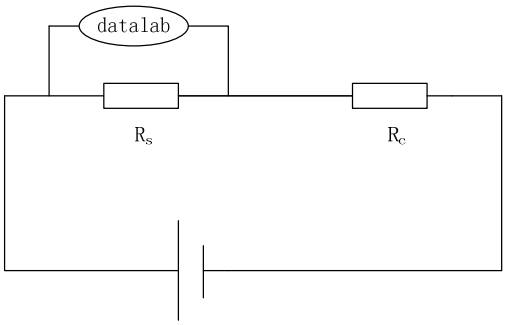

Fig. 2 DC series voltage divider circuit

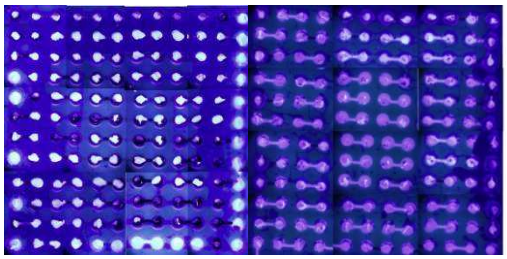
JEDEC22-B111 standard which recommended drop/ impact test method was adopted. RS-DP-03A drop tester was used to imitate the free-drop of the product under the real condition. The drop tester consists of vacuum head, digital control panel, and rigid base. There was a felt on the rigid base to control the duration of acceleration. Before the test, checked up the conductivity of the chip first, then connected the 2 Daisy chains to test system. The strain gauges were posted on PCB for recording PCB bending deformation in dropping impact process. Acceleration sensors installed in drop specimens were used to collect acceleration curve during the drops. In the experiment, specimens and vacuum head dropped from 650 mm in height freely, then they separated at 300 mm in height, and specimens fell with the same speed before separation. Dropping specimens stroke on the rigid base with the fixed posture, producing the specified pulse curve (pulse peak 1500 g, pulse duration 0.5 ms). With the real-time data acquisition system, the impact pulse, strain curve of PCB and voltage curve during drop were collected.

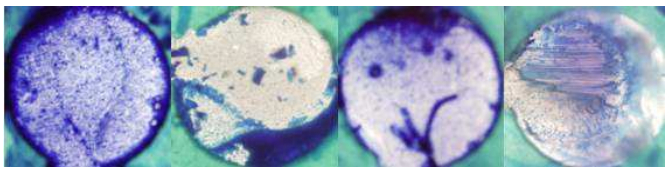


Experimental procedure

The daisy chains are placed in a DC series circuit with a static resistor (R_s) whose value is known as $100\,\Omega$ to construct a voltage divider circuit as shown in Fig. 2. The monitoring system record the voltage (V_s) which is the voltage of R_s .The relation between the dynamic resistance of daisy-chained solder joints and V_s can be described by EQ. 1.

$$V_s = \frac{V_{DC} R_s}{R_s + R_c} \tag{1}$$

The voltage curve of the encapsulation can indicate the crack inside the solder joints. The greater the fluctuation, the longer the cracks. The system registers a decline in voltage($V_s \to 0$) while the resistance rises ($R_c \to \infty$).When the dynamic voltage waves to zero, the package is invalid transiently. During 5 subsequent drops, if there are 3 additional transient failure, it is called the permanent failure of the packages[8]. Dyeing method was adopted to mark the dangerous area of the packages and the crack situation of solder joints. The morphology of internal cracks in solder joints was observed by optical microscope.



Experiment result

(a) (b)

Fig. 3 Solder joints dyeing photos

PCB and package were parted for observation of dyed solder joints as shown in figure 3. BGA was fixed in the center of the PCB board before the test, and the four corners in Figure 3 (a) are corresponding to the ones in figure 3 (b). The black spots on PCB are the solder joints which remain on the PCB after division. The closer to the boundary, the more the dyed solder joints . The completely dyed solder joint in the upper left explains that the solder joint is completely invalid, as shown in figure 4. That is to say, in the BGA package, the outermost area is the dangerous area solder ball, the solder joints in the outermost corners are trend to be invalid.

Fig. 4 Main failure modes of chip packages (×60)
a-Failure between bonding pad and substrate;
b-IMC layer failure; c-Base board failure; d-Bonding pad fatigue

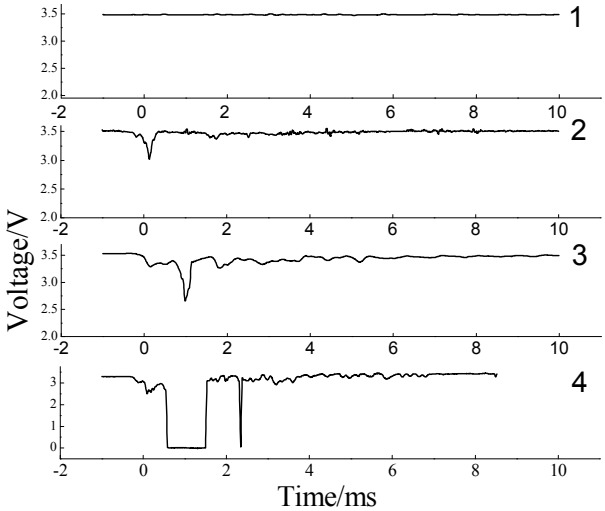

Fig. 5 Typical test data curve (resistance)

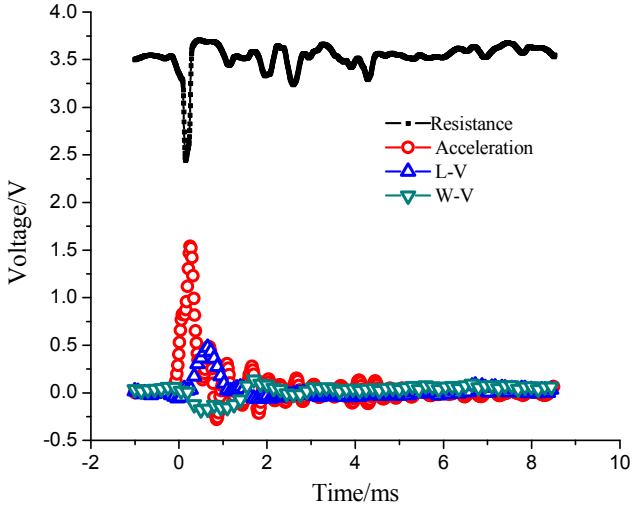

Fig. 6 Typical test data curve (acceleration&strain)

Solder joints' failure modes are different. The different failure modes of solder joints result to the different morphology after dyeing, as shown in figure 4. PCB substrate bends up and down repeatedly , creating the coupling effect of periodic tensile stress, compressive stress and shear stress in the solder joints [9]. Edge fatigue failure happened in the solder joint under the effect of stress firstly. The main failure mode along the plate width of solder joints is welding plate fracture failure, as shown in figure 5. Along the width direction of the board, the failure modes of solder joints are welding plate fracture, welding and welding plate of the ball between the IMC layer failure. Real-time dynamic pulse signal, PCB dynamic strain signal and the dynamic voltage signal were collected the moment the chip dropping on the block. In the drop test, the typical characteristic curve of the crack in the solder joints is shown in figure 6. As can be seen from the graph, the strain signal delays in pulse (acceleration) signal about 0.4 ms when pulse energy transfers to the PCB. The bending deformation in PCB length direction is bigger than the width of the direction, but the duration of deformation in the width direction is longer than length direction. Dynamic voltage fluctuation which shows the change of chip resistor is consistent with the impact pulse in the 0.5ms. During that time, PCB substrate have not bended, that is to say, the first factor which cause the cracks in solder ball is dropping impact energy, not reciprocating bending deformation of PCB.

Along with the increase of drop times, the cracks of solder joints propagate quickly, eventually chip become invalid. Figure 5 shows the typical dynamic voltage curves in different phases of a chip. Dynamic voltage curve 1 has no waves, so the solder joints are in a steady stage, and the chip could work regularly. Significant fluctuations appear firstly in dynamic voltage curve 2, and impact energy is the cause of the appearance of the cracks in solder ball .Dynamic voltage curve 3 appears the fluctuation twice as big as the one in curve 2, it is because that the bending of PCB makes the cracks continue expanding, and solder joints damage situation become worse. Curve 2, 3 are the derivative crack phases. The stages of encapsulation chip solder ball have effect on the crack, electric properties fall. Dynamic voltage curve 4 appears big fluctuations, dropping impact energy causes fluctuations firstly, too. Then the PCB board bending causes solder ball fracture, during the drop, dynamic voltage approach to zero, visible PCB reciprocating bending is the main factor. Observing curve 2, 3 and 4 , before 0.5ms, the first ball cracks emerge , after 0.5 ms, PCB board begin to bend, causing solder joint crack grows and eventually opens.

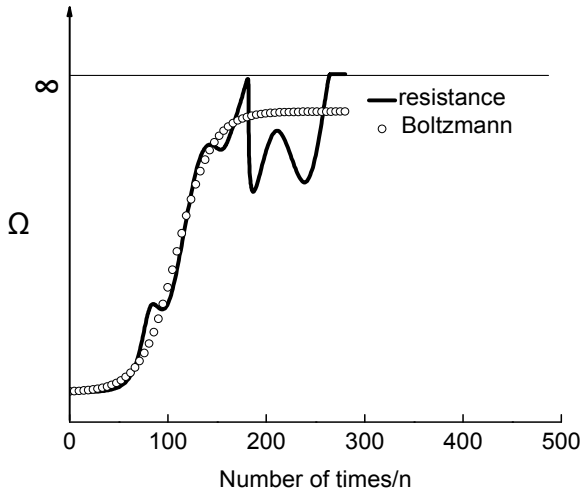

Fig.7 Relationship of chip peak resistor and drop times:

Stage 1: not produced crack area; Stage 2: the fatigue and growth area; Stage 3: failure area

The dynamic relationship between drop times and the peak resistance is available, according to the relation between the dynamic voltage and resistance. With the increase of drop times, the collected dynamic resistance peak curve can be divided into three stages. Drop times from 0 to 82 times are in the first stage. Electric resistance of this stage is in the steady state district, and does not change significantly. In this stage solder ball does not appear crack, and the chip works regularly. From 82 to 182 times, resistance has shown a sharp trend of crack expansion in the solder joints. Between 182 and 263 times, the cracks also in the expanding, and transient and steady state failure of solder joints happen（Transient failure in the test is defined as the first time in continuous

discontinuous circumstances; the first event of intermittent discontinuity as defined above followed by 3 additional such events during 5 subsequent drops）. In Transient failure, chip can continue to work, but its reliable performance has been greatly reduced. Continuous transient failure would cause the steady-state limitation, then chip function has been lost, and the chip become invalid.

Conclusions

In the free-drop test, impact energy is the cause of the appearance of cracks in solder ball .After crack appears, the reciprocating bending deformation of PCB is the main factors which lead to the propagation of cracks and the failure of package eventually. In drop process, substrate length direction has bigger value of bending deformation, shorter duration , and more effect on solder joints than the width direction. The deformation of PCB causes the cracks to open or close. With the increase of drop times, it can cause internal resistance of chip to reach to the peak of the dynamic change. Chip resistor peak steady-state continues growing until infinite, reflecting the process of the produces, expansion, and failure of the cracks. With the increase of dropping times, chip resistor peak showed "S" type of growth trend which fits poll Boltzmann curve, in the area to prevent possible failure at any time, for possible function is lost to prevent preparation, the failure of chip has certain tip role. The primary failure mode is pad cratering which indicates that solder joints may not be the weakest link of the assembly in this study.

Keywords: $Cu(In,Ga)Se_2$; band gap grading; Ga-Graded; solar cell.

Abstract: $Cu(In,Ga)Se_2$ (CIGS) compound is a p-type semiconductor that has been used as light absorber layer in high efficiency thin film solar cell. The CIGS compound can be adjusted the band gap energy by varying the ratio of [Ga]/([In] +[Ga]) ratio (x). From theoretical and simulation, it was found that band gap grading in CIGS thin films showed the advantages to increase the efficiency of solar cells. Generally, the band gap grading can be done by the growth of non homogeneous x-ratio in depth of CIGS thin films. In this work, we develop two approaches to create band gap grading in CIGS thin films; (1) modifying the growth profile and (2) using Na incorporation in the growth process. The effects of Ga-graded would be revealed and compared with homogeneous CIGS thin films. CIGS thin films were grown on soda-lime glass and Al_2O_3 coated soda-lime glass substrates by molecular beam deposition method. The growth process was based on 2-stage and 3-stage growth profiles. The as grown films were characterized for their structural property, chemical composition and optical transmission as well as solar cell performance. The Auger electron spectroscopy in depth profiles revealed the variation of x- ratio increasing from the surface toward the back contact in CIGS films with our modified growth profile and Na incorporation. This result indicated Ga-graded in CIGS thin films. The structural property of Ga-graded CIGS films showed the (112) preferred orientation of the chalcopyrite structure with a broad asymmetric spectrum related to the inhomogeneous structure. The optical transmission measurements of the Ga-graded CIGS film showed the broad transition near the absorption edge indicating the effect of the band gap grading as a result of the variation in depth of the Ga-content. From I-V measurements, the solar cell efficiencies significantly increase due to the advantages of Ga-graded constitute.

Introduction

Solar energy is an important alternative energy. It reduces the CO_2 emission and other greenhouse gases that are the cause of climate change and global warming problems [1]. Solar cell is a semiconductor device that can directly convert the light energy into the electrical energy by using a photovoltaic (PV) effect. Over the past three decades, the technology of solar cell has been developed in order to achieve high electrical conversion efficiency. Solar cells based on thin film technology have attracted commercials because of their high efficiency, low material usage and high yield processes. One of the most interesting thin film solar cells is $Cu(In,Ga)Se_2$ or CIGS based solar cell. CIGS solar cells are the 2nd generation of solar cell which have the high efficiency solar energy conversion. The world record of CIGS solar cells efficiency in lab scale is nearly 20 percent demonstrated by NREL [2].

CIGS is a ternary-compound semiconductor with a direct band gap. Due to its high absorption coefficient and sufficient long-term stability [3], it is then used as a photon absorber layer in high efficiency thin film solar cell with Ni-Al grid/ZnO/CdS/CIGS/Mo structure. A special property of CIGS material is that its band gap energy can be adjusted in the range between 1.04 -1.68 eV by

varying the [Ga]/([In]+[Ga] ratio (x). The composition of group III elements plays an important role to the performance of solar cell. The high efficiency solar cells of homogeneous CIGS thin films have been achieved with [Ga]/([In]+[Ga]) ratio about 0.3. A method that helps to increase the solar cell efficiency in CIGS thin film known as band gap grading has been proposed [4]. The variation of the band gap energy towards the back contact causes the electric field, namely back-surface field (BSF) [5]. It assists in sweeping electrons in the quasi-neutral region of absorbers across the junction, resulting in the increase of the minority carrier's life time and diffusion length as well as reduction of the recombination [6]. Thus the solar cell efficiency improves by the increase of probability for carrier collection. The variation of Ga-content in CIGS thin film can be obtained by growing the non-homogeneous [Ga]/([In]+[Ga]) ratio at different depths in the CIGS film. However, there is a trade-off between the increase of carrier collection and the loss of created electron-hole pair from low-energy photons due to the increase in band gap. The band gap grading is beneficial in reducing the thickness of the absorber layer. The optimization would be calculated by simulation and verified by experiment.

In order to obtain band gap grading, we develop two approaches (1) modifying the growth profile; the standard 2-stage was modified into double Ga-graded profile and (2) using Na incorporation; Na precursor was incorporated before the growth process was begun. O. Lundberga *et al*. reported the effect of Na on diffusion of Ga and In in CIGS thin film. The presence of Na reduces the inter-diffusion of In and Ga that could be observed in the broad peak of X-ray diffraction [7]. The properties of Ga-graded CIGS films such as chemical composition in depth profile, structural orientation and optical transmission as well as device performance were studied and compared with the standard homogeneous CIGS thin film solar cell.

Methodology

Substrate preparation

SLG commercial substrates (2 mm thick with the area of 3×3 cm^2) were sonicated in an ultrasonic bath with a mixture of detergent and deionized water at 60ºC for one hour. Then, the substrates were rinsed with deionized water and ultrasonic cleaned again in deionized water at 60ºC for one hour to completely decompose the detergent. Finally, the substrates were dried with compressed nitrogen gas. To reduce or block sodium from SLG, the Al_2O_3 films (alkaline barrier) were deposited on the SLG substrate using a 4-inch Al_2O_3 target. The thickness of Al_2O_3 layer was about 800 nm. The Al_2O_3 film was an amorphous structure, smooth surface with a nanoscale grain size. Then Mo films were deposited on SLG by DC magnetron sputtering from 4 inch in diameter Mo target using Univex 350 sputtering system. The thickness was about 0.6 μm. Note that, Mo/SLG and Mo/Al_2O_3/SLG substrates were used in the 1st approach and 2nd approach, respectively.

Growth profile of CIGS thin film

$CuIn_{1-x}Ga_xSe_2$ thin films were grown by molecular beam deposition (MBD) technique using molecular beam epitaxial (MBE) system (EIKO EW100) under a based pressure of 10^{-9} Torr. The element sources of Cu, In, Ga and Se were evaporated form Knudsen cells (K-cells) and the temperatures of these sources were calibrated by quartz crystal monitor (QCM) and beam flux monitor for the corresponding compositions of each element. The *in situ* monitoring signals were employed for process control and end point detection (EPD) [8].

The 2-stage growth process was used in the growth of the CIGS films as shown in Fig. 1(a). For the standard growth profile, the [Ga]/([In]+[Ga]) ratio (x) was always a constant x=0.3 (thick line) and [Cu]/([In]+[Ga]) ratio (y) was constant at 1.2 in the 1st stage. The substrate temperature was 550°C. The growth process time was about 160 minutes which typical yield the thickness of CIGS of about 1.5 μm. In the 1st approach, we modified 2-stage profile and used only a half process time (80 minutes) with the decreasing of substrate temperature (480°C). The profile began with x=1.0 about 25% of the process time and subsequently deposits with x=0 about 50% of the process time. Finally, In, Ga and Se vapor with x=0.35 were supplied until the end of the process as seen in Fig.

1(b). The process time was within 80 minutes for 0.7 μm thick of Ga-graded CIGS film. From the assumption, the inter-diffusion of Ga and In between the interface layer could create the variation of Ga-content.

The 3-stage process was used in the growth of high quality $Cu(In,Ga)Se_2$ thin film. The growth profile was shown in Fig. 1(c). The process started with the deposition of In, Ga and Se at a substrate temperature (T_{sub}) of 340°C in the first stage for a formation of $(In,Ga)_2Se_3$ layer. In the second stage, only Cu and Se vapors were allowed at T_{sub} of 550°C at which there was a transformation from $(In,Ga)_2Se_3$ layer via γ-CI(G)S and β–CI(G)S to α–CI(G)S. The formation of polycrystalline $Cu(In,Ga)Se_2$ occured until the composition of film is slightly Cu-rich (y>1) at the end of the second stage. Our standard three-stage process used y = 1.2. During the last stage, the deposition of In, Ga and Se at T_{sub} of 550 °C converted excess Cu_xSe entirely into Cu-poor at EPD (y=0.9). The duration of the growth process was about 90-120 minutes which typically yielded the thickness of CIGS of about 1.25-1.5 μm. In the 2nd approach, we studied the effects of Ga-graded due to Na incorporation. NaF precursors as a Na source with 50 Å thick were evaporated on $Mo/Al_2O_3/SLG$ substrates before growing the CIGS film. The critical thickness was optimized to gain the maximum solar cell efficiency.

The microstructure of the as grown films was characterized by scanning electron microscope (SEM). The crystal structure was measured by X-ray diffraction (Bruker model D8 x-ray diffractometer) and the chemical composition of CIGS was revealed by Auger electron spectroscopy (PHI700 AES) in the depth profile.

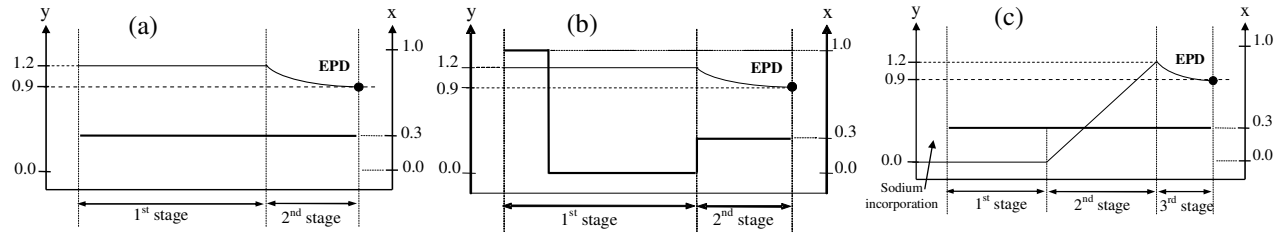

Fig. 1 The growth profile of CIGS thin films; (a) two-stage (b) modified two-stage and (c) three-stage with sodium incorporation where [Cu]/([In]+[Ga]) ratio (y) and [Ga]/([In]+[Ga]) ratio (x).

Solar cell fabrication

Photovoltaic devices were then prepared by chemical bath deposition (CBD) of 500 Å of CdS, followed by RF magnetron reactive sputtering of about 500 Å of intrinsic ZnO and 5000 Å of Al-doped ZnO. The solar cell devices were completed by the evaporation of 2 μm of Ni/Al grid contacts though a metal mask. The sample consisted of 10 solar cells per sample. The total area of each cell was about 0.5 cm^2 with approximately 2.5% shading loss. The current-voltage characteristics and device efficiencies were obtained by I-V solar simulator (YSS-50A).

Results and Discussion

Microstructure and Structural Property

SEM was used to characterize microstructure of CIGS thin films. The surface morphologies of the CIGS films typically showed rough surface consisting small and large grains as illustrated in Fig. 2. The CIGS film grown by modifying 2-stage had smoother surface than the film grown by 2-stage profile as seen from Fig. 2(b). The CIGS films grown on $Mo/Al_2O_3/SLG$ substrate showed flat round grains as shown in Fig. 2(c), whereas the CIGS films grown with Na incorporation on $Mo/Al_2O_3/SLG$ revealed relatively sharp grains as shown in Fig. 2(d). These results indicate that the growth profile and Na incorporation affected to the surface morphology of the CIGS films.

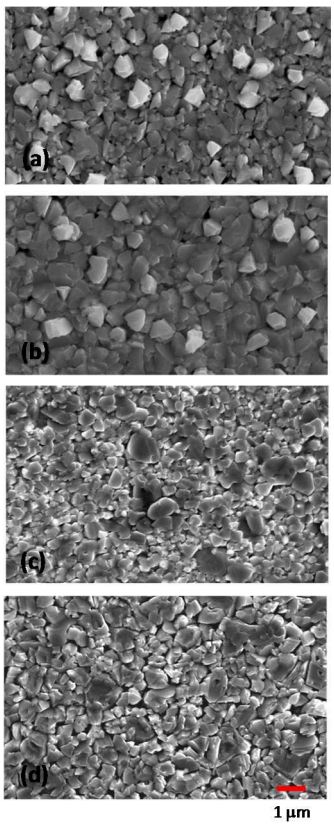

Fig. 2 Surface morphologies of the CIGS films grown by (a) standard 2-stage profile (b) modified two-stage (c) standard 3-stage profile and (d) Na incorporation in 3-stage profile.

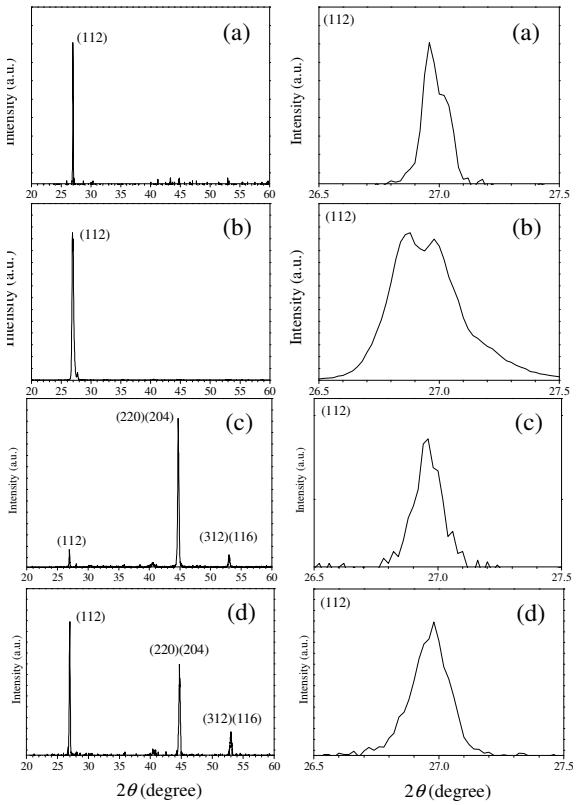

Fig. 3 XRD spectra of the CIGS films grown by (a) standard 2-stage profile (b) modified two-stage (c) standard 3-stage profile and (d) Na incorporation in 3-stage profile.

The structural property was determined from X-ray diffraction (XRD) as shown in Fig. 3. CIGS films grown by 2-stage profile showed (112) preferred orientation of the chalcopyrite structure. The standard CIGS film had a high sharp intensity peak corresponding to the homogeneous structure. However, the (112) oriented peak of the Ga-graded film had a broad asymmetric spectrum related to the inhomogeneous structure as seen in Fig. 3(b).This result indicated the variation of lattice constant due to the variation of [Ga]/([In]+[Ga]) ratio inside the CIGS film. XRD spectra of 3-stage CIGS films revealed that the CIGS thin films showed (220)(204) preferred orientation chalcopyrite structure that dominated by nature of three-stage growth process as seen in Fig. 3(c). However, Na affected to the change of preferred orientation from (220)(204) to (112) as seen in Fig. 3(d).

By considering the centers of the (112) CIGS peaks, they were nearly at the same positions in 2-stage and 3-stage profiles excepted in the modified 2-stage. Note that, the second peak with half intensity occurred by $Cu_{K\alpha 2}$ x-ray sources. The changes of preferred orientation directly related to the appearance of the surface morphology as seen from SEM images. The increase of (112) texture leaded to the increase of sharp grains that looked like the triangle shape. And the increase of (220)(204) texture leaded to the increase of flat grains as seen from surface morphology.

Optical Transmission (%T)

Optical property of semiconductor films could be determined by transmission and reflection measurements. Perkin Elmer model Lamba 900 double beam spectrometer in the wavelength 200-2600 nm was used to measure the CIGS thin films on an area of uncoated Mo film. The optical transmittance of the selective standard 2-stage and modified 2-stage CIGS films were shown in Fig. 4. We could see that the Ga-graded CIGS film had the lower thickness according to the number of interference fringes. The standard 2-stage CIGS film showed a sharp cut off band edge with small band tail near the absorption edge. The energy gap of 1.22 eV was calculated from both sharp cut

off and center of (112) peak in the following XRD result. For the modified 2-stage CIGS film, the band gap could not be calculated due to a broad of absorption band edge. This result indicated the variation of band gap grading CIGS film due to the Ga-graded.

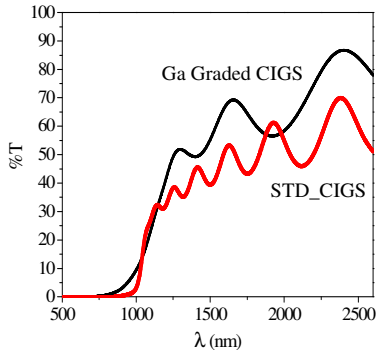

Fig.4 Optical transmission spectra of the CIGS film grown by (a) standard 2-stage profile (b) modified two-stage.

Auger electron spectroscopy depth profile

The compositional depth profiles of the CIGS films were characterized by Auger electron spectroscopy (AES). The depth profiles of the 2-stage and Ga-graded CIGS films were shown in Fig. 5(a) and 5(b). It revealed that the standard CIGS film had a uniform [Ga]/([In]+[Ga]) ratio about 0.3. However, the modified 2-stage CIGS films had the variation of [Ga]/([In]+[Ga]) ratio that increased from the surface toward the back contact due to the inter-diffusion of Ga and In between the interface layer. In another approach, the variations of [Ga]/([In]+[Ga]) in the film with Na incorporation could be observed but the slope was less than the modified 2-stage as shown in Fig. 5(d). The Ga grading was automatically obtained in the films with Na incorporation in 3-stage growth profile. In other words, Na affects the inter-diffusion between In and Ga in the CIGS film during the growth process of CIGS films. We suggested that Na atom would disturb the mobility of Ga that created Ga-graded through the back contact.

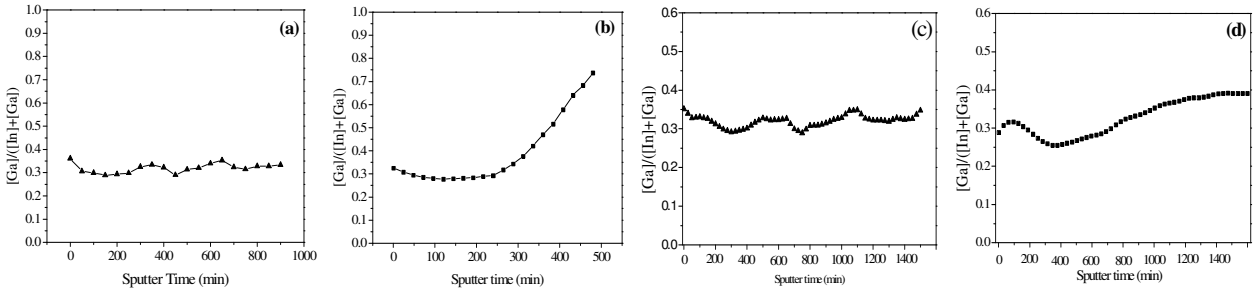

Fig. 5 AES depth profiling for the CIGS film grown by (a) standard 2-stage profile (b) modified two-stage (c) standard 3-stage profile and (d) Na incorporation in 3-stage profile.

Device Performance

The average device performances obtained from the I-V measurement were shown in Table 1. The standard 2-stage CIGS solar cells had the efficiency about 14% with 1.5 μm thick of absorber layer. However, we achieved the efficiency of 14% with only 0.7 μm thick of absorber layer by using the Ga-graded CIGS solar cells. It could be seen from the increasing of the short circuit current density as expected from band gap grading in the absorber layer. The solar cell using Mo/Al_2O_3/SLG substrate had a relatively lower efficiency compared to that of the solar cell using Mo/SLG substrate. It could be seen from the decrease of open circuit voltage (V_{oc}) and fill factor (*FF*). The decrease of V_{oc} directly corresponded with the mainly decrease of doping level or p-type defects in the CIGS film because the internal Na diffusion was interrupted by the Al_2O_3 barrier [9]. This result indicated the necessary of Na incorporation in CIGS thin film solar cells. However, the solar cell using a small amount of Na incorporation on Mo/Al_2O_3/SLG substrate showed the significantly increasing of the V_{oc}, *FF* and the solar cell efficiency. The increasing of the V_{oc} and *FF* related to

the increase doping in CIGS films and the junction formation respectively. The improvement of crystal quality and the increase of p-type defects as well as constitute of Ga-graded were the main parameters to gain the solar cell efficiency.

Table 1 Device performance of CIGS and Ga-graded CIGS solar cells; where V_{oc} = open-circuit voltage, J_{sc} = short-circuit current density, FF = fill factor and η = efficiency

Sample	V_{oc} (mV)	J_{sc} (mA/cm^2)	FF (%)	η (%)
2-stage Profile	620	32.7	70	14.2
Modified 2-stage Profile	600	34.5	70	14.5
3-stage Profile	530	33.6	61	10.6
Na incorporate 3-stage profile	651	35.5	67	15.5

Conclusion

We have obtained the approaches to grow the Ga-graded CIGS thin films for increasing the efficiency solar cell. AES confirmed the variation in depth of composition, i.e. [Ga]/([In]+[Ga]) ratio that increased from the surface toward the back contact by modifying growth profile and using Na incorporation. The XRD spectrum of Ga-graded films showed the broad asymmetric intensity with variations of lattice. The optical transmittance showed the variation of band gap in Ga-graded CIGS absorber. Because of the lower material used and the device performances increasing compared with standard device, these were the advantages of Ga-graded due to the band gap grading in CIGS thin film solar cells.

Keywords: Light transparency; plasmon resonance; cavity effects; transmission.

Abstract: This work presents a broadband optical transparency structure consisting of a metal film perforated by an array of strip cavities. We theoretically demonstrate the metal film with side-coupled grooves system in model structure by the coupled model theory. The transparent light with a great bandwidth is obtained as a result of the tunneling and the resonance effect of the cavities by employing the finite-difference time-domain method simulation. By changing the parameter of the grooves in the structure, the transparency property shows a great adjustment in both wavelength and bandwidth. These structures have potential applications for transparent conductor devices.

Introduction

Surface plasmon polaritons (SPPs) are electromagnetic surface waves at an interface between metal and dielectric [1]. One typical way to realize the excitations and control the propagations of SPPs by incident light is to corrugate periodical subwavelength metallic grooves on the interface [2,3]. This way has attracted great attention due to its potential applications in optoelectronics, such as the enhancement of light absorption in solar cells and the optical elements of switching and transparent conductors. It is well known that metal transparent conductors are essential components of modern flat panel displays, and light emitting diodes (LEDs). On a flat metal surface, the electronic charges concentrate on the interface and decay exponentially into both media. As a result, the localized SPP modes occur in the grooves or grating, and the resonant tunneling effect caused by the excitation of standing waves of SPPs in the grooves on two opposite surfaces can lead to great enhanced transmission [4]. Therefore, thanks to the advantage of metal film with grooves or gratings, the study of resonant tunneling of localized SPP modes play an great important on the optical transparent phenomena both the fundamental theory and device applications. To the best of our knowledge, the extraordinary optical enhanced behaviors depend on the geometry shape of grooves largely [5].

In this paper, we theoretically demonstrate the transmission behavior in coupled grooves by using coupled model theory [6]. The thin metal film perforated grooves on the up or down sides are investigated respectively in this paper. Their optical properties are calculated and analyzed by employing the finite-difference time-domain (FDTD) method accompanied with the perfectly matched layer. The parameters of the shape of grooves are investigated to obtain the perfect transparent spectra in the metal film with grooves. After the analysis and optimization, a great broad near-field optical transparency is achieved in the metal film with one-side coupled grooves. These results may be helpful for the new study and designing of transparent conductor devices.

Structure Model and Simulation

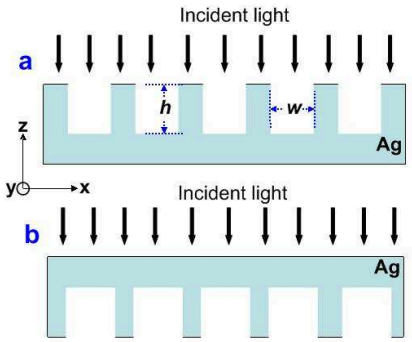

Fig. 1. Schematic diagrams of the optically transparent structure with upside (a) and downside (b) coupled grooves.

The proposed structures are shown in Fig. 1. Fig. 1 (a) shows the silver film with side coupled grooves on the upside, where the height and width of the rectangular grooves is denoted by h and w, respectively. Fig. 1 (b) shows the silver film with side coupled grooves on the downside. The light is directly incident on the top of the structures along the negative z axis direction. Periodic boundary conditions are utilized in the x and y directions and perfectly match layer (PML) boundary condition is employed in the z direction. The thickness of silver film is fixed at 60 nm. We first set h = 40 nm, w = 60 nm to study the optical phenomenon. The single groove can be considered as a lossy optical resonator. The resonant frequency can be tuned by the parameters of the grooves including h and w. Simulation calculations were performed using the three-dimensional (FDTD) method to obtain the optical transmission spectra.

It is necessary to note that the similar physical model in isolated groove acting as a Fabry-Pérot has been proposed by Lin *et al* [7]. When the light with transverse magnetic polarization is launched normally on the grooves, it will be reflected at both the mouth and the bottom of the grooves. The amplitude of the localized mode is a, the resonant frequency is ω_0. γ_{ref} and γ_{sca} represent the decay rate of reflected, and the scattering wave, respectively. γ_0 denote the total decay rate of a, which includes scattering, excitation of SPPs, and absorption in other channels, *i.e.* $\gamma_0 = \gamma_{sca} + \gamma_{spp} + \gamma_{ab.}$ s_{in} and s_{ref} represent normalized amplitudes of the incident and reflected waves, respectively. As a result, the reflectance is $R = |s_{ref}/s_{in}|$ the localized energy in the groove, expressed as $|a|^2$. The relationship equations can be obtained:

$$\frac{d_a}{d_t} = \left(j\omega_0 - \gamma_{ref} - \gamma_0\right)a + \sqrt{2\gamma_{ref}}\, s_{in} \tag{1}$$

$$s_{ref} = -s_{in} + \sqrt{2\gamma_{ref}}\, a \tag{2}$$

$$R = \frac{(\omega-\omega_0)^2 + (\gamma_{ref} - \gamma_0)^2}{(\omega-\omega_0)^2 + (\gamma_{ref} + \gamma_0)^2} \tag{3}$$

$$|a|^2 = \frac{2\gamma_{ref}}{(\omega-\omega_0)^2 + (\gamma_0 + \gamma_{ref})^2}\,|s_{in}|^2 \tag{4}$$

Results and Discussion

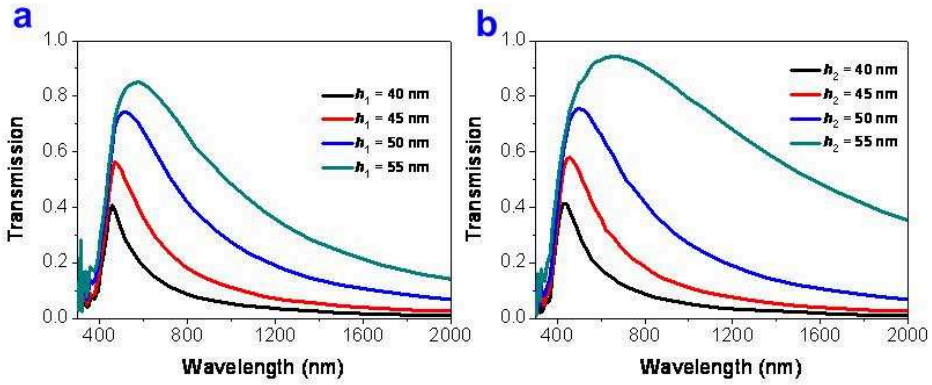

Fig. 2. The power transmission spectra of a pure Ag film perforated by an array of rectangular grooves on its upside (a), or on its downside (b) as a function of the height of the grooves. h_1, h_2 represent the height of the up and down groove, respectively. The width (w) is kept 60 nm.

The transmission behaviors of the proposed structure with the upside coupled grooves and the downside coupled grooves are investigated respectively, as shown in Fig. 2 (a) and (b). Clearly, the transmission intensity show a great increase accompanied by a slightly red-shift in peak position as h_1 changes from 40 to 55 nm. The tremendous increase in bandwidth is also observed. The transmission maximum is exceeding 88% and the bandwidth ($T > 50\%$) is even over 600 nm, shown in Fig. 2(a). And T is transmittance. In addition, it is interesting to note similar responses are also observed in Fig. 2(b), which indicates the same physical mechanism in the downside coupled grooves structure. The higher transmission intensity with broader bandwidth occurs when h_2 increases. The transmission maximum even exceeding 95% with the bandwidth ($T > 50\%$) over 1200 nm is obtained, which implies the tunneling effect in downside grooves structure is more efficient than that in upside grooves structure. The change of transmission behaviors result from resonant mode depends on the shape of the grooves. The tunneling and cavity resonant effect mainly contribute to the broadband transparent property in our proposed structures.

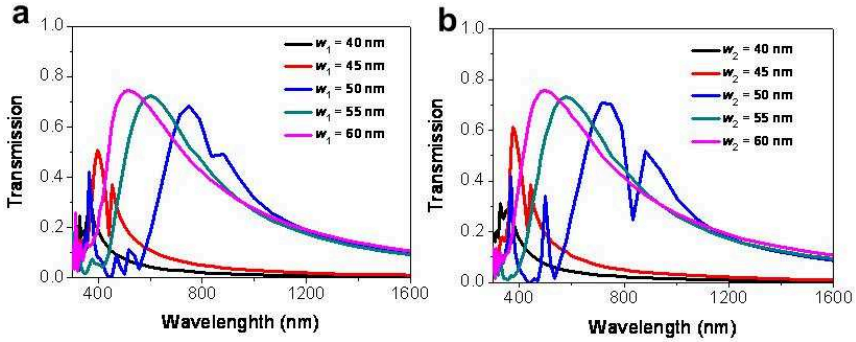

Fig. 3. The power transmission spectra of a pure Ag film perforated an array of rectangular grooves on its upside (a), on its downside (b) as a function of the width of the grooves. w_1, w_2 represent the width of the up and down groove, respectively. The height (h) is kept 50 nm.

Inspired of the extremely broad transparency phenomenon by changing the height of grooves, we further investigate the effect of the width on the spectra response. Contrast with the red-shift in Fig. 2 (a) and (b), an obvious blue-shift is observed in Fig. 3 (a) and (b) as a function of the width of the grooves in the structures. The wavelength center position of peak with high transmission intensity

changes from 800 nm to 500 nm. The transmission maximum is close 0.78 and the bandwidth is over 300 nm when w_1 is set to 60 nm. In addition, the spectra in two structure are very similar, which indicates the same physical mechanism both the tunneling and cavities effects are suitable for the structure with downside coupled grooves. In addition, the tunneling effect is more intense in the downside coupled groove structure, causing a more transparent bandwidth. These results indicate our structure has great potential applications in transparent conductor devices due to its highly tunable peak position and bandwidth and the perfect conductivity of silver.

Summary

In this paper, we theoretically investigate two metal transparent structures of the thin metal film with upside or downside coupled grooves. A great broad transparent with high transmission is obtained due to the tunneling and cavity model effects in the grooves in our structures. The FDTD with perfect matched layers are employed to calculate the optical transmission response. The peak position and transparent bandwidth show a great adjustable property by changing the height and width of the grooves in our proposed structures. After the analysis and optimization, the transmission maximum exceeding 95% with the bandwidth (T > 50%) over 1200 nm in optical frequency range is obtained in the upside coupled grooves structures. It has potential applications for solar cells and other optoelectronic devices. These results may be helpful for the new study and designing of transparent conductor devices.

Keywords: DHDPS, PTS, Epoxy resin, Modification, Encapsulant

Abstract: The reaction was carried out with a solventless (hot-melt) method using epoxy resin (E-20) as a base material and dihydroxydiphenylsilane (DHDPS) or polymethyltriethoxysilane (PTS) as a modifier. IR spectrum, epoxy value of modified epoxy resins indicated that DHDPS and PTS were incorporated into epoxy resin respectively. The influences of silicone contents on softening point and thermal resistance of cured silicone modified epoxy resin systems were studied. The thermal stability was investigated by thermogravimetic analysis (TGA). Effects of the viscosity of packaging slurry on the performance of encapsulated electronic elements were also investigated. In contrast to ED-20 cured system, the thermal resistance, toughness, humidity resistance of ETS-20 cured systems improved more obvious. And ETS-20 has exhibited excellent resistance to the thermal shock cycling test. It indicated that ETS-20 can be applicated for electronic encapsulation. The viscosity of packaging slurry was most appropriate when it was 170~200 mPa•s.

Introduction

Epoxy encapsulat is one of the main materials used in encapaulation for semiconductor. It is composed of many raw materials, which contains epoxy resin, curing agent, curing accelereator, ionrganic filler, pigment, etc. Epoxy encapsulat is the resin indispensably employed to encapsulate electronic elements because of its wellbalanced properties including low curing shrinkage, excellent moisture, superior mechanical and electrical properties, and good adherence to many substrates [1,2,3]. However, in the crosslinked state, they are intrinsically brittle[4,5,6] with very low fracture energy [7]. Also, they have comparatively low hydrophobicity[8] and poor weathering resistance [9]. Major disadvantage for their application are their thermal resistance and low impact resistance [10,11]. The low pigment-holding ability and yellowing of epoxy resins further resist their wide application in coatings [12].

Hence, modification of epoxy resins with flexible polymeric segments like rubber, polyurethane, silicone and some other thermoplastics are mandatory as these modifiers when incorporated with epoxy resin have been proved to improve its thermal and mechanical properties [13-17]. Silicone is considered to be one of the suitable modifiers for epoxy resins, owing to its superior thermal and thermo-oxidative stability, excellent moisture resistance, low surface energy, free rotation of chains about Si-O bonds and good hydrophobicity [15,18]. However, silicones possess poor mechanical properties. The incorporation of silicone in epoxy resin results in the enhancement of physico-mechanical properties, thermal stability and so on. The latter can be attributed to the high bond dissociation energy of Si-O unit bond i.e. 443.7 KJ/mol, compared to those of C-O bond (357.9 KJ/mol) [4,19-21].

In recent years, there are more researches on silicone modified epoxy resins, but the properties of the modified epoxy resin encapsulat are reported relatively less. In this study, E-20 was modifide by DHDPS and PTS respectively through some chemical reaction. The structure of modified epoxy resins (ED and ETS) were confirmed by FT-IR. The physicochemical test such as epoxy values

(EV), softening point were carried out by ring and ball method. ED and ETS were further formulated into encapsulant and packaging slurry. The coating vehicle was cured by trimellitic anhydride (TMA) and aluminum(III) acetylacetonate. The performance of ED and ETS cured systems and packaging slurries were evaluated by standard methods. The electronic elements encapsulated by modified epoxy resins were also evaluated by the thermal shock cycling test.

Experimental

Materials

Epoxy resin, E-20 (epoxy equivalent 455–556, softening point 64~76°C).

DHDPS and PTS were used as modifiers. Stannous octanoate (the concentration of petroleum ether liquor is 30%) and dibutyltindilaurate (DBTDL) were used as catalysts. TMA was used as a curing agent. Aluminum(III) acetylacetonate was used as a curing accelerator. Filler were used as extenders. Acetone and methanol were used as solvents.

Synthesis of DHDPS-modified epoxy resin

E-20 was placed in a three-necked flask fitted with a mechanical stirrer, thermometer and a reflux condensation unit. The resin was melted at 120°C for 30 min under a reduced pressure (ca. 37.5 mm Hg) to remove water and solvent. The melted epoxy resin and DHDPS in 10:0.5, 10:1, 10:2 ratio (by weight) was taken into the three-necked flask. 1% (mass fraction) of stannous octanoate was added. The reactants was maintained at 120°C along with constant stirring for 2h. Epoxy values and softening point of modified epoxy resins (EDs) were determined. The structure of ED was confirmed by FT-IR spectral analysis.

Synthesis of PTS-modified epoxy resin

E-20 was placed in a four-necked flask fitted with a mechanical stirrer, thermometer, a reflux condensation unit and a constant pressure funnel. The resin was melted at 120°C for 30 min under a reduced pressure (ca. 37.5 mmHg) to remove water and solvent. The melted epoxy resin and PTS in 10:1, 10:2, 10:3 ratio (by weight) was taken into the four-necked flask when the temperature fell to 100°C. A few distilled water and 0.5% (mass fraction) of DBTDL was added in drops within 20~30 min and then maintained for 4h at 100°C. The resultant product was further removed small moleculars which were produced during the progress of the reaction under full vacuum for 30 min at 100°C. Epoxy values and softening point of modified epoxy resin (ETSs) were determined. The structure of ETS was confirmed by FT-IR spectral analysis.

Curing procedure

The unmodified and the modified epoxy resins were dissolved in cetone in 3/1 ratio (by weight) and mixed with a stoichiometric amount of TMA. Moderate Aluminum(III) acetylacetonate was also added as a curing accelerator. The mixture was stirred uniformly and transferred to a vacuum oven to remove the solvent. The solvent-free epoxy/curing agent system was cured at 120°C for 2h and then post-cured at 160°C for 2h.

Characterizations

The pure epoxy (E-20) and silicone modified epoxy resins were characterized by FT-IR spectroscopic techniques. FT-IR spectra of these resins were taken on a model WQF-310 FT-IR spectrophotometer (The second optical instrument factory, Beijing, China) with KBr pellet. The thermal analyses of these resins was carried out via thermogravimetric analysis (TGA) (SDTQ600, TA Instrument, USA) in nitrogen atmosphere. Scanning electron micrograph (SEM) of fracture surfaces of cured resins were also taken on a model VEGA 3 XMU/XMH tester (TESCAN Instrument, CZE) scanning electron microscope under gold film.

Formulation of silicone modified epoxy resins-based packaging slurries

The modified resin, curing agent, curing accelerator, filler were weighed according to a certain proportion. In order to obtain even powder encapsulant, the mixture was premixed under a mill machine with high speed. In this study, electronic elements were encapsulanted by solvent method. The packaging slurry was made of powder encapsulants and mixed solvent of acetone and methanol.

Testing of silicone modified epoxy encapsulant

The fluidity of powder encapsulant was characterized by the length of flow trace (WH/WI-03) and the gel time (IEC 60455-2-2). The viscosity of packaging slurry was measured via a model NDJ-79 rotational viscometer. The encapuslated film hardness was measured by a QHQ-A type pencil hardness test apparatus. The physical properties such as water absorption, drying time, solvent resistance and temperatureshock strength were evaluated by standard methods.

Results and discussion

Synthesis and characterization

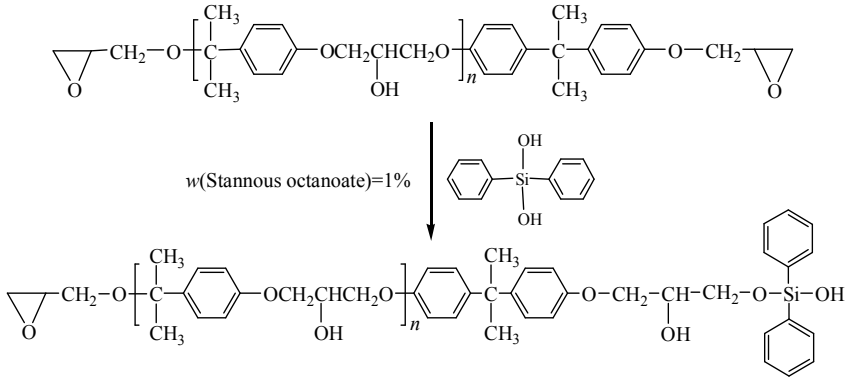
Stannous octanoate which is known as a condensation catalyst is used to aid the reaction between the OH or silanol groups of silicone and the groups of epoxy resin. There will be two kinds of reactions between the OH of DHDPS and epoxy resin. The one is the ring opening addition reaction of epoxy groups with DHDPS, the other one is the condensation reaction of OH groups of epoxy resin with DHDPS. In addtion, the autocondensation between DHDPS will also take place. Table 1 shows an reduce in the epoxy values from pure epoxy to siloxane-modified epoxy system. In contrast to the theoretical values of epoxy values, which dose't consumpt epoxy group during the reaction, the measured values are lower. This shows that the ring opening addition reaction has occured.

Compared with stannous octanoate, the catalytic activity of DBTDL is lower. Due to Si-OR is sensitive to water, the PTS will produce more pendent functional groups of OH under catalysis. In this study, DBTDL was used to aid the polycondensation reaction between the OH groups of silicone and the OH groups of epoxy resin. The measured and calculated EV of PTS-modified resins and pure epoxy are listed in Table 2. EV calculation is made based on the proposed reaction which doesn't involve the ring opening of the epoxy.

TABLE 1 EPOXY VALUES OF E-20/DHDPS SYSTEMS

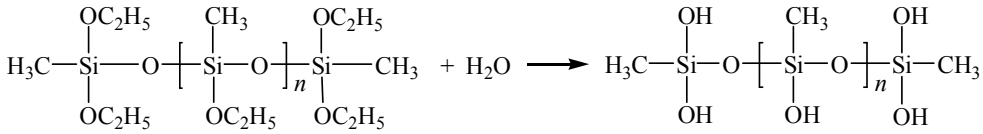
m(E-20):m(DHDPS)	Theoretical value/(eq/100g)	Measured value/(eq/100g)
10:0	0.214	0.214
10:0.5	0.204	0.179
10:1	0.195	0.172
10:2	0.178	0.153

TABLE 2 EPOXY VALUES OF E-20/PTS SYSTEMS



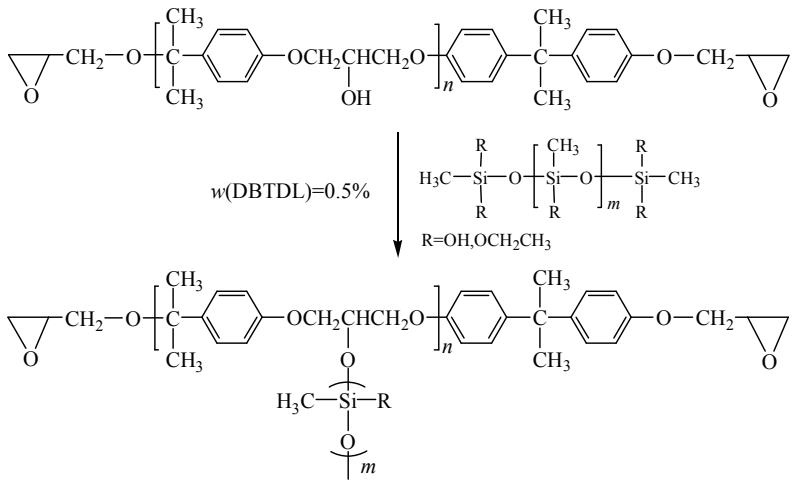
m(E-20):m(PTS)	Theoretical value/(eq/100g)	Measured value/(eq/100g)
10:0	0.214	0.214
10:1	0.195	0.189
10:2	0.178	0.178
10:3	0.165	0.164

Scheme 1 shows the chemical reaction between E-20 and DHDPS to form ED. Scheme 2 shows the hydrolysis of PTS. Scheme 3 shows the chemical reaction between E-20 and PTS to form ETS. The proposed structure of ED and ETS were confirmed by FT-IR.



Pure epoxy (IR, cm^{-1}): 1297–1182 (C-O-C, aryl alkyl ether, asym str), 1087 (aryl alkyl ether, sym str), 2964 (-CH_3 of quaternary carbon), 3036, 1581, 828, 770 (aromatic rings, str), 2929 (-CH_2 sym str), 2871 (-CH_2 asym str), 912.7 (oxirane ring), 1384 $(CH_3)_2C$), 3432.5 (-OH) [4].

In case of IR spectra of ED, the bands of oxirane ring are found to be shorter than those of pure epoxy; the band at 3432.5cm^{-1} for the OH stronger. A characteristic pronounced band appears at 1127.4cm^{-1} for Si-O-C confirming the occurrence of ring opening addition reaction between epoxy and DHDPS [17,19]. The chemically bonded silicon in the back bone of the silicone modified epoxy resin enhance the stiffness, thermal stability and hydrophobicity of the resin, which ultimately influence the physico-mechanical.



From the IR spectra of ETS, the bands of oxirane ring are almost invariant. The Si-O-C absorption at 1107.7 cm^{-1} can be seen in Figure 1 (C) [17,19]. The reaction between E-20 and PTS can form a modified epoxy resins with moderate crosslinking density, which can not only reduce the internal stress of epoxy resin, improve the compatibility of the systems, but also enhance the thermal stability and so on.

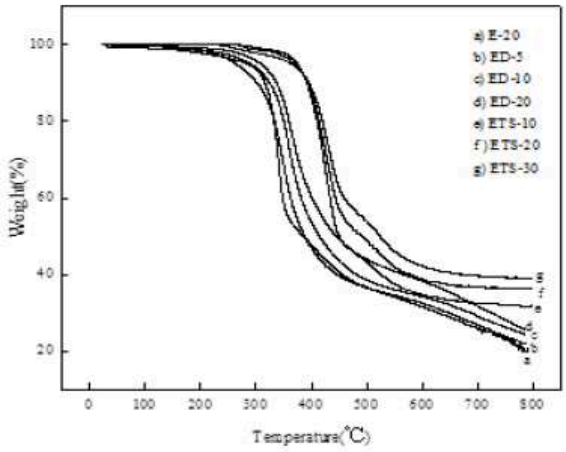

Fig.2 TGA thermogram for the cured systems E-20, DHDPS and PTS modified epoxy resin

Softening point analysis

The softening point has a great impact on the performance of epoxy encapsulat. On the one hand, the encapsulat shows good fluidity but is easy to sag with low softening point. On the other hand, the encapsulat shows poor fluidity, leveling, gloss and is easy to crust with high softening point. Thus the softening point is most appropriate when it is 65~90°C. Table 3 shows that the softening point of DHDPS-modified epoxy resins and ETS-20 meet the requirement.

TABLE 3 SOFTENING POINT OF MODIFIED EPOXY RESIN

Sample number	E-20	ED-5	ED-10	ED-20	ETS-10	ETS-20	ETS-30
Softening point /°C	67	66	67	65	58	66	62

Thermal analysis

The effects of different contents of silicone on the thermal stability of ED and ETS have been investigated by TGA. The results for TGA thermogram (Fig.2) of cured systems reveal that the temperature for 5 wt.% decomposition of E-20, ED-20 and ETS-20 are 263.8, 308.3 and 368.6 °C, respectively, while the tempareture for 50% weight loss are 382.3, 445.0 and 491.2 °C. And the residue percent of E-20, ED-20 and ETS-20 at 800 °C are 20.3%, 25.9% and 36.2%. These results also show that the presence of siloxane in epoxy noticeably enhances the thermal stability of E-20. The increase in thermal stability can be attributed to higher bond dissociation energy of Si-O bond [22]. In addition, it forms a moderate crosslinked network since PTS is introduced into epoxy resin, which contains more reactive groups. The crosslinked network can increase crosslinking degree, so that ETS has a greater improvement of thermal stability.

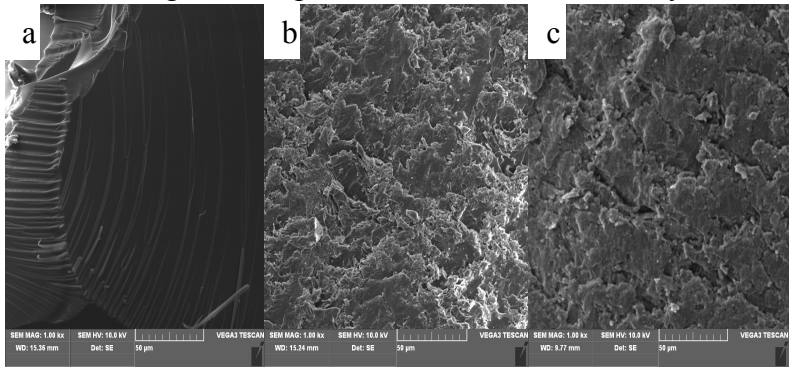

Fig.3 SEM micrograph of fractured surfaces of E-20 (a), ED (b) and ETS (c) cured system

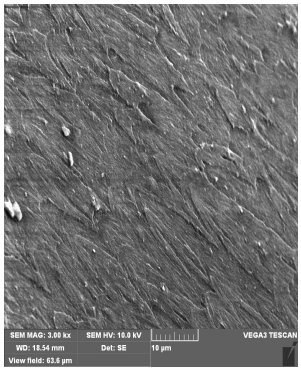

Fig.4 SEM micrograph of fractured surfaces of ETS-20

Scanning electron micrograph

The scanning electron micrograph (Fig.3) studies of unmodified and modified epoxy cured systems at 1000 magnifications show that the limits of fractured surface of unmodified epoxy resin is clear, and the propagating direction of the cracks is relatively concentrate. However, the limits of fractured surface of ED and ETS are blur, and the propagating direction of the cracks is dispersive. The above shows the toughening of silicone modified epoxy resins is obvious. Also Fig.4 shows no sign of phase separation of modified epoxy resin. The interface between epoxy resin and silicone is blur, which reveals the two are interconnected by chemicalbonds and have good compatibility.

The viscosity of packaging slurries

The influencing factors of the viscosity of packaging slurry include temperature, proportion of powders, solvent quantity, ect. The study between solvent quantity and the performance of encapsulation was carried out at a certain temperature and percentage of resin and filler. The performance of encapsulation and drying time are influenced by the viscosity of packaging slurry. As shown in Table 4, with increasing of the viscosity of slurry, the surface drying time is shortened. But the excessive viscosity will result in poor fluidity and leveling. Also with increasing of the viscosity of slurry, the actual drying time is lengthened. The actual drying time is more than 24h when the viscosity is 290 mPa•s, which dosen't meet the requirements of electronic encapsulation. The surface performance of cured encapsulated electronic elements is shown in Table 4. The surface occurs sag when the viscosity is less than 140 mPa•s. The surface is smooth and non-cracking when the viscosity is 170~200 mPa•s. The surface occurs cracks when the viscosity is more than 200 mPa•s. The solvent volatilizes uneasily in the internal of paint film at room temperature when the viscosity is excessive. And the solvent volatilizes quickly during high temperature curing, which lead to cracks on the surface of encapsulated electronic elements. By comprehensive consideration, the viscosity of packaging slurries is most appropriate when it is 170~200 mPa•s.

TABLE 4 EFFECT OF THE VISCOSITY ON THE PERFORMANCE OF ENCAPSULATION

Viscosity /mPa·s	140	170	200	230	260	290
Surface drying time	5h25min	5h10min	5h5min	4h55min	4h45min	4h20min
Actual drying time	＜24h	＜24h	＜24h	＜24h	＜24h	＞24h
Surface performance	sag	smooth/non-cracking	smooth/non-cracking	microcracks	microcracks	cracks

The properties of encapsulat powder and cured resins

Table 5 provides information about the properties of encapsulat powder and cured resins. A considerable improvemens were achieved in the water absorption, which can be attributed to the hydrophobic nature of the methyl or phenyl groups as well as the hydrophobic nature of the silicones, which hindered the ingress of water molecules [8,12].

The systems were subjected to an solvent resistance performance evaluation under solvents. The ED-20 and ETS-20 encapsulat systems showed a fair-to-satisfactory performance when immersed in mixed solvent [acetone:methanol (3:1) (m/m)] for 15 min after cured. The highly crosslinked network of ED-20 and ETS-20 hindered the easy penetration of solvent into the encapsulat system and thus enhanced the solvent resistance performance.

The pencil hardness of ETS-20 encapsulat systems is greater than ED-20 encapsulat systems. The result was in contrast to our expectations because DHDPS contains hard benzene rings,

whereas PTS have unusual flexibility on account of the flexible Si-O linkages and mobile silicone chains, which possess poor mechanical characteristics [12]. However, in this case, PTS incorporation actually enhanced the physicomechanical properties. It is assumed that in ETS-20 encapsulat systems, the siloxane behaves as chain entanglements rather than as a flexibilizer [11]. The long, mobile siloxane chains assist in the formation of a highly crosslinked network between two E-20 molecular units through a curing agent. Thus it leads to the formation of a highly crosslinked network and dense structure and results in a tremendous increase in the pencil hardness.

The modified epoxy resin were used to encapsulate the electronic elements and the encapsulated elements were subjected to a thermal shock cycling test. The thermal shock cycling test involves cycling the encapsulated elements at -55 and 125°C and observing the crack (failure) of encapsulated elements at a cycle (both of the low temperature and high temperature keep 30 min). The result indicates that failure happened after 3 cycles for ED-20 encapsulat. Compared with above, non-cracking occurs to ETS-20 encapsulated elements after 5 cycles. PTS-modified epoxy resin has much better thermal shock resistance and lower stress than ED-20.

TABLE 5 THE PROPERTIES OF ENCAPSULAT POWDER AND CURED RESINS

	Test condition	System		Reference
		ED-20	ETS-20	
Length of flow trace, mm	150°C, 45° inclined plate	28.14	27.31	18~30
Gel time, s	150°C	187	193	50~200
Water absorption, %	25°C/24h	0.34	0.36	⩽0.4
Solvent resistance	acetone:methanol (3:1) (m/m)	eligible	eligible	non-swelling, non-cracking, non-peeling
Pencil hardness	—	H	2H	⩾H
Thermal shock cycling test	-55°C~125°C	microcracks	non-cracking	non-cracking after 5 cycles

Conclusions

Modified epoxy resins (ED and ETS) were synthesized by the reaction of DHDPS and PTS with E-20 respectively. FT-IR was used to characterize the structure of the synthesized ED and ETS. The morphology of fractured surface of unmodified and modified epoxy resin cured systems was observed via SEM. It revealed that the two are interconnected by chemicalbonds and no sign of phase separation. The thermal analysis through TGA confirmed that the incorporation of Si into the E backbone had a synergistic effect on its thermal stability, especially ETS cured systems. Fairly good physicomechanical properties were achieved for ED-20 and ETS-20 encapsulat systems. Electronic elements encapsulated with ETS-20 encapsulat system have exhibited excellent resistance to the thermal shock cycling test. In addtion, the viscosity of packaging slurries was most appropriate when it was 170~200 mPa•s at a certain temperature and percentage of resin and filler.

Keywords: Vanadium oxide; Annealing oxygen flow rate; Insulator-metal transition; Thin films

Abstract: Vanadium oxide films were prepared on indium-tin oxide glass substrates at low temperature by means of reactive direct current magnetron sputtering and subsequent in-situ annealing process in pure oxygen ambient. In the process of annealing, the oxygen flow rates were varied from 0 to 15 SCCM in order to investigate the effect of annealing oxygen flow rates on the properties of the deposited films. The experimental results indicate that only the vanadium oxide films annealed under relatively high oxygen flow rates (≥ 0.8 SCCM) displayed insulator-metal transition. In addition, it was found that vanadium valence states, surface morphology, optical transmittance and phase transition temperature of the deposited films were sensitive to the annealing oxygen flow rates while the width of thermal hysteresis was relatively insensitive to the annealing oxygen flow rates.

Introduction

Vanadium oxide (VOx) films have been intensively investigated due to their potential applications in switching elements, storage devices, smart windows and terahertz modulators [1-3]. Up to now, many techniques including reactive magnetron sputtering, pulsed laser deposition, laser ablation, chemical vapour deposition, ion implantation, polymer-assisted deposition and sol-gel method have been used to prepare VOx films [2-4]. Among these techniques, reactive magnetron sputtering is outstanding for low deposition temperature, high growth rate and good adhension [3]. For reactive magnetron sputtering, the annealing process is commonly needed in order to improve the properties of the deposited films. In the case of reactive magnetron sputtering, the annealing oxygen flow rate was a key parameter and would affect the films' properties. However, to the best of our knowledge, the effect of annealing oxygen flow rate on the properties of VOx films was rarely studied. Thus, it is necessary to investigate the effect of annealing oxygen flow rate on the properties of the sputtered VOx films.

In this work, VOx films were deposited by reactive direct current magnetron sputtering followed by in-situ annealing process in pure oxygen ambient. The effect of annealing oxygen flow rate on the vanadium valence states, surface morphology, optical transmittance and insulator-metal transition properties of the deposited films was investigated in detail.

Experimental details

VOx films were deposited on indium-tin-oxide (15 nm thickness) coated glass substrate by direct current magnetron sputtering from a metallic vanadium target (99.9% purity) in $Ar+O_2$ atmosphere

and subsequent in-situ annealing in high-purity O_2 ambient. In the process of preparation, the annealing oxygen flow rate was varied from 0 to 15 SCCM. The film annealed at an oxygen flow rate of 0, 0.8, 5 and 15 SCCM was named S1, S2, S3 and S4, respectively. Both sputtering time and annealing time are 30 min. The substrate temperature and annealing temperature are 100 and 300 ^{o}C, respectively. The other detailed experimental conditions as well as the cleaning of substrates have been described in our previous work [3].

X-ray photoelectron spectroscopy (XPS, XSAM 800), field emission scanning electron microscope (SEM, Hitachi S4800) and UV–vis spectrophotometers (Shimadzu, Spec-1700) were used to characterize the valence and composition, the surface morphology, the thermochromic properties of the deposited VOx films, respectively.

Results and discussions

XPS analysis. Fig.1 shows the XPS spectra of S2 and S4. Obviously, the vanadium exists in two valences, namely, +4 valence with the binding energy of 516.06-516.24 eV [3,5] and +5 valence with the binding energy of 517.37-517.69 eV [6]. According to the corresponding areas and atom sensitive factors, the atom concentrations of +5 valences for S2 and S4 were evaluated as 35.6 and 64.4 %, respectively. This indicates that the annealing oxygen flow rates have a significant effect on the vanadium valence states.

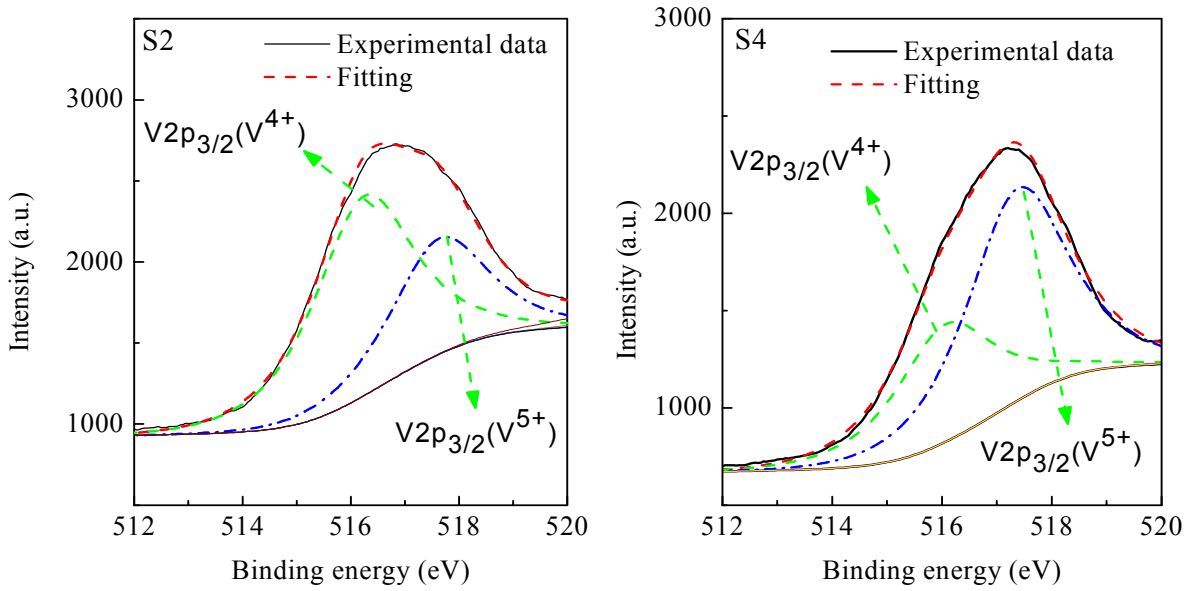

Fig.1 XPS spectra for S2 and S4.

Surface morphology. Fig.2 shows the surface morphologies for S2, S3 and S4. It can be seen that the surface morphologies of the deposited films are strongly dependent on the annealing oxygen flow rate. For a small annealing oxygen flow rate of 0.8 SCCM, the film surface of S2 is smooth and compact although a few cracks are found. As the annealing oxygen flow rate increases, the film surface begins to become loosely. One can also find that the grain size increases obviously as the annealing oxygen flow rate increases.

Thermochromic properties. Fig.3 shows the transmittance spectra of the films below and above the transition temperature. The films annealed at a small oxygen flow rate (<0.8 SCCM) did not show insulator-metal transition while the films annealed at high oxygen flow rates displayed obvious insulator-metal transition. It can be seen that the higher the annealing oxygen flow rate, the higher the transmittance of the films at room temperature (RT). However, the transmittance at high temperature (HT) was almost independent of the annealing oxygen flow rate.

The details of temperature dependence of transmittance at the infrared light of 1100 nm and the corresponding plots of $d(Tr)/d(T) - T$ were shown in Fig.4 and Fig.5, respectively. Tr and T represent

the corresponding optical transmittance and the temperature, respectively. T_{TC} and T_{TH} represent the phase transition temperature upon cooling and heating, respectively. The width of the hysteresis loops is defined as $\triangle H=T_{TH}-T_{TC}$. It can be seen from Fig.4 and Fig.5 that the phase transition temperature increases obviously with the increase in annealing oxygen flow rate. However, the width of the hysteresis loops was found to be relatively insensitive to the annealing oxygen flow rate. This agrees with the reported results that transition temperature is dependent on the oxygen content while the width of the hysteresis loops is not related to the oxygen content [7].

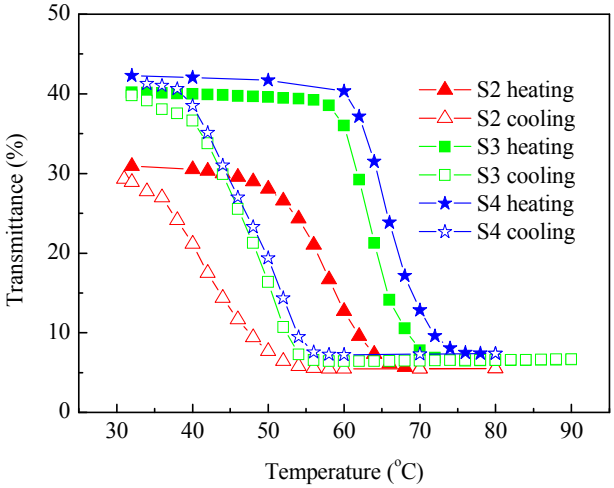

Fig.4 Temperature dependence of transmittance

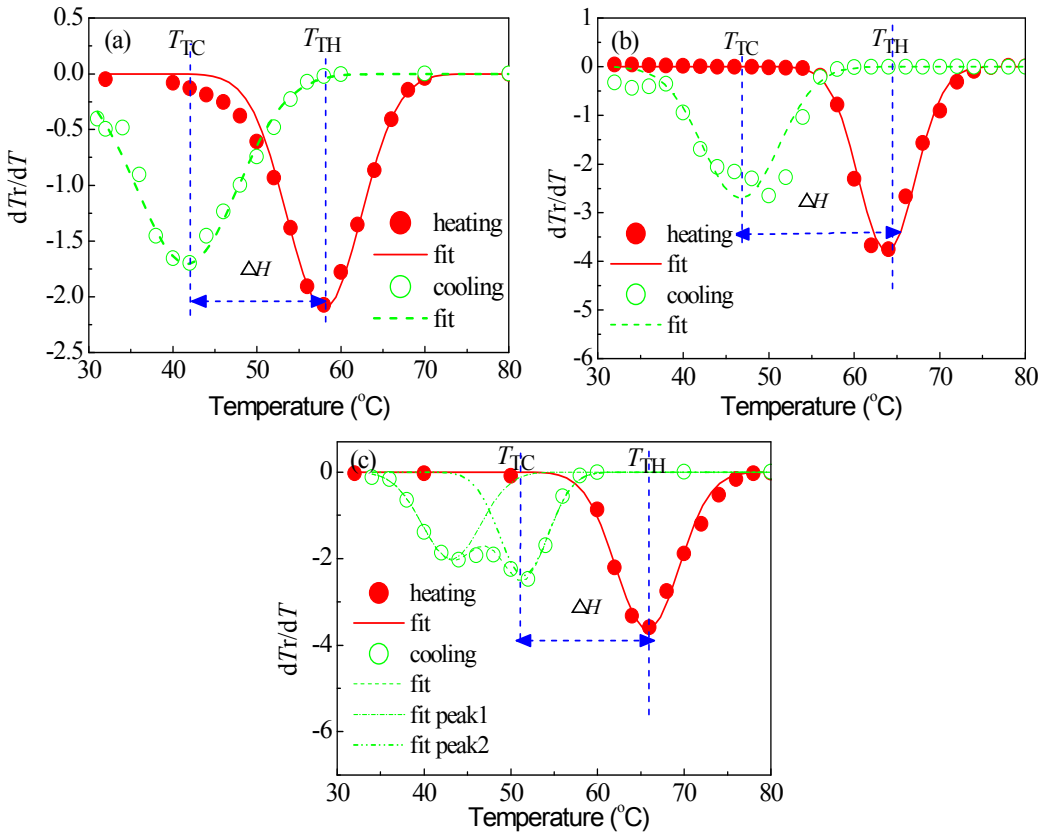

Fig.5 The plots of d(*Tr*)/d(*T*) – *T* for S2 (a), S3 (b) and S4 (c).

Conclusions

Using reactive direct current magnetron sputtering technique, we prepared VOx films and investigated the effect of the annealing oxygen flow rate on the properties of the deposited films. The experimental results indicate that only the vanadium oxide films annealed under relatively high oxygen flow rates (≥ 0.8 SCCM) displayed insulator-metal transition. In addition, it was found that vanadium valence states, surface morphology, optical transmittance and phase transition temperature of the deposited films were sensitive to the annealing oxygen flow rate while the width of thermal hysteresis was relatively insensitive to the annealing oxygen flow rate.

Keywords: GaN, SiC, heteroepitaxy, TEM

Abstract. The present work concerns the microstructural characterization of a multi-component (based on GaN and related materials) and multi-layered (5 layers) film, grown on 6H-SiC substrate (with a misorientation of 1 degree off from the (0001) plane), using transmission electron microscopy (TEM). The TEM characterization showed no surface undulation, despite the presence of steps in the SiC/AlN interface.

Introduction

Switching from silicon electronics to wide bandgap alternatives promises to deliver improvements in the performance of electronic devices. Nowadays, there has been an increasing interest for GaN- and SiC-based electronic devices, although both kinds of devices have their advantages and disadvantages. GaN-based devices have higher electron mobility and saturation velocity, as well as a variable band gap due to the alloying with AlN and InN (realizing higher frequency devices [1]). SiC-based devices have a higher thermal conductivity and a higher breakdown voltage (realizing higher power devices [2]).

A high quality GaN film is essential for device fabrication. Due to the lack of sufficiently high quality bulk GaN substrate, the growth of GaN epitaxial layer has so far been carried out on various foreign substrates such as sapphire and silicon carbide (SiC). Most commercially available GaN-based devices are normally grown on sapphire substrates because of the relatively low cost and general availability, although their lattice parameter and coefficient of thermal expansion are significantly different from that of GaN. For power device applications, however, it is desirable for a substrate with higher thermal conductivity, such as SiC.

6H-SiC has a thermal conductivity coefficient (room temperature) of 4.9 W/(cm·K), which is an order of magnitude higher than sapphire (0.5 W/(cm·K)). Meanwhile, SiC also has a lower lattice mismatch to GaN (~3.5%) and AlN (~1%) compared to sapphire. However, the thermal expansion coefficient of 6H-SiC (4.2×10^{-6} K^{-1}) is lower than that of GaN (5.59×10^{-6} K^{-1}), which produces a strain of ~0.1% for a growth temperature of 1000°C [3]. As a result, GaN layers grown directly on SiC (0001) are usually under tensile strain at room temperature and there are high amounts of dislocations and even cracks in the GaN films caused by strain. To resolve the problems, an AlN buffer layer has been widely used to reduce this tensile strain and even producing compressively strained GaN layers grown on SiC [4-7] and AlN buffer has been repeatedly found to be necessary to achieve a GaN layer with a smooth surface and a reasonably low density of threading dislocations via the metal organic chemical vapor deposition technique (MOCVD) [3].

So far, most of the SiC homoepitaxy has been realized on 8-degree-off and 4-degree-off substrates, whereas GaN heteroepitaxy is done on SiC on-axis (up to 0.3 degrees off) [8]. As 6-inch SiC wafers are being introduced into the market, a decrease of the substrate cut-off to 2 degrees for SiC

homoepitaxy is desirable to reduce the manufacturing costs. The purpose of this paper is to show the microstructural and morphological characteristics of the AlGaN/GaN HEMT structure and to study the influence of the off-axis angle on the surface quality of the device.

Experimental results

A sample of AlGaN/GaN HEMT structure was grown on a 1-degree-off 6H-SiC substrate. An EMCORE D75 MOVPE system was used for the growth. The AlGaN/GaN heterostructure was grown on 6H-SiC substrate sandwiched with an AlN spacer layer. The complete structure of the sample consists of an AlN nucleation layer, a GaN buffer, a GaN undoped thin AlN spacer, a AlGaN layer and finally a GaN cap layer. The layers are grown epitaxially, which is confirmed from the corresponding electron diffraction patterns (with the [0001] SiC direction parallel to the [0001] GaN direction). A typical electron diffraction pattern is shown in Fig. 1.

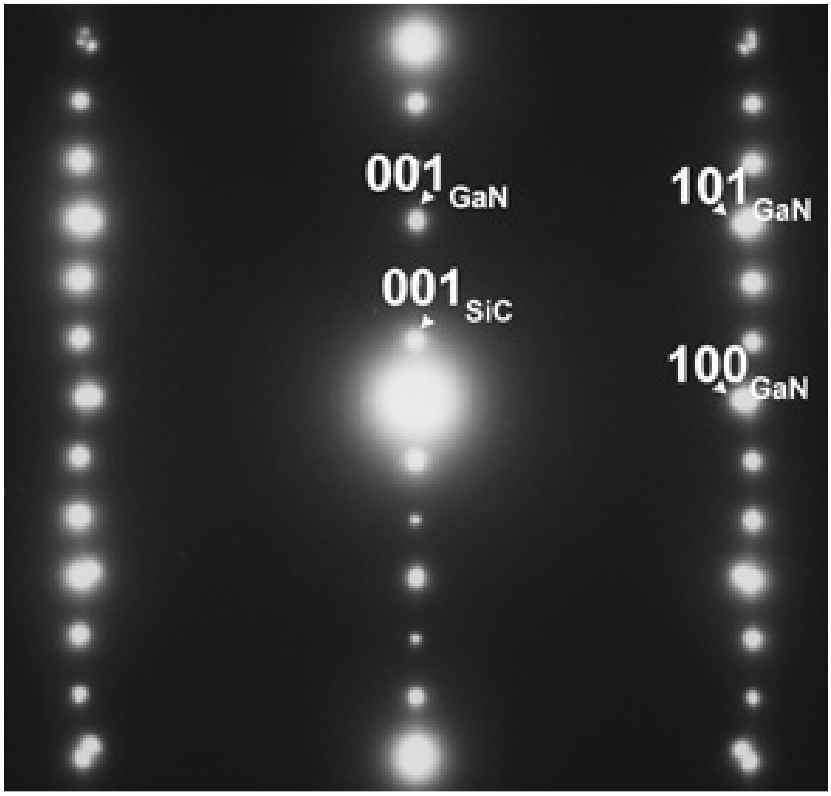

Fig. 1. An electron diffraction pattern taken close to SiC /GaN interface, revealing the very good epitaxial growth of GaN on the 6H-SiC substrate.

The conventional bright field TEM image of Fig. 2 shows the structure of the sample and allows the accurate measurement of the layers' thickness. Sharp interfaces are observed between most of the layers. The layers of the upper part of the structure are not clearly distinguished in this magnification, so for this reason higher magnification TEM images are needed and shown below.

Fig. 2. A multilayer structure grown on a 6H-SiC substrate. Five layers were grown epitaxially on the substrate.

The black colored rectangular marked in the upper part of Fig. 2 is magnified and showed in Fig. 3. In this HRTEM image, which reveals the upper part of the multilayer structure, the surface of the GaN cap layer appears atomically flat (despite the cut-off substrate).

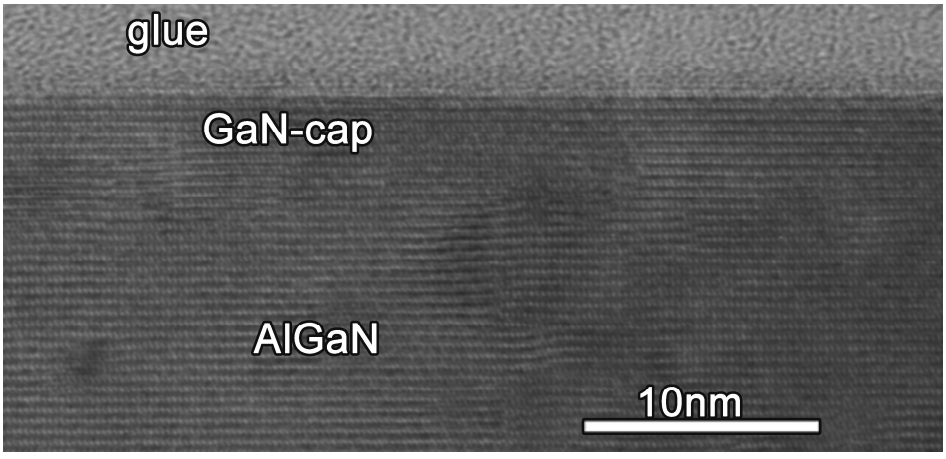

Fig. 3. HRTEM image showing the upper part of the multilayer structure

In Table 1 the nominal and experimental thicknesses of the multilayer structure are presented.

Table 1: Nominal and experimental thicknesses of the structure

Layers (top to bottom)	Nominal thickness [nm]	Experimental thickness [nm]
GaN cap	2-2.5	20-21
AlGaN (~20%Al)	20	
AlN spacer	1	2-4
GaN undoped channel	80	1680-1700
GaN buffer	2500	
AlN nucleation layer	60-90	13-33
Substrate 6H-SiC (1° off)		

It is obvious that on the surface of the 1-degree cut-off substrate characteristic steps would appear. The High Resolution TEM (HRTEM) image of Fig. 4 shows these steps at the interface between the 6H-SiC substrate and the AlN nucleation layer. The white colored arrows indicate the steps' positions. The characteristic contrast suggests the growth of threading dislocations in the AlN layer that begin from the SiC/AlN interface at the steps' positions.

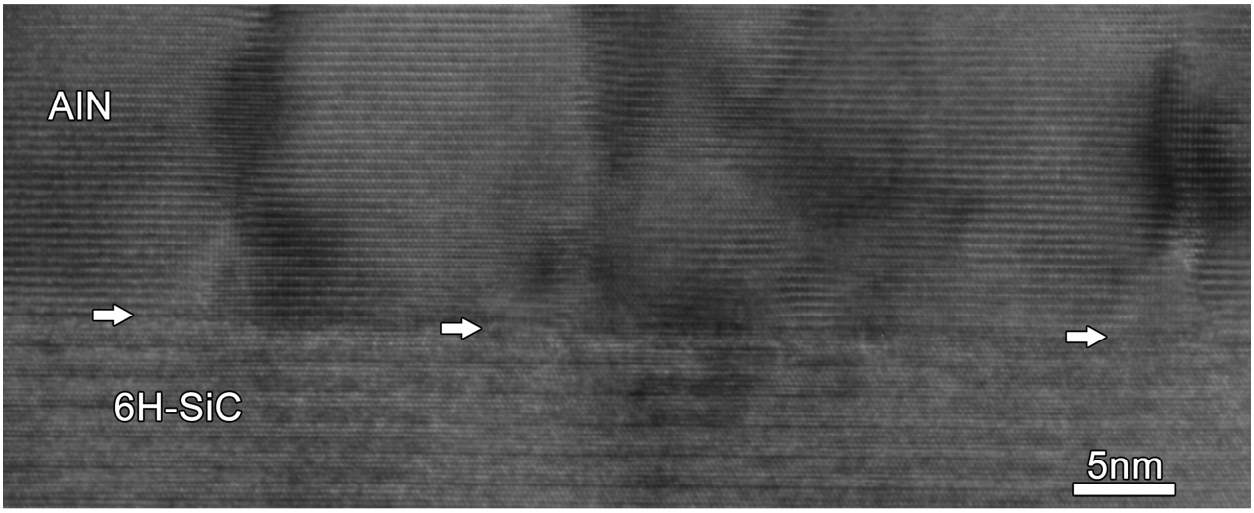

Fig. 4. HRTEM image revealing the steps in the SiC/AlN interface indicated by white colored arrows

Summary

In this paper, we showed that the AlGaN/GaN HEMT structure grown on a 1-degree-off 6H-SiC substrate appears to have an atomically flat free surface, although the SiC/AlN interface shows the expected steps.

Keywords: Gelatin methacrylate hydrogel; Protein adsorption; Titanium surface modification

Abstract: Gelatin methacrylate (GelMA) hydrogel comprised of modified natural extracellular matrix (ECM) components, making it a potentially attractive material for surface modification. In this paper, we hypothesize that establishing a GelMA hydrogel coating on titanium surface will accelerate osseointegration. Titanium substrates were silanized with 3-Aminopropyltriethoxysilane (APTES), which was treated by alkali-heated treatment firstly. The GelMA hydrogel coating was constructed on the silanized titanium surface by in situ photopolymerization under UV illumination. Adsorption of bovine serum albumin (BSA) onto modifed titanium surfaces was investigated. The results showed that GelMA-coated titanium adsorbed greater amount of protein than other Ti surfaces. The differences in protein adsorption behavior could result in very different initial cellular behavior on GelMA-coated titanium implant surfaces.

Introduction

Titanium (Ti) is widely used as orthopedic implants because of its good biocompatibility, superior mechanical properties and excellent corrosion resistance. However, it cannot meet clinical requirements due to the lack in integration with the surrounding bone environment. Protein adsorption mediated cell behavior is regarded as a fundamental reaction at biomaterial/tissue interface. It is well recognized that protein adsorption is sensitive to physicochemical surface properties of the implant. Various surface modifications have been developed to facilitate bone tissue responses toward titanium surfaces including hydroxyapatite coating, biomolecular immobilization [1], and control of the surface topography [2].

Gelatin is partially denatured derivative of collagen and it is biodegradable, biocompatible and non-immunogenic. Furthermore, due to the large number of functional side groups, gelatin readily undergoes chemical cross-linking, which is very important for its widely use in tissue engineering and drug delivery system [3]. It has been reported that hydrogels based on methacrylamide-modified gelatin were attractive materials for biomedical applications because of their controllable chemical networks, high water content, biocompatibility and mechanical properties [4]. In this paper, we supposed that establishing a gelatin methacrylate (GelMA) hydrogel coating on titanium surface would be a potential surface optimization method to enhance osseointegration of titanium implant. For one thing, the hydrogel can mimic extracellular matrix (ECM) to be beneficial for biomaterial/tissue interface and gelatin has been previously reported to act as nucleators of mineral deposition onto biomaterials [5]. Besides, its macroporous topographical features may promote cell adhesion, differentiation and proliferation, as reported previously [6]. Therefore, the objective of this study was to construct and characterize macroporous GelMA hydrogel coating on Ti by

photopolymerization, and focuse the study on the potential of protein adsorption onto this coating. We hypothesized that this modified gelatin coating would be helpful for enhancing protein adsorption on titanium substrates, which would enhance subsequent cellular binding.

Experimental Procedures

Fabrication of GelMA Hydrogel Coating on Ti Surface

Commercially pure titanium sheets (0.1mm thick) were etched in a mixture of HF, HNO_3 and distilled water and named as "Ti". The NaOH-heat-treated and 3-Aminopropyltriethoxysilane (APTES, 99.0 %, Acros) -silanized titanium samples were prepared as described [7] and denoted as Ti-OH and Ti-APTES respectively. Gelatin methacrylate were synthesized with gelatin (Sigma) and methacrylic anhydride (Sigma) using techniques previously demonstrated [4]. The GelMA-coated Ti sample was prepared as follows. Briefly, GelMA macromonomer solution in PBS (10%, w/v) containing the photoinitiator Irgacure 2959 (1%, w/v) was pipetted between a Ti-APTES plate and an octadecyltrichlorosilane (OST, Sigma) modified coverslip separated by a 500μm spacer, then irradiated with UV light (6.9 mW/cm^2, Omnicure S1500, Canada). After that, the GelMA-coated Ti samples were incubated in milliQ-water for 3h in order to remove the GelMA physically adsorbed on Ti surface, and then lyophilized.

Protein Adsorption

Bovine serum albumin (Sigma, purity of 99.8%) was dissolved in phosphate buffered saline (PBS) buffer one day before use. To investigate the protein adsorption kinetics, titanium samples were immersed in 1.5 mg/mL BSA solution and protein concentration of different time points was determined by using the bicinchoninic acid (BCA) assay according to the instruction of the manufacturer. The analysis was performed by using a microplatereader (RT-2100C, Rayto, China) at 595nm ($n=3$, $p<0.05$). The adsorbed amount was determined by subtracting the residual protein from the initial added protein.

Surface Analysis

The topography of the modified titanium surfaces was measured by scanning electronic microscopy (SEM). Attenuated total refraction-Fourier transform infrared spectroscopy (ATR-FTIR, FTS400 spectrometer, Shimadzu) was employed to determine the surface chemical changes after samples incubation in 1.5 mg/mL BSA solution for 6h. After incubation in Cy3-labeled bovine serum albumin (Beijing Biosynthesis Biotechnology Co., LCD) solution (50 μg/mL in 0 .01M PBS buffer) for 60 min at 37 ℃, samples were washed twice with PBS buffer and observed by fluorescent microscope (Zeiss Axioskop 40 POL, Germany).

Results and Discussion

As shown in Fig. 1A, gelatin molecule was introduced methacrylate pendant groups by reacting with methacrylic anhydride (MA). To enhance the stability of GelMA coating, titanium substrates were firstly silanized using APTES (Fig. 1B), which could become a "molecular bridge" between the interface of organic materials and inorganic substrates. Then GelMA hydrogel was immobilized onto titanium surfaces by applying a photochemical reaction. After photo-crosslinking, GelMA hydrogel coatings on titanium surface showed interconnected macroporous structure with the pore size ranging from 20-200μm. When incubated in BSA solution, the amino and carboxyl groups in GelMA structure will be charged and they will interact with the charged amino acid residues presented on the outside of protein by forming hydrogen bonds and electrostatic force. Meanwhile, the mesh size of hydrogel was large enough to allow diffusion of BSA into the internal structure. Therefore, protein can be adsorbed within membrane pores and on the surface as well. It is reasonable to suspect that the GelMA hydrogel coating will promote the protein adsorption on titanium.

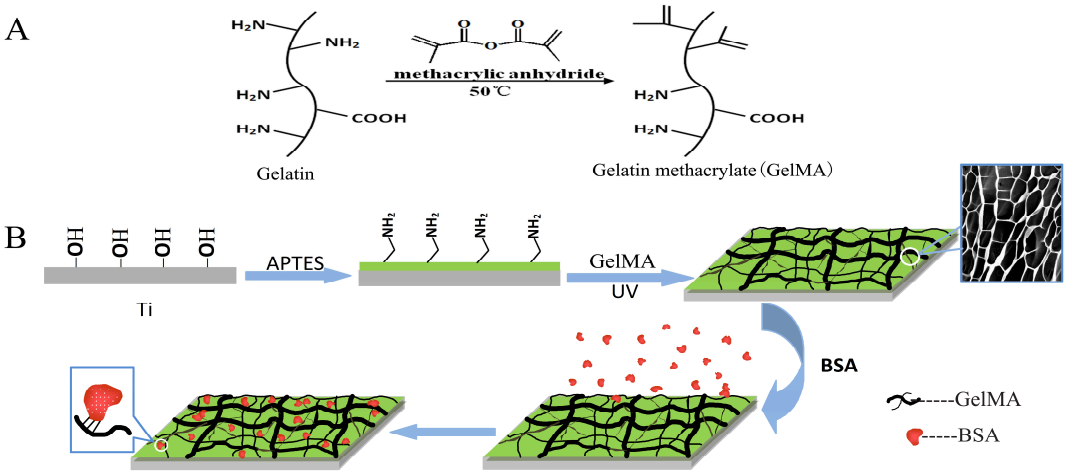

Fig. 1. Schematic illustration of **(A)** synthesis of gelatin methacrylate (GelMA) and **(B)** construction of GelMA coating on titanium surface.

Fig. 2A showed the ATR-FTIR spectra corresponding to samples by different treatments. Ti-OH sample exhibited the typical hydroxyl group peak at around 3235 cm^{-1} and 1625 cm^{-1}, respectively. After bonding the APTES films, the hydroxyl group disappeared and new peaks located around 1090cm^{-1} (Si –O –Si) and 1199 cm^{-1} ($–OCH_2CH_3$) indicated that silane agent had been grafted onto the surface of Ti-OH substrate. The characteristic bands for GelMA functionalized titanium surface were observed at 1645 cm^{-1} (amide I), 1530 cm^{-1} (amide II) and 1446 cm^{-1} (amide III), corresponding to the stretching of C=O bond, bending of N-H bond and plane vibration of C-N and N-H, respectively [8]. The observation of characteristic peaks of -CONH- and $-NH_2$ in the spectrum of Ti-GelMA suggested the successful immobilization of GelMA hydrogel coating on titanium surface.

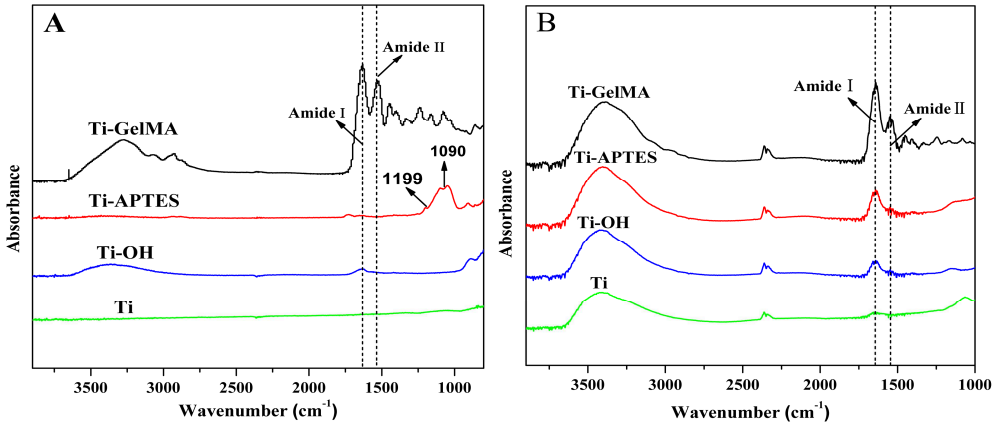

Fig. 2. ATR-FTIR spectra of (A) before and (B) after the protein adsorbed samples.

After the protein adsorption (Fig. 2B), both amide I (centered at 1645 cm^{-1}) and amide II (centered at 1540 cm^{-1}) adsorption bands can be observed in the ATR-FTIR spectra of the protein adsorbed samples. The relative intensity of signals corresponding amide I was significantly higher for Ti-GelMA sample than for all other groups, which partly came from the amide I of molecular structure of GelMA itself. In contrast, the amides I and II bands were hardly to be observed on Ti sample. It has been reported that peak intensity of amide I increases linearly with the amount of protein statistically adsorbed on the surface [9]. Therefore, we can assume that Ti sample adsorbed least BSA for a given geometric surface area than other three titanium surfaces and no significant change was observed for Ti-OH and Ti-APTES samples. In order to verify that Ti-GelMA surface adsorbed most protein, quantitative analysis of protein adsorption on modified titanium surfaces was discussed in the next chapter.

For evaluation of protein adsorption properties of GelMA coating, modified titanium samples were incubated with fluorescently labeled BSA. Integration time was kept constant for all samples to allow compatibility of the results. Sporadic fluorescence was observed on the control Ti surface (Fig. 3a),

indicating minimized protein adsorption. The fluorescence intensity of the other three Ti samples was larger than the control Ti, especially for Ti-GelMA sample with the strongest fluorescence. Proteins tend to adhere more strongly to charged than to uncharged substrates [10]. Therefore, negatively charged Ti-OH, positively charged APTES film and zwitterionic GelMA coating could adsorb more proteins than the neutral Ti sample. Besides the functional groups, topography also plays a significant role in protein adsorption and that not just the size distribution, but also the detailed shape of topographical features is of paramount importance [11]. As shown in Fig.3d, fluorescence could be observed in the inner region of the GelMA hydrogel, implying that the labeled protein could diffuse into and form bind with the network structure. The amount of protein adhered on the nanoporous structure (Fig. 3b and 3c) was higher than that on nanosteps-like structure of control Ti (Fig. 3a), suggesting that increased surface roughness provides more surface area for protein adsorption. A similar result has been reported previously [12]. As shown in the figure proteins adhered on the Ti-APTES surface in slightly higher amounts than on Ti-OH surface. This is because the $-NH_2$ of APTES could be the binding sites for protein to form hydrogen bonding .

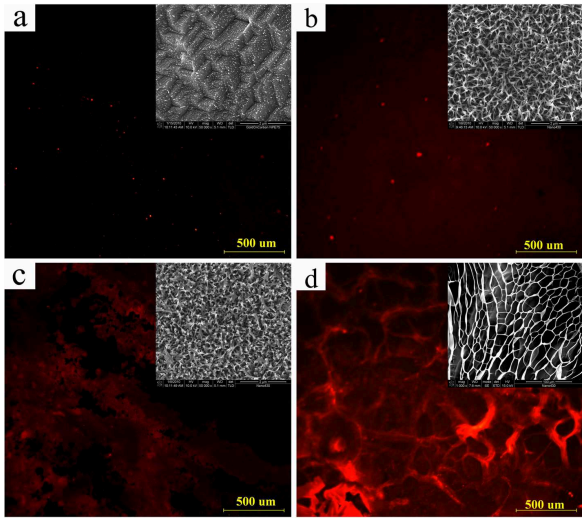

Fig. 3. Fluorescence images of BSA absorbed for 60min on different Ti surfaces with SEM images (a-c: 50000×, d: 1000×) inserted (a: Ti, b: Ti-OH, c: Ti-APTES, d: Ti-GelMA)

The protein adsorption onto the surfaces of titanium may proceed in two different processes [13]. The first process is the direct attachment of the protein molecules. The second process probably involves the slow rearrangement of the adsorbed layer due to the changes of orientation and conformation of the adsorbed molecules. Protein absorption kinetics of BSA on modified titanium surfaces was showed in Fig. 4. At the first 3 h, the degree of BSA adsorption was similar for all treatment groups. The amount of BSA adsorbed on Ti-GelMA samples was statistically significantly higher than other groups after 5 hours incubation. Equilibrium adsorption occurred at 8h for all samples. Hydrophobic surfaces tend to adsorb more proteins. Adsorption reached the maximum on the Ti-GelMA with a surface coverage of 0.97 mg/m2, and got less on the hydrophilic Ti-OH sample (approximately 0.64mg/m^2). As the cellular response to implant surface topography is governed by the adsorbed protein layer, it is assumed that the GelMA hydrogel coating would enhance subsequent cellular binding. There was no statistically significant difference between Ti-APTES and Ti-OH samples in BSA adsorption, which was in accord with the results mentioned above. Taken together, each of surface properties such as chemistry, charge, morphology and wettability can affect protein adsorption differently. While these surface properties are connected, it is difficult to distinguish the effect of individual surface properties on protein adsorption since changing one property often changes others. To understand the mechanism of protein-material interaction, further studies are in progress.

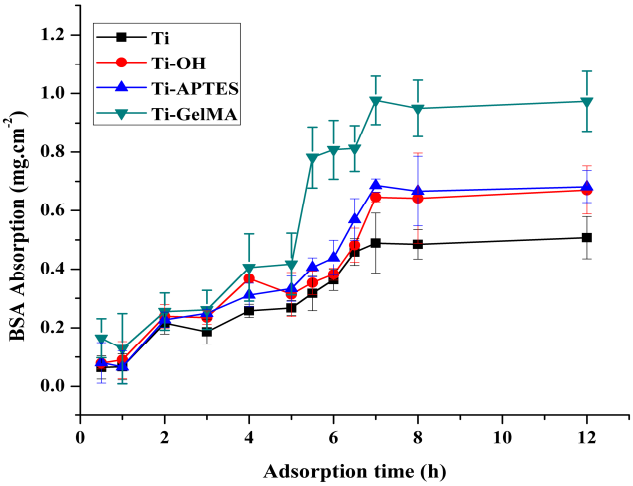

Fig. 4. Kinetics of BSA adsorption on different titanium surfaces (mean±standard deviation).

Conclusions

We have developed a simple method for fabricating macroporous GelMA hydrogel coating on titanium by using the combination of silanization and photochemical cross-linking. In contrast to uncoated titanium surface, GelMA hydrogel coating showed a good bioactivity with higher affinity to proteins, presumably due to the interconnected network structure and change of adhesion sites for proteins. It is envisioned that our method could be an optimized surface modification method to accelerate osseointegration.

Keywords: Biosurfacant; Lipopeptide; Antimicrobial activity

Abstract: A kind of biosurfactant produced by ascendant strain BS01 was screened by detecting the surface tension , diameter of oil spreading. The structure of the biosurfactant extracted from fermentation broth of strain BS01 was verified by IR and UV .It has superior surfactive properties. Its critical micelle concentration (CMC) is 25mg/l and the surface tension is 29.6mN/m in CMC. The biosurfactant shows excellent antibacterial spectrum against agricultural pathogenic fungi and human pathogenic bacteria. Especially, it presents good antibiotic activity against Sclerotinia sclerotiorum ,staphylococcus aureus Rosenbach and pseudomonas aeruginosa .

Introduction

Biosurfactants take advantages over synthetic surfactants from the viewpoint of their biodegradability, lower toxicity, stable activities at extreme temperature, pH and salinity when applied for enhancing bioremediation, food processing and crude oil drilling[1]. Thus, biosurfactants have been a research hot spot in the last decade. In view of a short metabolism period of biosurfactant produced by microorganisms, the preparation of the biosurfactant has great economic benefits by means of microorganism fermentation. Lipopeptide is an amphiphilic biosurfactant containing lipid and peptide as hydrophobic and hydrophilic moiety, respectively.Lipopeptide biosurfactants exhibit some powerful biological actions such as plant diseases control [2], anti-tumour and anti-viral activities[3] and awide antimicrobial spectrum. [4] The latter is due to their exceptional surface activity that allows modifications of the bacterial surface hydrophobicity and can consequently interfere with the microbial adhesion to solid surfaces, like those of medical devices. [5] However, while the industrial demand for surfactants has increased nearly 300% in the US chemical industry during the last decade, all these usable surfactants in practice originate from chemical synthesis strategies at present. This fact, an increasing demand of high-quality surfactants (for example, environmentally friendly biosurfactants) and the lack of cost-competitive bioprocess of biosurfactants for commercial utilization, motivates researchers to develop cost-effective strategies for biosurfactant production[6]. To solve this problem, new biosurfactant producers with stable surface-active properties need to be investigated and their cultural conditions also need to be optimized. Here, we isolated a strain from waste soybean oil and named to BS01. The strain produced new biosurfactant and it has very strong emulsification activity for hydrophobic materials. In addition, we purified and characterized the biosurfactant then its antibacterial and antifungal properties were researched.

Methods

Preliminary Screening Assays for Biosurfactant Production

In order to determine the ability of the strain to produce biosurfactant, the pure culture was subjected to preliminary screening methods namely oil displacement test and emulsification assay., All the above mentioned experiments were carried out based on the methodology previously described in Sriram et al. [7]All the experiments were done in triplicates.

Production Media Composition and Cultivation Conditions

Using the nutrient broth (NB) media (HiMedia, Mumbai, India), inoculum was prepared and incubated at 37 ℃ for 12 h. The seedculture at 3% was utilized to inoculate the biosurfactant production media of 100 ml in a 500 ml Erlenmeyer conical flask and incubated at 160 rpm at 37 ℃ for 5 days. The production media contained (g/L): $(NH_4)_2SO_4$, 10; NaCl, 1.1; KCl, 1.1; $FeSO_4$.7H2O, 2.8 X 10-4;$K_2HPO_4.3H_2O$, 4.4; KH_2PO_4, 3.4; $MgSO_4$, 0.5; Yeast Extract, 0.5; trace elements solution, 0.5 ml/L and diesel oil, 2% (v/v) as the sole carbon source. The composition of trace elements solution involved (g/L): $CaCl_2$, 0.24; $ZnSO_4$, 0.29; $MnSO_4$, 0.17 and $CuSO_4$, 0.25. After the production media was autoclaved, the trace elements solution was added prior to inoculation by filtering it with a 0.22 lm pore membrane [8].

Solation, Extraction and Purification of Biosurfactant

The cell free supernatant was obtained by centrifuging the broth culture at 4,000 rpm at 4℃ for 20 min. The supernatant was acidified with 6 N HCl, thereby reducing its pH to 2.0 and then incubated overnight at 4℃. It was further extracted twice with chloroform–methanol (2:1, v/v).then selected the lower organic layer ,removed the solvent by rotary evaporation,and lyophilization, Yellow powdered solid was obtained . After the coarse product was reduced to powder,it was extracted by methylene chloride for 24h.then the solvent was removed and the solid was washed with hexane , Purification of biosurfactant was achieved by recrystallization. White powdered solid was obtained .

Chemical Characterization of Biosurfactant

The primary characterization of the biosurfactant was carried through TLC as per the methodology described above in purification and the separated compound was visualized under UV light. Further characterization was accomplished with the help of IR and UV spectrum.

Critical Micelle Concentration

Surface tension measurements were carried out using De–Nouy Tensiometer Kruss K-6 with platinum ring. Freshly prepared aqueous solutions of surfactants were used with concentration range of 0–100 mg/L at 25℃. The critical micelle concentration (CMC) values were estimated from the break point of each surface tension versus concentration (on log scale) curves at 25℃.

The Diameter of Oil Spreading

To 15cm diameter dish, adding 60mL of distilled water, adding 2mL water liquid paraffin, uniform and stable film to be formed, the center of the film gradually added 2mL fermentation broth of the test, the oil film formed around the exhaust is discharged to circle. Circle area with rows of biosurfactants content into a linear relationship. The oil phase and the aqueous phase component is small, images acquisition time, be unable to record clear oil discharge ring. the oil phase can be stained with Sudan, Between the oil phase and the water phase is formed a good color. Its can be clearly observed oil spreading.

Antimicrobial Studies

The antibacterial activities of the biosurfactant were tested with *PDA* medium against various agricultural pathomycetes such as Cordana musae, Sclerotinia, sclerotiorum, Cladosporium cucumerinum, Fusarium roseum, Colletotrichum atramentarium, Fusarium oxysporum f.sp., Fusarium moniliforme, Rhizoctonia cerealisRhizoctonia solani, Phytophthora capsici, Cladosporium cucumerinum by using agar well diffusion method at 1g/L, Aditionnally, the effect of the biosurfactant on E. Coli, Staphyloccocus aureus Rosenbach, P.Aeruginosa were detected with beef extract andpeptone medium using the previous mentioned method.

Results and Discussion

Screening Assays for Biosurfactant Production

After Preliminary screening assays for biosurfactant production ,we cultivated four bacteria strains named BS01, BS02, BS03 and BS04. Preliminary stains medium were fermented for 72 hours,then were centrifuged twice for each time 15 min on the condition of low temperature and 4000r/min. Leave to rest for 30 minutes.surface tension and oil displacement of the supernatant were tested.

Table 1 showed that stain BS01 posses lower surface tension and better oil displacement compared with other three preliminary screened stains BS02~BS04.Consequently,we selected BS01 as the following test stain.

TABLE 1 THE ISOLATION OF MICROORGANISMS PRODUCTING BIOSURIFACTANTS

strain	Surface tension（mN m）	The diameter of oil spreading (mm)
BS01	35.6	12.6
BS02	37.2	11.0
BS03	39.6	10.2
BS04	40.4	9.6

Isolation, extraction and purification of biosurfactant

This crude biosurfactant was further purified by using the Silicagel TLC plates. Different mobile phase system were detected. TLC plates were in stiu acid hydrolysized ,and regularly sprayed with chromogenic agent ninhydrin ,a yellow spot with the Rf value of 0.51 confirms the presence of amino acids.We deduced the biosurfactant extracted from stain BS01 is a kind of lipopeptide biosurfactant.

Characterization of biosurfactant

The structure of biosurfactant was detected by IR (Fig.1) and UV(Fig.2)The N-H stretching vibrations in the transmittance range 3282cm^{-1} and 3064 cm^{-1} indicated the presence of N-H group.The distinct peak values observed at and 1645 cm^{-1} and 1535 cm^{-1} corresponded to the hydrophilic lipopeptide bond. The peak of 2924 cm^{-1}, 2854 cm^{-1}, 1469 cm^{-1} and 1381 cm^{-1} are attibuted to the hydrophobic hydrocarbon chains.The IR spectra revealed the biosurfactant was a type of lipopeptide biosurfactant.

Fig2 showed the tensive peak of 215nm firmly confirmed the biosurfactant containning lipopeptide chain,which is accordance with the privious refered reviews.

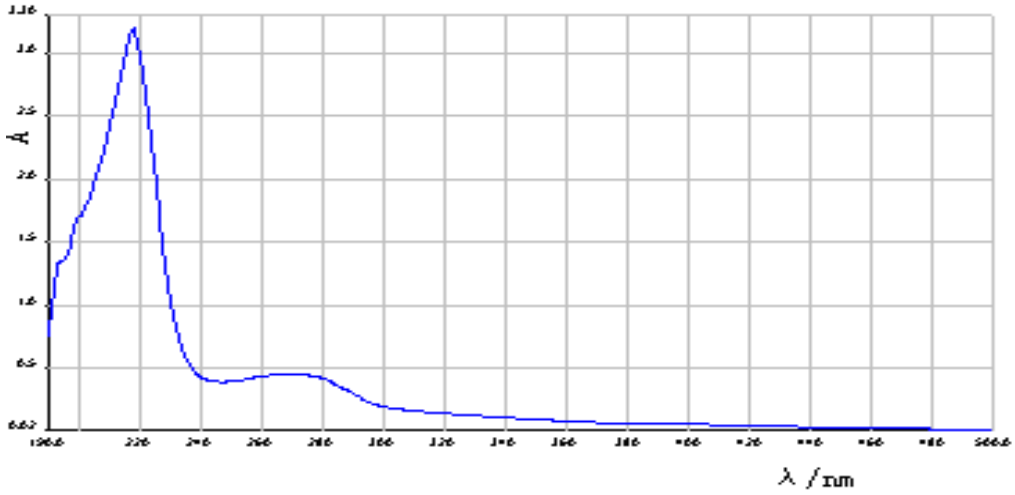

Fig. 2 The UV spectra of the biosurfactant

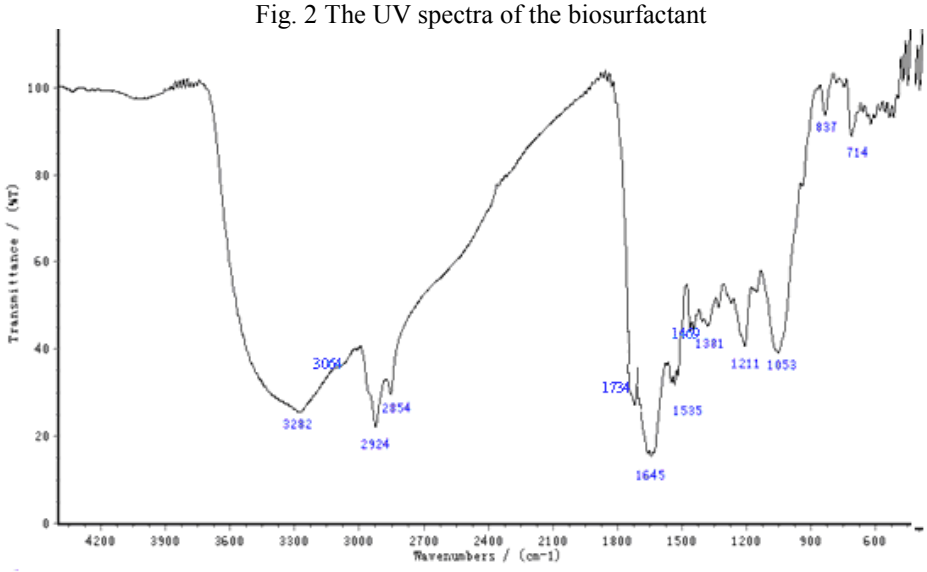

Fig. 1 The IR spectra of the biosurfactant

Critical micelle concentration

The variation of the surface tensionγ with the biosurfactant concentration are shown in the Fig. 3. The plot of γ vs logC show a break at a concentration corresponding to the CMC. The value of CMC is 25mg/l and the value ofγat the CMC is 29.6mN/m. The surface activity of the biosurfactant is significant.

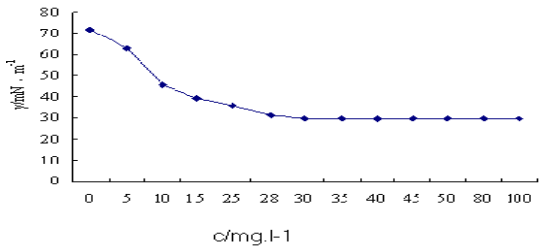

Fig. 3 The curves of relationship between the surfacetension of the biosurfactants aqueous solution and concentration

Antimicrobial Activity

The biosurfactant was screened for their antimicrobial activity against 11 kinds of agricultural pathomycetes and three human pathogenic bacteria as shown in Table.2.

The biosurfactant exhibited extensive inhibitive activity against 11 type of agricultural pathogenic fungi. Notely, it produced the halo of diameter 31mm against the *Sclerotiniasclerotiorum*. Additonally, it was found that the biosurfactant posses good anti bacteria ability against *Staptehyloccocus aureus Rosenbach* and *P.Aeruginosa.*

The adsorption of the amphipathic biosurfactant at the cellular membranes reaches its maximum extent at higher dose leading to complete coverage of the membranes by the surfactant molecules. After the complete coverage, the molecules penetrate through it. Furthermore, the positive charges in the cationic molecules neutralize the negative charges on the bacterial cell membranes. Accordingly, the selective permeability which characterizes the outer cellular membrane is completely deactivated. Hence, the vital transportation of essential components for cell bioreactions and activities is disturbed, causing death for these microorganisms.

Conclusions

In this work, a lipopeptide biosurfactant was isolated, extracted and purified from BS01 stain. The lipopeptide biosurfactant represent great significance in surface activity and extensive inhibition performance. We have full confidence to believe the it will be a potential , effective and broad -spectrum antimicrobial agents.

Keywords: magnetic nanoparticles; carboxyl; recombinant chitinase; immobilized enzyme; Botrytis cinerea

Abstract: To isolate recombinant chitinase quickly and boost its anti-fungi activities in vitro, functional magnetic nanometer carrier was used to immobilize recombinant chitinase from the crude enzyme solution and immobilized recombinant chitinase was applied to test whether it would inhibit the growth of gray mold from fruits. In this study, the carboxyl magnetic carrier was produced by solvent thermal reduction method and characterized by scanning electron microscope (SEM) and fourier transform infrared spectrometer (FTIR). Then, the carboxyl magnetic carrier activated by EDC/NHS was applied to immobilize recombinant chitinase and the immobilization efficiency was investigated by quantitative analysis. To obtain the highest immobilization efficiency, reaction conditions were optimized through combining different pH, temperature and reaction period. The results show that the surface of magnetic carrier was successfully carboxyl and the average diameter was 200nm. The immobilization efdiciency could reach the peak 64.43% after 7h reaction at the condition of pH 6 and 25℃. It also shows that immobilized recombinant chitinase can significantly inhibit the growth of gray mold isolated from table grape compared with the enzyme without immobilization with magnetic nanometer carrier.

Introduction

Fungus as an serious pathogenic factor for postharvest fruits and vegetables have been included in the HACCP system (hazard analysis and critical control point system), since they generally cause postharvest diseases and finally result in large decay of fruits and vegetables [1]. Botrytis cinerea is one such major pathogenic fungal that cause postharvest diseases. Chitinase from plant have been shown the abilities to make most of the pathogenic fungi lose the ability of infecting and causing diseases of plants. These suggest an important role of chitinase in plant disease resistance[2, 3]. However, chitinase is less stable, and difficult to be purified and reused. All these restrain its wide application to protection of the postharvest fruits and vegetables from fungal.

In order to increase chitinase's stability and extend the period for its activity, magnetic carrier was introduced to immobilize chitinase. Magnetic carrier is consist of magnetic nanoparticles coated with organic polymer shell and can be introduced with a variety of function groups, such as epoxy group, carboxyl, chloride, aldehyde, etc.. Magnetic carrier can immobilize enzyme by covalent bond which is generally very stable. Then, magnetic field can be used to easily separate magnetic carrier covalent with enzyme. Therefore, magnetic carrier as one kind of new functional

polymer materials in recent years are widely used in drug controlled release, the immune test, magnetic resonance imaging, medical diagnosis, enzyme immobilization and biological separation, and so on[1].

The magnetic carrier covalent with carboxyl group was used to immobilize recombinant chitinase in this study, realizing the pupose of fast purifing chitinase, boosting the stability of purified chitinase, prolonging the active period of the purified chitinase. This study could provide theoretical basis and technical support for the application of restructuring chitinase in industry. Meanwhile，this study shows some insights into the inhibition of mycelium of grey mould (Botrytis cinerea) with immobilized recombinant chitinase.

Materials and methods

Synthesis of carboxyl magnetic carriers

To synthesize magnetic carriers covalent with carboxyl, 1.08g of FeCl3·6H2O, 2.4g of anhydrous sodium acetate, 2.4g of sodium citrate soluble and 40ml of ethylene glycol were mixed and stirred for 30min. Then the mixture was turned into the reaction kettle for 10h at 200℃. Thereafter, the carboxyl Fe3O4 magnetic microspheres were synthesized. The carriers were collected with external magnet and washed with high pure water followed by ethanol at least 3 times. Then, the carriers were dried at 60℃ under vacuum for at least 8 hours.

Characterization of carboxyl magnetic carrier

A small amount of magnetic carrier was sprayed with gold. The morphology of magnetic nanoparticles was observed by the scanning electron microscope (SEM, Japanese Seiko JEOL).

The carboxyl magnetic carriers were mixed with KBr and sample slices were made with the . The FT-IR spectra of the mixture were recorded by using a Spectrophotometer (Brook instruments, VECTOR22).

Preparation of the immobilized chitinases

30mg of the magnetic carriers was mixed with 1.0ml of MES buffer (25mmol/L, pH5.0) and shaked at 40 rpm for 24h. 100μL of the magnetic particle solution was mixed with, 50μL of 50mmol/ml EDC and NHS solution and shaked at 40 rpm for 30min at room temperature. Under magnetic field, supernatant was discarded and the carriers were, washed with MES solution for 3 times.

The activated carrier were added into the crude recombinant chitinase solution, and shaked for 5h at 25℃ and 40 rpm. Then, the immobilized chitinase was washed 3 times with phosphate buffer solution（0.1mol/L, pH6.0）. The elution was collected to detect the amount of residual chitinase. The resulting immobilized chitinases were held at 4℃ prior to use.

The amount of protein in the crude enzyme solution of recombinant chitinase and in supernatant after immobilization was determined by the Bradford method [2].

Protein load=(weight of crude enzyme protein–weight of residual protein after immobilization)/weight of carboxyl magnetic carrier

Immobilization efficiency=(weight of protein crude enzyme–weight of residual protein after immobilization)/weight of crude enzyme protein

Determination of activity

Determination of activity of free chitinases activity and immobilized chitinases was based on reference Tan[3].

The enzyme action of 1 ml enzyme solution to release the 1μg N-acetyl-D-glucosamine in a minute was defined as enzyme activity units (U). The enzyme activity of U (u/g) =OD585/ (a * tmin), where a is the parameters of enzyme activity linear regression equation, a=0.009

Specific activity of enzyme = enzyme activity / protein content;

Purification factor = immobilized enzyme specific activity / free specific activity of enzyme;

The relative activity (%) was the ratio between the activity of every sample and the maximum activity of sample.

Optimum conditions of chitinases immobilization

The optimum reaction conditions of immobilized chitinase were determined based on the relative activity under a variety of pH (from5.0 to 7.5) value, reaction temperature (from15 to 40℃) and reaction time (from 1-11h).

2.6 Inhibition effect of immobilized chitinases on Botrytis cinerea mycelium

Botrytis cinerea involved in the test was separated and purified from the grapes fruit, which provided by Tianjin key laboratory of postharvest physiology and storage of agricultural products.

Six pieces of diameter 0.06cm bacteria cake was placed into 50mL culture medium, ten parallel samples were followed by adding immobilized chitinase and free chitinase which have been placed for 0d, 2 d, 4 d and 6 d, inactivation of immobilized enzyme and free chitinase as the control. The treatment was shacked in water bath for 3 days at 26±0.5℃. The mycelia was acquired by filtering medium then was washed three times, and then drying to constant weight at 105℃. The experiment was repeated for three times.

The inhibitory rate=(weight of control sample-weight of mycelium mycelial)/(weightof control mycelial)*100%.

Results and discussion

Characterization of magnetic carriers

The size and morphology of carboxyl functional Fe3O4 magnetic carriers were characterized by scanning electron microscopy (SEM) and shown in figure 1. Results showed that the carboxyl Fe3O4 magnetic carriers appear spherical shapes, uniform dispersion, smooth surface, with a mean diameter of 200 nm. This study adopted solvent thermal reduction method. Ethylene glycol as solvent, sodium citrate as complexing agent and sodium acetic acid as reducing agent were used to prepare carboxyl magnetic carrier in the reaction kettle of coating with PTFE. Based on the theory of homogeneous nucleation of LaMer model [4], after the crystal nucleus formation, the more slowly particle formation rate, the narrower nanoparticles size distribution was. Therefore, the surface of Fe ions form complexes after suitable amount of sodium citrate was added into the reaction system. The concentration of Fe ion was reduced, so the generation rate of Fe atoms was reduced. The new crystal nucleus formation was obstructed in the growing process of the old crystal nucleus. All Fe atoms can evenly add to previously crystal nucleus, so Fe particles grew up at uniform rate. In this case, particle size distribution of ferromagnetic nanoparticles is more narrow, even get monodisperse nanoparticles might be obtained[5].

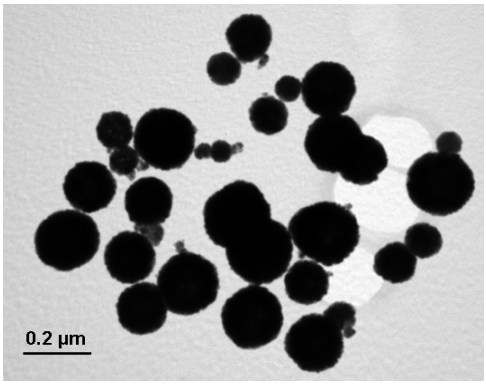

Fig.1 SEM Photos of magnetic carriers

FT-IR analysis

FTIR spectra of carboxyl magnetic carrier were shown in figure 2. The absorption peaks of the stretching vibration of Fe-O keys from Fe3O4 should be at 570cm-1 and 375cm-1 in the macroscopic state. When the size of Fe3O4 was reduced to nanoscale, a large number of cohesion among surface atoms were damaged, leading to the particle's surface electron rearrangement. Therefore, the absorption peaks of Fe-O keys from Fe3O4 appear blue shift phenomenon and characteristic absorption at 430cm-1 and 580cm-1 appeared in the FTIR spectra figure [9]. FTIR results also showed that the absorption peaks presented at 3400 cm-1 and 1652 and1396cm-1 should be attached to the stretching vibrations of O–H, C=O and C–O from carboxyl groups respectively. All these suggest that carboxyl group was successfully introduced to the surface of the magnetic microspheres.

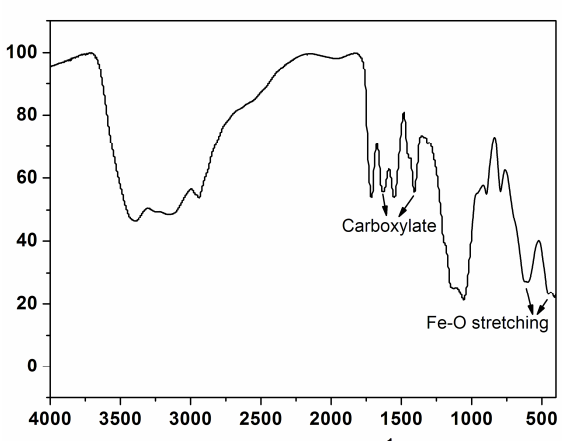

Fig.2 FTIR of magnetic carrier

The effect of temperature on enzyme activity of the immbilized recombinant chitinase

The effects of temperature on the enzyme activity of immobilized recombinant chitinase were shown in figure 3.

It shows that immobilized temperature evidently affects enzyme activity. When the temperature is below 25℃, the higher the temperature was, the higher the relative enzyme activity showed. However, when the temperature exceeds 25℃, the relative enzyme activity decreased linearly, which suggesting that free enzyme quickly deactivated in the immobilization process with increasing temperature increasing. Therefore, the suitable immobilized temperature was 25℃.

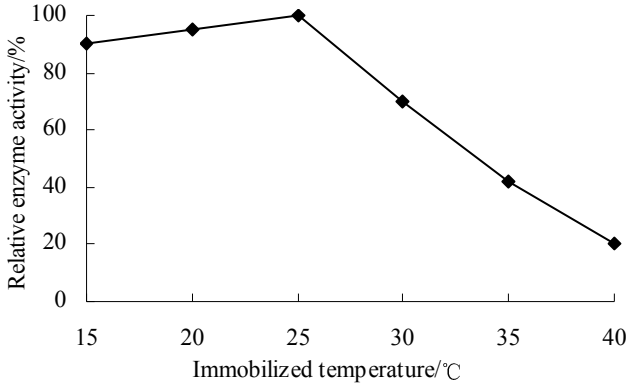

Fig. 3 The effect of immobilized temperature on the relative enzyme activity of immobilized chitinase

The effect of immobilized time on enzyme activity of the immobilized recombinant chitinase

The effects of immobilized time on the enzyme activity of immobilized recombinant chitinase were shown in figure 4.

It can be seen that the enzyme activity of the immobilized enzyme increased with the increasing of immobilization time. When the immobilized time was 7h, the enzyme activity reached maximum. Thereafter, the immobilized enzyme activity slightly decreased.

With the extension of immobilization time, more enzyme molecules combined to binding sites of the carriers. When the binding site reached saturation, the enzyme molecules could not bind up to the sites. Therefore, longer immobilized time will lead to the steric hindrance of enzyme molecules [10], wich will reduce the affinity between enzyme and immobilized carriers and prevent enzyme and substrate binding. These would result in the decrease of enzyme activity. Therefore, 7h should be the right immobilized time in this study.

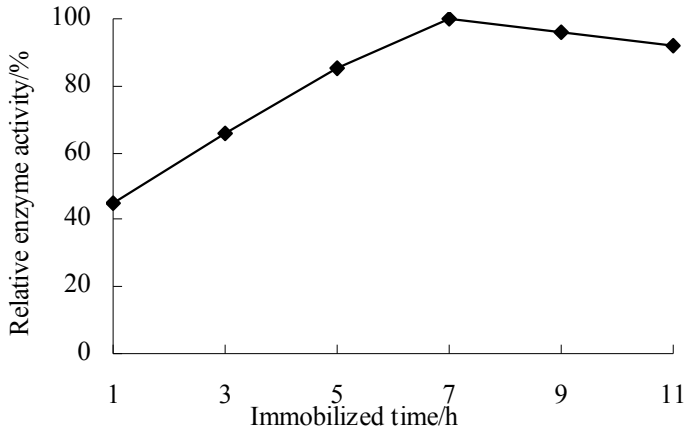

Fig.4 The effect of immobilized time of magnetic carrier on the relative enzyme activity

The effect of immobilized pH on enzyme activity of the recombinant chitinase

Reactions catalyzed by enzymes are very sensitive to the pH value. The effect of immobilized pH on the recombinant chitinase enzyme activity was shown in figure 5.

It shows that the activity of immobilized enzyme increased gradually with the increasing of pH value. When pH value reached 6, the immobilized enzyme activity reached a maximum value. When the pH continue to increase, activity of immobilized enzyme rapidly declined,indicating that immobilized enzyme is sensitive to the change of pH value and pH 6 seems to be the opitimum value for the immobilized chitinase.

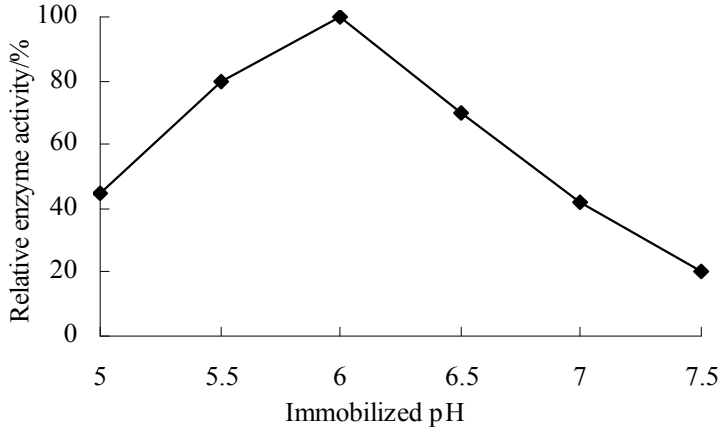

Fig.5 The effect of immobilized pH on the relative enzyme activity

The immobilized efficiency of magnetic carrier on recombinant chitinase

The recombinant chitinase crude enzyme was immobilized by the carboxyl functional magnetic carrier, then the total protein content of crude enzyme and the supernatant was determined to calculate immobilization efficiency. Thereafter, the enzyme activity of crude enzyme and immobilized enzyme was determined to calculate purification multiple. Results were shown in table 1.

As seen in table 1, immobilized efficiency of carboxyl functional magnetic carrier to recombinant chitinase was 64.43%, and purification rate was 3.47, which means the magnetic carrier is a nice way of purification and separation of recombinant chitinase.

Table1 The immobilization rate of magnetic carrier

Crude enzyme protein content (mg/L)	Crude enzyme activity (U/g)	Residue protein content (mg/L)	Immobilized enzyme activity (U/g)	Protein loading (mg/g)	The immobilized efficiency (%)	purification multiple
85.43	9.21	30.39	20.57	55.04	64.43	3.47

Inhibition of Botrytis cinerea mycelium by immobilized recombinant chitinase

Immobilized chitinase enzyme and free chitinase both can inhibit Botrytis cinerea mycelium to grow. As seen in Fig6, the inhibitory rate decreased with the increasing of enzyme storage period, but the inhibition rate of immobilized chitinase decreased more slowly than free enzyme. This is mainly because the stability of immobilized enzyme was better. After stored for 2-6 d, Immobilized enzyme still had strong inhibitory effects on Botrytis cinerea hyphae. However, free enzyme's inhibitory effect on Botrytis cinerea hyphae was significantly decreased and the inhibition rate of Botrytis cinerea hyphae dropped to 5% after 4 d storage of free chitinase enzyme. After 6 d storage, the free enzyme completely loss activity and the inhibition rate fell to 0%. Although inhibition of the immobilized chitinase after storage is gradually reduced, but the inhibitory effect of immobilized enzyme on mycelium was still higher than free enzyme stored for the same period. These demonstrate that enzyme immobilization reaction can keep the activity of chitinase enzyme and improve enzyme stability. Generally, this immobilized recombinant chitinase is conducive to the application in postharvest diseases control.

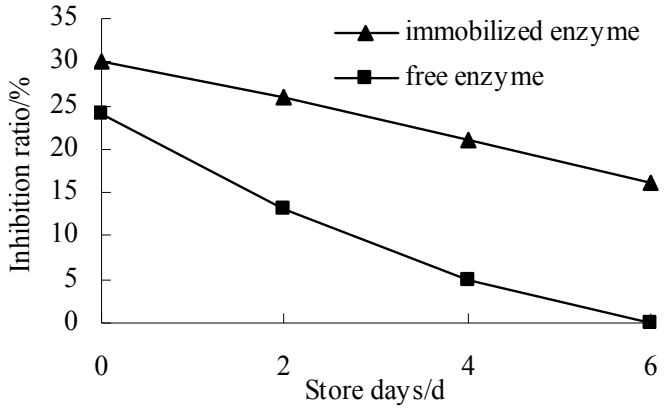

Fig.6 Inhibitory effect of chitinase and immobilized chitinase on Botrytis cinerea in liquid cultures

Conclusions

(1)The carboxyl magnetic nanoparticles that prepared by solvent melting method is functional and the average diameter was 200nm. (2)The magnetic carrier activated by EDC and NHS can stably bind recombinant chitinase and keep the enzyme activity. This suugests that the carboxyl magnetic carrier activated by EDC and NHS might also be stably combined with other enzyme/protein. (3) The optimum immobilized conditions of recombinant chitinase immobilized by carboxyl magnetic carrier are that pH value equals 6, temperature is 25℃, immobilized time is for 7h. (4)Immobilization efficiency of carboxyl magnetic carrier on recombinant chitinase is 64.43%, and purification multiple was 3.47. (5) Immobilized recombinant chitinase could inhibit the growth of Botrytis cinerea hypha of postharvest fruits and vegetables, and the inhibitory effect of immobilized enzyme on hypha only reduced by half after stored for 6d, significantly better than the free enzyme. However, the detailed mechanism how the inhibitory effect on the gray mold on the surface of fruits and vegetables need to be further studied in the future.

Keywords: PLA; Silver nanorods; Antimicrobial properties

Abstract: Poly(L-lactide) (PLA) fiber film containing silver nanorods were prepared via electrospinning. Morphology of the PLA/Ag fibers and distribution of the silver nanoparticles were characterized. These fibers showed antimicrobial activities against Gram-negative E. coli, because of the presence of a small amount of silver nanorods.

Introduction

Poly(L-lactide) (PLA) is a kind of biodegradable material. PLA has good biocompatibility, biodegradability, and non-toxic. In orthopedic fixation repair, artificial skin and tissue engineering and other fields have a wide range of applications. The electrospinning fibers of polymer, which have great specific surface area and high porosity, developed in the wound dressing has a great advantage.

In the past decades, metal nanostructures, for instance nanorods, nanowires and tetrahedron have been widely researched. They were different from other materials, because of their thermal, catalytic and other excellent properties. Silver is a powerful antimicrobial agent, which fit three antimicrobial methods such as antiadhesive, biocide release and contactactive antimicrobial modification [1]. Silver nanorods have been used in medical polymer materials in this paper. Electrospinning technology has received much more interested in fabricating medical polymer fiber film materials which have high specific surface areas [2]. The fibers are collected as a porous fiber film which is suitable for biomedical use such as wound dressing [3-5].

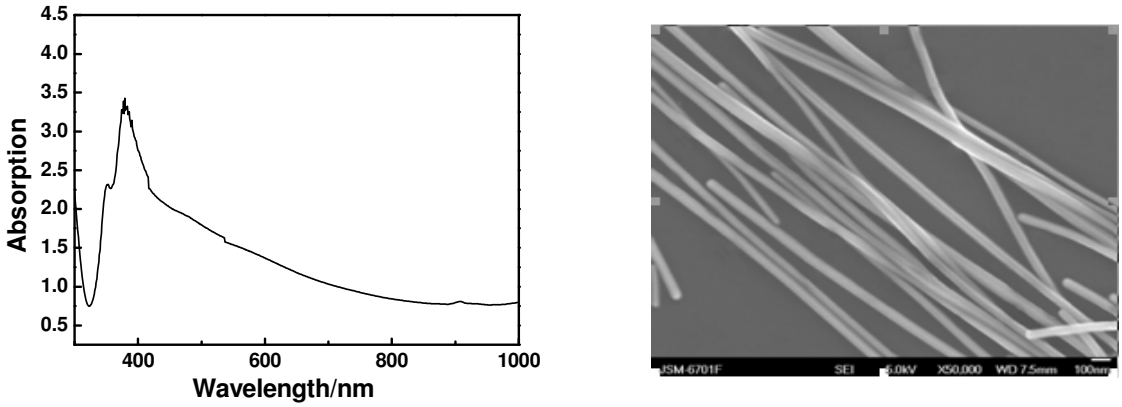
In this study, we added the silver nanorods into spinning dope which used to obtain the PLA composite fiber film. We tested the antibacterial properties of this fiber film. The experimental results were indicated that the film of PLA fibers has antimicrobial effect because of the containing of a small amount of silver nanorods.

Experimental

Materials

Poly(L-lactide) (PLA) (Mw=8,000) was purchased from Changchun institute of applied chemistry academy of sciences. Methylene chloride, silver nitrate ($AgNO_3$), ferric chloride, ethylene glycol (EG), and polyvinyl pyrrolidone (PVP) were all purchased from Beijing chemical factory.

Synthesis and Electrospinning process



In the process of synthesis, 13 ml solution of $FeCl_3 \cdot 6H_2O$ (4.62×10^{-5} mol L^{-1}, in EG) in a conical flask which was heated to 130 ℃ for 10 min, after that 12 ml of EG dissolve including 0.098 mol L^{-1} $AgNO_3$ and 0.061 mol L^{-1} PVP (Mw=90 000) mixture solution was mixed into the previous hot solution. The mixture was kept at 130 ℃ until all the $AgNO_3$ was dissolved completely, which lasted 1.5 h. With the purpose of examine the morphology of Ag nanorods, 1 mL of the resulted suspension solution was centrifuged at 9000 rpm for 10 min then washed with ethanol, three times. The precipitate was diluted with 10 ml of ethanol, measured as the sample of UV-vis and scanning electron microscopy (SEM) [6].

The electrospinning experiments were performed at 22 ℃, and the electrospinning equipment was assembled according to Lee et al. [7]. The polymer solution was placed in a syringe with the needle attached to a metal clamp, which connected to the high voltage power supply. It offered a positive voltage of 15 KV. An aluminum foil as a negative electrode was placed 15 cm away from the tip.

Measurements

The UV-vis spectrum was taken at room temperature with a Shimadzu UVmini-1240 spectrometer. The morphology of the electrospinning fibers were observed by using a field emission scanning electron microscope (JEOL JSM-6701F). The FTIR spectra were acquired using Shimadzu IR-8400s spectrometer. The X-ray diffraction (Bruker D8 Advance) patterns were performed in a 2-theta scan configuration in the range of 10-80°.

Results and discussion

(a) (b)

Fig. 1 UV–vis absorption spectra (a) and SEM image (b) of silver nanorods.

Fig. 1 (a) shows the UV–vis absorption spectrum of silver nanorods product. The spectrum of precipitation clearly exhibits two surface plasmon resonance peaks at 350 and 380 nm, which are the optical finger prints of silver nanorods [8-10]. Fig. 1 (b) shows the SEM image of silver nanorods that have a length of about 5 μm and a diameter of about 46 nm.

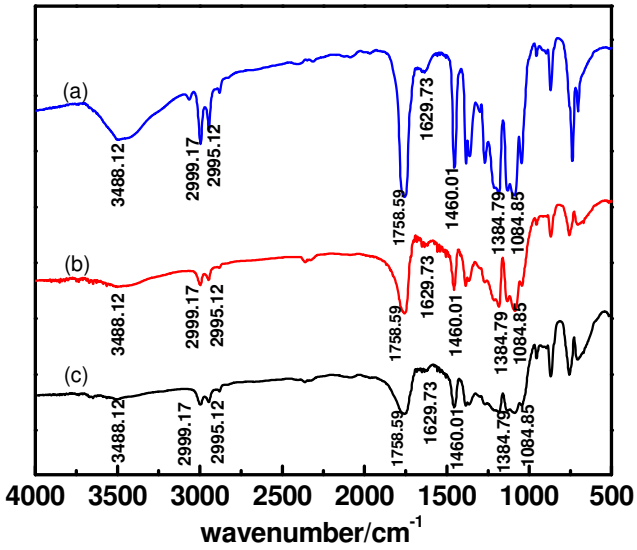


Fig. 2 FTIR spectra of PLA in methylene chloride (a), PLA/Ag fibers (b) and PLA fiber film (c)

The FTIR spectra of PLA in methylene chloride, PLA/Ag fibers and PLA fiber film shows in Fig. 2 respectively. The characteristic peaks of the hydroxy group (3488.12 cm^{-1}) can be seen obviously in Fig. 2 (b) and (c), which indicate the disappearance of hydrogen bonds that presents between PLA and methylene chloride. 2997.17 cm^{-1} and 1629.73 cm^{-1} belongs to methyl stretching and bending vibration peaks, 2995.12 cm^{-1} and 1758.59 cm^{-1} belongs to methyne stretching and bending vibration peak, 1460.01 cm^{-1} belongs to carbonyl stretching vibration peak and 1384.79 cm^{-1}, 1085.84 cm^{-1} belongs to carbony antisymmetric and symmetric stretching vibration peak. But, methyne stretching and bending vibration peak in Fig. 2 (a) are stronger than that in (b) and (c) because they are methylene chloride solvent peaks. The spectra of FTIR prove that dichloromethane solvents can be volatile out completely during the process of spinning.

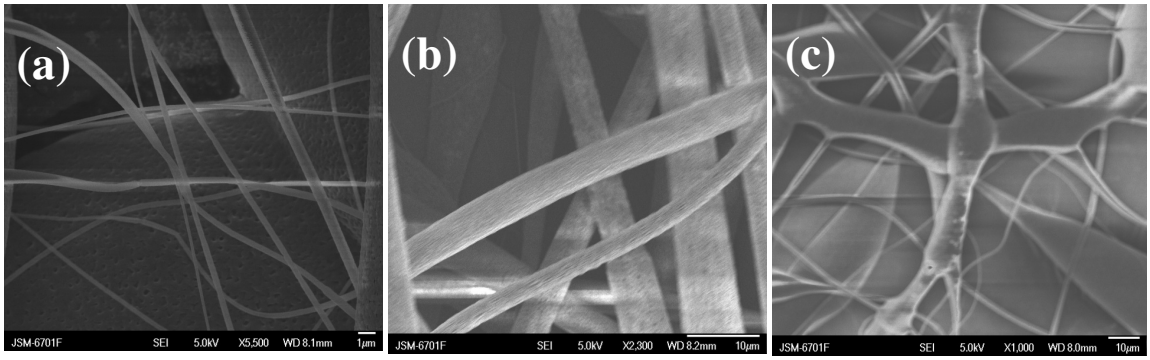

Fig. 3 SEM images of (a) 8 wt% PLA, (b)10 wt% PLA and (c)12 wt%PLA electrospnning fibers

Fig. 3 demonstrates SEM images of the electrospnning fibers of PLA of 8 wt%, 10 wt% and 12 wt%. The SEM results show that the electrospinning get best film properties in three conditions of PLA mass fraction of 10 wt%, spinning voltage of 15 KV and receiving distance of 15 cm.

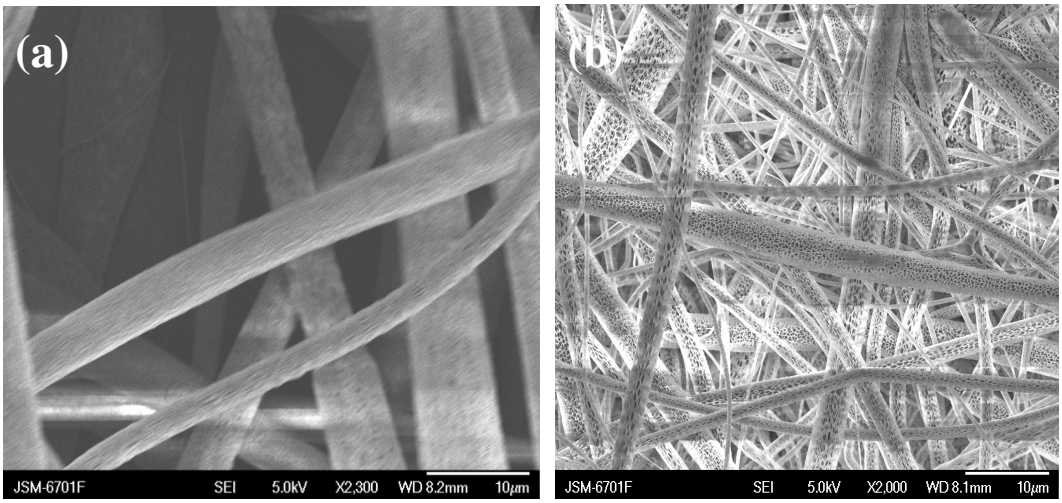

Fig. 4 SEM images of (a) PLA and (b) PLA/Ag 0.1 electrospinning fibers.

Fig. 4 illustrates SEM images of electrospinning fibers from 10 wt% PLA and 10 wt% PLA/Ag 0.1 solution. The average diameter of the fibers slightly decreased from 10 μm in Fig. 4 (a) to 6 μm in Fig. 4 (b), as the silver content increased [11]. A porous fiber film was observed. With the addition of nanorods, the filbers appear the porous structure that increase the specific surface area of fiber film, which improved the application as a biological material.

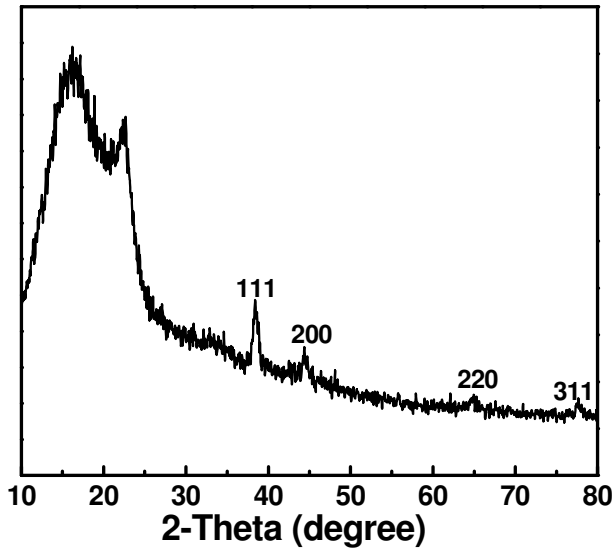

Fig. 5 XRD patterns of PLA/Ag composite fibers

Fig. 5 shows the XRD patterns of PLA/Ag composite fiber film. They respectively corresponding to the diffraction planes of (111), (200), (220) and (311) of silver [12]. It proves that the silver nanorods are embedded in the PLA fibers.

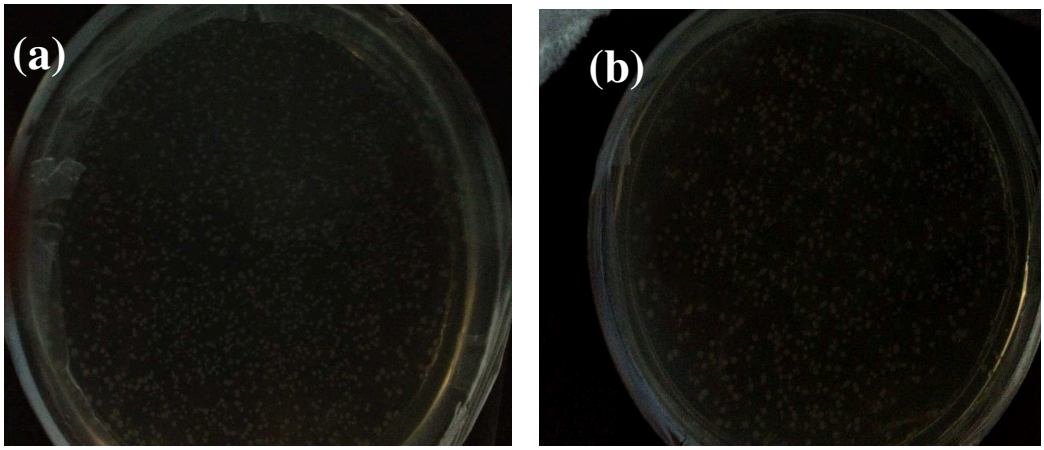

Figure 6 The antibacterial experiments of PLA(a) and PLA/Ag 0.1 fiber film

Fig. 6 shows the result of the antibacterial test for the PLA and PLA/Ag 0.1 fiber film against Gram-negative E. coli. As a result, the PLA fiber films containing silver nanorods have a certain role of inhibited the proliferation of Gram-negative E. coli. These results illustrate the silver nanorods in charge of the antibacterial activity of the composite fibers. The antibacterial improving experiments will report in future.

Summary

PLA fiber film containing silver nanorods were successfully prepared via electrospinning and characterized by multiple characterization methods. The results show that electrospinning synthesis of PLA fiber film containing silver nanorods have a structure of porous fiber film. The PLA fiber film containing silver nanorods have a certain role of inhibited the proliferation of Gram-negative E. coli. The antimicrobial porous fiber film of PLA containing silver nanorods could have a good application as wound dressing.

Keywords: Bioceramics, Microstructure, Microporosity, Characterization.

Abstract: The calcium phosphate microporous bioceramics, and hydroxyapatite (HA) and β-tricalcium phosphate (β-TCP) biphasic compositions, in the granular form of microporous biomaterials, are research themes and present potential biomedical applications in rebuilding and repairing maxillofacial bone and tooth structure and in orthopedic applications. This is associated with microstructural characteristics of biocompatibility and bioactivity and osteoconductivity properties that these biomaterials offer when applied *in vivo* or in simulated environment. Another differential point of these biomaterials is the solubilization capacity that they present when applied in the biological environment. These compositions of calcium phosphates (hydroxyapatite matrix and/or β-tricalcium phosphate) allow for the gradual release of calcium and phosphate ions for the biological environment, which are absorbed and promote the formation of new bone tissue. These materials are also promising in applications in the field of traumatology as in the repair of traumatized bone tissue and drugs controlled release and bone structure treatments. The favorable results of these biomaterials as bone reconstruction matrix and drugs controlled release are associated with crystallographic characteristics, morphology, surface and solubility that these biomaterials present when in contact with body fluids. This work aimed to describe three types of calcium phosphate microporous granulated biomaterials. The biomaterials used were provided by the Biomaterials' Group from Universidade do Estado de Santa Catarina - UDESC and are: hydroxyapatite, β-tricalcium phosphate and biphasic composition 60% hydroxyapatite/40% β-tricalcium phosphate. The Scanning Electron Microscopy technique (SEM) was used for carrying out the morphological characterization and microstructure studies of granulated biomaterials. The X-Ray Diffractometry (XRD) served for characterization of crystalline phases. Arthur Method was used for determining open porosity and hydrostatic density of biomaterials. The BET technique served to support determination of the surface area of microporous granulated biomaterials. The results are encouraging and show that these biomaterials present promising morphological characteristics and microporous microstructure as wettability and capillarity. These characteristics may contribute to biomaterial osteointegration by new tissue, bone formation and mineralization process.

Introduction

The calcium phosphate bioceramics and hydroxyapatite–β-tricalcium phosphate biphasic compositions are biocompatible biomaterials and present crystallographic similarity to bone tissue and teeth apatites and play the role of osteoinduction and osteointegration when applied *in vivo* [1,2,3,4].

The calcium phosphate bioceramics in the form of granules or microporous blocks had been featured in research as materials for repairing defects and bone tissue reconstruction, as already

observed by different authors, who performed *in vitro* and *in vivo* tests and observed the good performance of these bioceramics in bone neoformation [5, 6, 7, 8]. This is because these biomaterials have bioactivity, solubilization capacity, wettability and interconnected microporous microstructures and high grain surface area and micropores [9, 10, 11]. These properties are promising for adhesion of osteoblasts cells on the granules surface through the inter-granular micropores. These microporous microstructures also favor the extension of osteoblasts cells to the interior of the interconnected microporosity of granulated biomaterial, providing better conditions for bone tissue mineralization [12,13]. These bioceramics are generally manufactured with an architecture composed of macro and microporosity, which has generated favorable results to the mechanism of adhesion and cell proliferation, thus contributing to the osteoinduction system, bone tissue repair and reconstruction [13, 14, 15, 16].

The biomaterials used in this study were obtained by the wet synthesis method, through the dissolution/precipitation of liquid-solid phase involving CaO and phosphoric acid solution necessary for formation of Ca/P molar compositions. Three compositions of granulated materials were used as follows: microporous hydroxyapatite, β-tricalcium phosphate and a biphasic composition of 60% hydroxyapatite /40% β-tricalcium phosphate.

The results presented refer to studies of morphological, microstructural, physical and chemical characterization. The characterization studies were carried out with the help of the Scanning Electron Microscopy technique (SEM), X-Ray Diffractometry (DRX). and by Fourier Transform Infra-Red spectrometry (FTIR).The hydrostatic density and open porosity were determined by Arthur Method and surface area by BET.

Experimental Method

Three compositions of calcium phosphate microporous granulated biomaterials were used in this work: hydroxyapatite, β-tricalcium phosphate and biphasic 60% HA/40%β-TCP (HA/β-TCP). These were elaborated in the microporous granulated biomaterials form with size between 200μm and 500μm.

The preparation of nanostructured powders was performed with help of a high-energy NETZSCH attrition mill, with zircon beads with a diameter of 2.0 mm and distilled water. The attrition mill process was conducted with a solid/liquid concentration of 50%/50% in volume. This process in attrition mill was kept under stirring for a period of one hour, as described by [10, 17].

The colloidal suspension retrieved from the attrition mill was dried in rotary evaporator, providing agglomerated calcium phosphates nanostructured powders. These pellets went through the process of classification by sieves through #500 mesh and the accumulated granulated material was recovered in #200 mesh.

The granulated material obtained was submitted to sintering at a temperature of 1100ºC/2h, providing microporous granulated biomaterials.

Morphological and microstructural characterization studies of microporous granulated biomaterials were carried out with the help of a ZEISS scanning electron microscope, model DSM 940A, through the secondary electrons system (SE) and retro-scattered (BSE).

In order to facilitate the characterization work through the scanning electron microscopy technique, the biomaterials were prepared using a disc sample holder made of aluminum with smooth surface. A double-sided carbon ribbon was attached on the smooth surface of the disc, on which the biomaterials were deposited.

In order to avoid the charge effects inside the chamber, all biomaterials underwent metallization process by sputtering, with deposition of a gold film on the surface of the samples. This deposition was performed through Bal-Tec model SCD 050 Sputter Coater. The ion-deposition parameters were set as follows: temperature at 25ºC in metallization chamber, 40mA current, 2kV voltage and deposition time of 140 seconds, providing a gold film on the samples surface at order of 30nm [18].

For the determination of open porosity (%) and hydrostatic density (g/cm^3), the Arthur Method was used [19]. Previously the granulated biomaterials were dried in a kiln at temperature of

100°C/24h. This method consists in measuring the weight of air-dried samples (*Par*), then they are soaked with xylene inside a vacuum chamber at about 10^{-3}mbar and this low pressure is maintained for 20 minutes, then the vacuum is broken and the granulated biomaterial is removed for realization of measures of weight of microporous biomaterial soaked in xylene (*Pxa*); shortly after, the weight of biomaterial soaked in xylene immersed in distilled water (*Pxe*) is measured. With the results of these measurements the values of open porosity and hydrostatic density are determined, with the help of the (Eq. 01) about open porosity (%) and with the (Eq. 02) about hydrostatic density (g/cm^3). These calculations were performed for the granulated biomaterials: HA, β-TCP and biphasic composition 60% HA/40% β-TCP.

$$d_h = \frac{Par.de}{Pxa - Pxe} \quad (1)$$

$$P.A. = \frac{(Pxa - Par).de}{(Pxa - Pxe).dx}.100 \quad (2)$$

With:

Par – air-dried weight (g);
Pxa – soaked in xylene weight (g);
Pxe – soaked in xylene immersed in distilled water weight (g);
d_h – hydrostatic density (g/cm^3);
dx – xylene density (0,8802 g/cm^3);
de – water density (g/cm^3);
P.A – open porosity (%).

The BET method (Brunauer, Emmett and Teller) was used in this study to determine surface area of microporous granulated biomaterials: HA, β-TCP and biphasic 60% HA/40% β-TCP. This method consists of physical absorption of a gas (N_2, H_2 or He) at low temperature, on open porosity and on the grains surface and micropores of granulated biomaterial, thus filling the entire surface of the microporous granulated biomaterials.

The x-ray diffractometry (XRD) served on crystallographic characterization of microporous granulated biomaterials. In this study a SHIMADZU x-ray diffractometer model XRD LAB X-6000, with anti-cathode copper tube, was used. To obtain the x-rays diffraction, a 40kV voltage and current of 30mA were used, being the scanning angular range from 5° to 80°, with a goniometer speed of 2º/min in function of 2θ.

The Fourier Transform Infrared Spectroscopy technique assisted in this characterization study of microporous granulated biomaterials. This method consists of identifying the vibrational modes of the OH^- and PO_4^{-3}grouping. The analyses were carried out in the wavelength range from 4000 to 500cm^{-1} with 4.0cm^{-1} precision.

Results and Discussion

The results of morphological and microstructural characterization obtained from microporous granulated biomaterials revealed, through their micrographs, the granules morphology, with irregular shapes presenting sizes between 200μm and 500μm, as can be observed in figures 1a, 2b and 1c. Another observation was the interconnected microporous microstructure of granulated biomaterials, as shown on the micrographs represented in figures 2a, 2b and 2c. Relating the micrographs obtained from microstructure of microporous granulated biomaterials, it was observed there is finer grain morphology, indicating there is greater microporosity for HA granulated biomaterials and biphasic composition, compared to β-TCP granulated biomaterial.

The open porosity in percent and the hydrostatic density were determined using the Arthur Method [19]. Open porosity and hydrostatic density measurements were performed for the different compositions of microporous granulated biomaterials: HA, β-TCP and biphasic 60%HA/40%β-TCP, obtained from the sintering at temperature of 1100ºC/2h. The results are represented in table1.

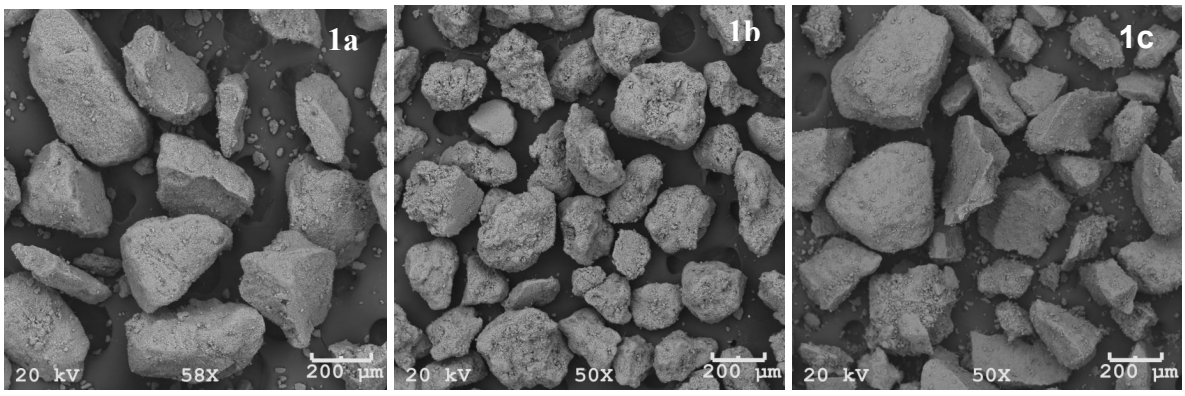

Figure (1a). Hydroxyapatite (HA) granulated biomaterial morphology; (1b). β-TCP granulated biomaterial morphology and (1c) Biphasic 60%HA/40%β-TCP granulated biomaterial morphology

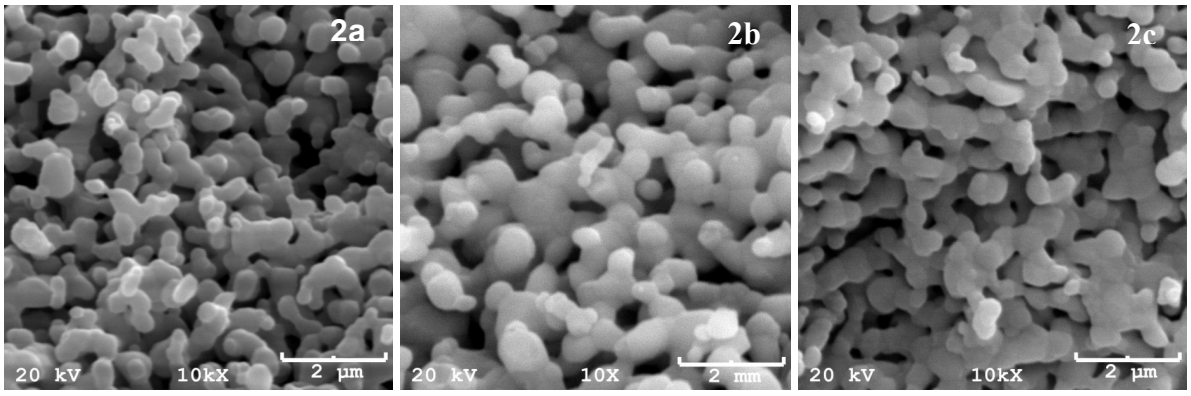

Figure (2a). HA granulated biomaterial microstructure; (2b) β-TCP granulated biomaterial microstructure and (2c) 60%HA/40%β-TCP biphasic granulated biomaterial microstructure

TABLE 1. OPEN POROSITY, THEORETICAL DENSITY AND HYDROSTATIC DENSITY RESULTS OBTAINED FOR THE MICROPOROUS GRANULATED BIOMATERIALS.

Granulated Biomaterial	PA (%)	d_{th} (g/cm^3)	d_h (g/cm^3)
HA	77.64±1.67	3.16±0.001	1.96±0.04
β-TCP	76.57±0.82	3.07±0.001	2.18±0.04
60%HA/40%β-TCP	77.76±1.69	3.12±0.004	1.87±0.03

PA = open porosity; $\mathbf{d_{th}}$ = theoretical density; $\mathbf{d_h}$ = hydrostatic density

The results about open porosity presented in table 1 showed approximate values between microporous granulated biomaterials. A slight variation between the hydrostatic density values was also found, showing lower value for the biphasic granulated microporous biomaterial (1.87 g/cm^3). The bibliography shows that calcium phosphate biomaterials with interconnected microporous microstructures are promising in biomedical applications, in defects repairing and bone tissue reconstruction. These interconnected microporous microstructures formed by fine grains offer the best conditions of wettability, capillarity, oxygenation, cellular adhesion on the grain and micropores surface, promoting osteoinduction, osteointegration and new bone tissue neoformation, as already observed by different authors [3, 4, 5, 6, 20].

The surface area analysis was performed to microporous granulated biomaterials: HA, β-TCP and biphasic 60%HA/40%β-TCP. The results are shown in table 2, compared to the values obtained from the open porosity and hydrostatic density. It can be noticed in the table 2 that surface area values are close between the microporous granulated biomaterials in study, showing greater surface area value for the hydroxyapatite granulated biomaterial: 3.62 m^2/g. The explanation is that hydroxyapatite biomaterials present slightly finer grain morphology in relation to other biomaterials in study, as can be observed in micrographs represented in figures 2a, 2b and 2c.

TABLE 2. SURFACE AREA, OPEN POROSITY, THEORETICAL DENSITY AND HYDROSTATIC DENSITY RESULTS FOR THE MICROPOROUS GRANULATED BIOMATERIALS STUDIED.

Granulated Biomaterial	BET (m^2/g)	PA (%)	$d_{th}(g/cm^3)$	$d_h(g/cm^3)$
HA	3.62	77.64 ± 1.67	3.16 ± 0.001	1.96 ± 0.04
β-TCP	2.67	73.67 ± 0.82	3.07 ± 0.001	2.33 ± 0.04
HA/β-TCP	2.78	77.96 ± 1.69	3.12 ± 0.004	1.87 ± 0.03

The results obtained by x-ray diffractometry of the granulated biomaterials clearly revealed in their x-ray diffractograms the presence of hydroxyapatite phase, β-tricalcium phosphate and hydroxyapatite/β-tricalcium phosphate for biphasic composition, as shown in the x-ray diffractograms represented in figures 3, 4 and 5. In figure 3 the presence of well-defined peaks of stoichiometric hydroxyapatite phase in the composition $Ca_{10}(PO_4)_6(OH)_2$ can be noticed, with main diffraction plane of [211] and hexagonal crystalline structural system.

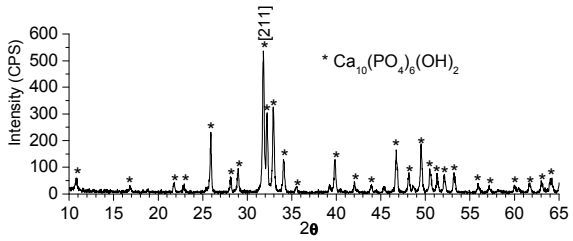

Figure 3. X-ray diffractograms obtained from HA granulated biomaterial.

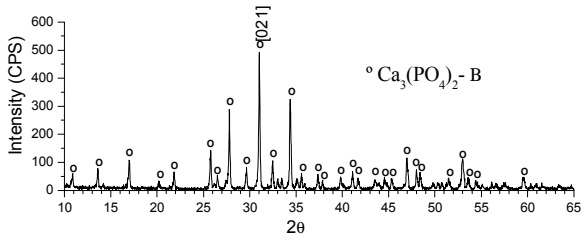

Figure 4. X-ray diffractograms obtained from β-TCP granulated biomaterial.

Figure 4 illustrates the diffractogram obtained from β-tricalcium phosphate granulated biomaterial. The well-defined peaks of β-TCP (Whitlockite) phase at composition β-$Ca_3(PO_4)_2$ rhombohedral crystalline system can be noticed, with main diffraction plane of [021].

Figure 5 illustrates the diffractogram obtained from biphasic 60% HA/40% β-TCP granulated biomaterial. The representative peaks of stoichiometric hydroxyapatite phase and β-TCP phase are noticeable in the diffractogram, with main plane of diffraction [211] to HA phase and [021] for β-TCP phase.

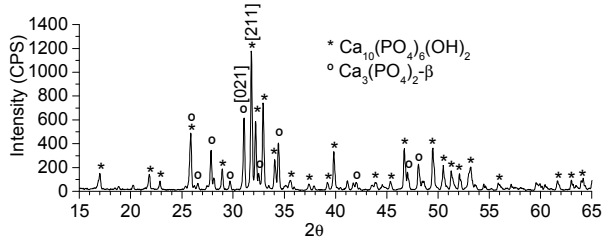

Figure 5. X-ray diffractograms obtained from biphasic HA/β-TCP granulated biomaterial.

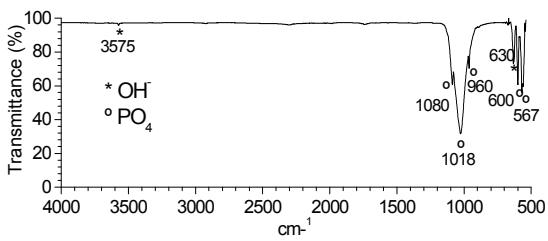

Figure 6. Spectrogram obtained from HA granulated biomaterial.

The infrared spectroscopy technique was used to complement the characterization studies about microporous granulated biomaterials. This method allowed the identification of the vibrational bands of functional PO_4^{-3} and OH^- groupings. Figure 6 shows the spectrogram obtained from granulated microporous HA. The presence of the vibrational bands in 3575cm^{-1} and 630cm^{-1} is observed, indicating the presence of vibrational OH^- grouping. PO_4 groupings are also noted in the spectrogram, evidenced by presence of the vibrational bands in 1087cm^{-1}, 1022cm^{-1}, 960cm^{-1}, 600cm^{-1}, 567cm^{-1}. This result clearly shows the vibrational bands of the OH^- and PO_4 groupings, typical from hydroxyapatite biomaterial, as already observed by other authors [2.9, 21, 22, 23]. The result obtained by FTIR confirms those already obtained by x-ray diffractometry, which indicated the hydroxyapatite phase (Fig. 3).

In the case of β-TCP microporous granulated biomaterials (Fig. 7), only the PO_4 grouping in 1083cm^{-1}, 1080cm^{-1}, 976cm^{-1}, 943cm^{-1} and 600cm^{-1}, that are typical to the β-TCP, is noted in the spectrogram. These same vibrational bands have already been noted by other authors [24]. These analyzed results along with the results obtained by x-ray diffractometry show that the biomaterial is formed by β-TCP phase (Fig. 4).

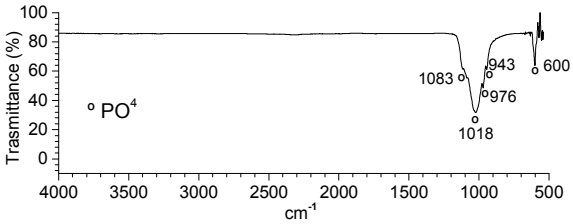

Figure 7. Spectrogram obtained from β-TCP granulated biomaterial.

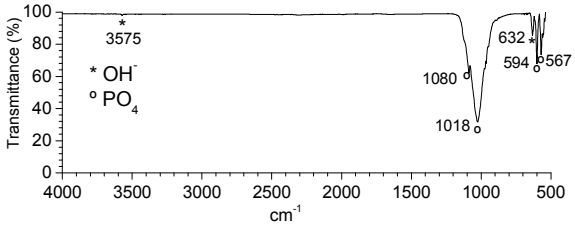

Figure 8. Spectrogram obtained from HA/β-TCP granulated biomaterial.

For the biphasic composition 60% HA/40% β-TCP (Fig. 8), the OH^- grouping in 3575cm^{-1} and 632cm^{-1} was observed. The vibrational PO_4 groupings are present in 1080cm^{-1}, 1018cm^{-1}, 594cm^{-1} and 567cm^{-1}, as can be seen in figure 8, as already observed for the hydroxyapatite and β-tricalcium phosphate biomaterials.

Conclusion

The microstructural and morphological characterization clearly showed that the biomaterials are formed by granules with various forms, which presented microporous microstructures formed by fine grains with equiaxial forms. These properties are promising to adhesion and cell proliferation in micropores and grain surface.

The open porosity and hydrostatic density studies highlighted the presence of significant porosity for all biomaterials, showing open porosity's best result for the biphasic biomaterial HA/β-TCP. This result certainly can contribute in the process of osteointegration of biomaterial and new bone tissue mineralization.

The results obtained by BET showed greater value of surface area for the biomaterial HA (3,62 m^2/g), which is justified by the slightly inferior grain morphology than other biomaterials and also due to its microporosity.

The results obtained by x-ray diffractometry showed the presence of the respective phases for each composition: hydroxyapatite, β-tricalcium phosphate and biphasic composition HA/β-TCP.

The result obtained by FTIR clearly showed the presence of the vibrational bands of PO_4^{-3} and OH^-, present in calcium phosphates. This result came to supplement those obtained by x-ray diffractometry, showing that the biomaterials are formed by HA and β-TCP phases respectively.

The results found in this work are encouraging and show that microporous granulated biomaterials are promising for use as bone substitutes. This is associated with the interconnected microporous microstructures formed by fine grains and their porosity higher than 70%. These

properties are favorable to wettability, capillary action, cell adhesion on the surface of grains and micropores, thus giving better conditions to osteoinduction and osteointegration process and formation of new bone tissue.

Keywords: Calcium phosphates; Hydroxyapatite; Nanostructure; Bone substitutes; Biomaterials.

Abstract: The present research paper centers on physicochemical characterization of six nanostructured alloplastic bone substitutes developed at Santa Catarina State University (UDESC – Brazil). In addition to identifying the main phases, the focus was to measure the morphological and microstructural features, which are believed to be crucial for controlling and guiding biological and molecular events. The studied samples exhibited rounded granules measuring 200μm <d <500μm. It was observed the presence of nanograins (<100nm) for all samples, with average grain diameter under 300nm. Hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] was found as main phase for HAp, BCP and HAp/Al_2O_3 biomaterials. For HAp/TiO2n, HAp/SiO_2n and β-TCP, the major phase was beta tricalcium phosphate [$Ca_3(PO_4)_2$-β]. The results demonstrate that the presence of a second phase of nanometer order, at a hydroxyapatite bioceramic matrix, may modify the surface diffusion of the grains and the phase transformation kinetics of hydroxyapatite and beta tricalcium phosphate at temperatures up to 1100°C.

Introduction

The marked increase in world population, combined with an increment of life expectancy in the last century, leads to enormous demands each year for various biomedical implants to repair diseased or lost bone tissue. However, conventional tissue replacements (such as autografts and allografts) have a variety of problems that cannot satisfy high performance demands necessary for today's patient [1]. Alloplastic biomaterials have the property of not transmitting any pathogen, since they can be synthesized in a safe environment and sterilized to prevent handling contamination. Of these, calcium phosphates (CaP) biomaterials such as hydroxyapatite (HAp) and beta tricalcium phosphate (β-TCP) have been extensively studied and employed for the last thirty years as bone graft substitutes, mostly due to their composition closely resembling the inorganic phase of bone [2].

Some studies suggest that in addition to chemical and crystallographic properties, the microstructure seems to be a key factor for calcium phosphates bioactivity [3-5]. Indeed, there is clear evidence that surfaces exert a differential activity on proteins by promoting or limiting their adhesion to the substrate. In particular, nanoscale surface cues are pivotal in controlling and guiding biological and molecular events [6]. The present research aims to characterize six different compounds of nanostructured calcium phosphate biomaterials developed at Santa Catarina State University (UDESC – Brazil).

Materials and Methods

The examined biomaterials included three compounds of calcium phosphate: HAp, β-TCP and a biphasic calcium phosphate (BCP) composed of HAp and β-TCP at a concentration of 60/40 by volume; and three hydroxyapatite matrices added 5% of nanostructured secondary phases: Al2O3-αn, TiO2n or SiO2n (Table 1). All of the biomaterials were supplied by the Biomaterials Research Group of Santa Catarina State University (UDESC - Brazil). The biomaterials were produced by attrition milling process, sintered at 1100°C for 2 hours and provided in a granular form.

TABLE 1. LIST OF EVALUATED BIOMATERIALS AND RELATED CHEMICAL FORMULA.

HAp	β-TCP	BCP	HAp/Al_2O_3	HAp/TiO2	HAp/SiO_2n
$Ca_{10}(PO_4)_6(OH)_2$	$Ca_3(PO_4)_2$-β	60% $Ca_{10}(PO_4)_6(OH)_2$ 40% $Ca_3(PO_4)_2$-β	95% $Ca_{10}(PO_4)_6(OH)_2$ 5% Al_2O_3-αn	95% $Ca_{10}(PO_4)_6(OH)_2$ 5% TiO_2n	95% $Ca_{10}(PO_4)_6(OH)_2$ 5% SiO_2n

To identify phase and composition features, X-ray diffraction (XRD) was used. Diffraction data were collected using an SHIMADZU XRD-6000 (Shimadzu, Tokyo, Japan), operating with Cu-Kα radiation (λ = 1.54060 Å) at a current of 30mA and an accelerating voltage of 40kV. Spectra were recorded in the range of 5º < 2θ < 80° at a scanning speed of 2º/min. The obtained X-ray patterns were compared to corresponding data from International Centre for Diffraction Data (ICDD).

Fourier transform infrared spectroscopy (FTIR) was employed to provide information concerning the chemical composition and the major functional groups. FTIR spectra were obtained within the range between 4000 and 450 cm^{-1}, with resolution of 4cm^{-1}, and the number of scans was 32. Total reflectance (ATR) technique was used at room temperature.

Studies of morphological and microstructural characterization were carried out by scanning electron microscopy (SEM) with ZEISS DSM 940A microscope (Carl Zeiss, Oberkochen, Germany), through the method of secondary electrons (SE), with a working distance of 10 mm and accelerating voltage of electrons of 20 kV. The samples were mounted on double-coated, carbon-conductive tape and then sputter-coated with gold.

The grain size of the biomaterials was measured through SEM images. Five different samples of each biomaterial were obtained at 5000x magnification. The perimeter of the grains was manually demarcated within the images, and the average diameter calculation was carried out with ImageJ software (v. 1.43, National Institutes of Health, USA).

Results

The results of morphological and microstructural characterization were conducted on the different biomaterials using the technique of scanning electron microscopy (SEM). Results are illustrated in Fig. 1 (a-f) and exhibited slight variations. The morphology revealed rounded granules with size between 200μm <d <500μm. Extensively interconnected microporous microstructure was also observed, formed by fine grains with a few preferred sinterability regions.

The image analysis method for grain size measuring allowed a statistical statement average of grains diameter. The data are depicted in Table 2. It was noticed an average diameter below 300 nm for all biomaterials, with the presence of nanostructured grains (d < 100nm).

TABLE 2. RESULTS FOR AVERAGE GRAINS SIZE FOR THE DIFFERENT BIOMATERIALS (SD = STANDARD DEVIATION).

Biomaterial	Average (nm)	SD (nm)	Minimum (nm)	Maximum (nm)
HAp	279	111	80	541
β-TCP	294	95	76	678
BCP	288	90	92	560
HAp/Al_2O_3	204	85	72	482
HAp/TiO_2	249	128	49	625
HAp/SiO_2	207	99	62	487

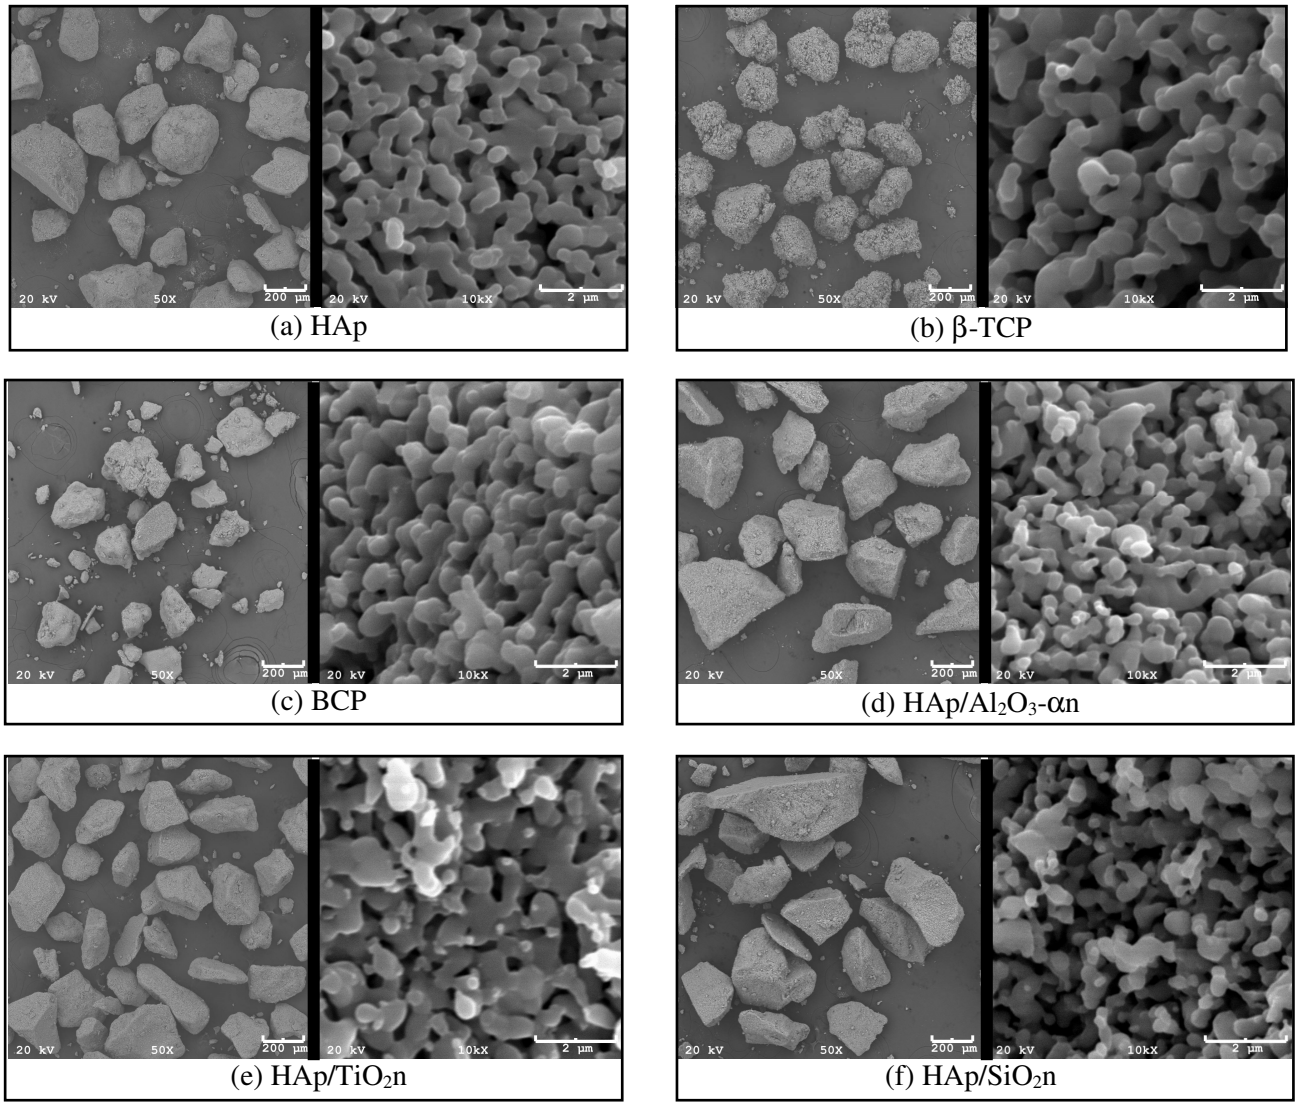

Fig. 1. Morphology (50X magnification) and microstructure (10kX magnification) of the granular biomaterials: (a) hydroxyapatite, (b) beta tricalcium phosphate, (c) 60/40 biphasic HAp/β-TCP, (d) nanocomposite HAp/Al_2O_3, (e) nanocomposite HAp/TiO_2, and (f) nanocomposite HAp/SiO_2.

The XRD technique was used for phase identification of different biomaterials (Figs. 2 and 3). The diffractograms were compared with ICDD data and pertinent literature. All samples presented high degree of crystallinity. As expected, the XRD results of HAp and β-TCP showed coincident peak positions and intensities with their related ICDD patterns. BCP presented peak positions of HAp and β-TCP in the estimated proportion of 60/40 (Fig. 2). The secondary phases of 5% nanocomposites (Al_2O_3, TiO_2 and SiO_2) were not identified at diffractograms (Fig. 3). The main finding at nanocomposites diffractograms was the appearance of peaks of an undesigned phase: β-TCP. Its amount ranged from 24% for HAp/Al_2O_3 sample, to about 83% for HAp/TiO2 and HAp/SiO_2 nanocomposites.

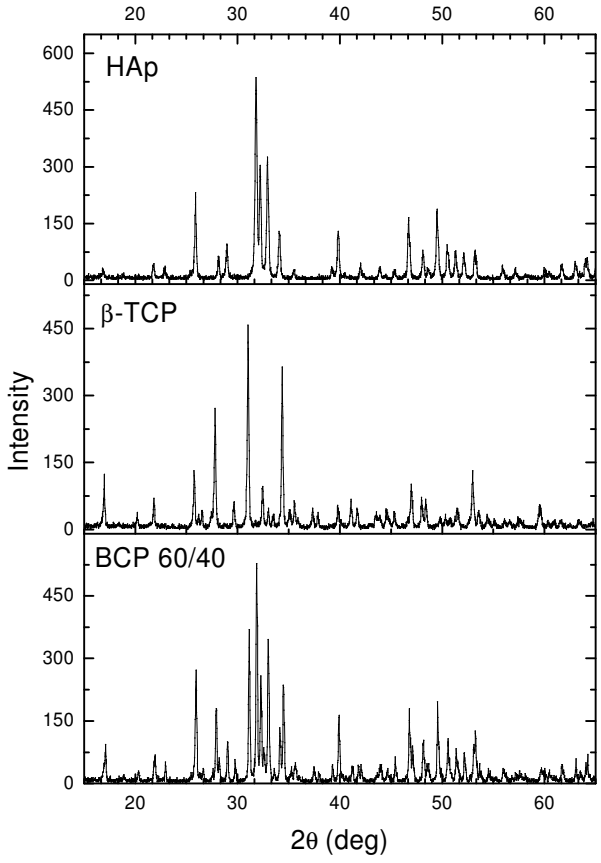

Fig. 2. Diffractograms of HAp, β-TCP and BCP, with peaks related to their own composition.

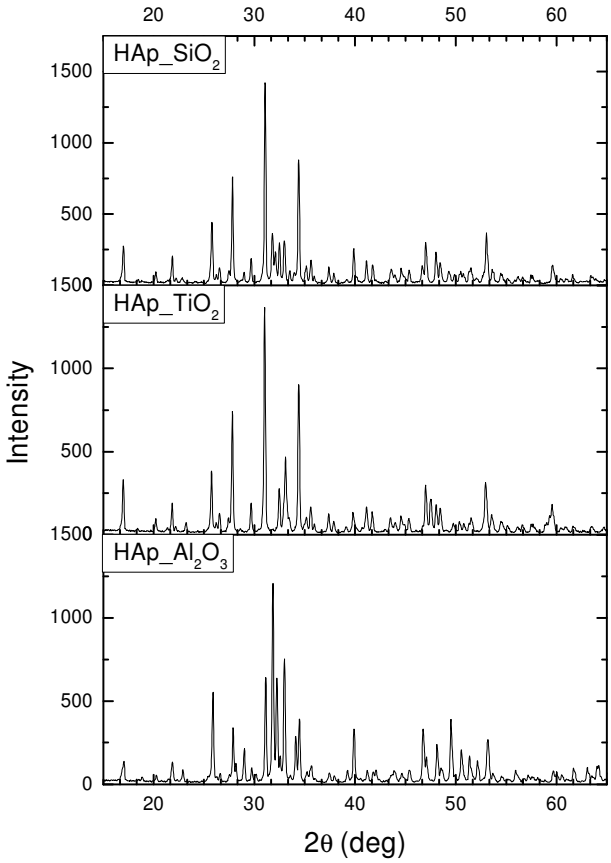

Fig. 3. Diffractograms of HAp/Al_2O_3, HAp/TiO2 and HAp/SiO_2 nanocomposites, with peaks of β-TCP phase in addition to HAp matrix peaks.
